 // If this is state 2, multiply EAX by EAX and switch to state 3:

 intmul(ebx, eax);
 mov(&State3, State); // State 2 becomes State 3.
 exit StateMachine;

 // State 3: divide eax by ebx and switch back to state zero.

```

---

5. Actually, it remembers how many times, *MOD 4*, that it has been called.

```

State3:
 push(edx); // Preserve this 'cause it gets whacked by DIV.
 xor(edx, edx); // Zero extend EAX into EDX.
 div(ebx, edx:eax);
 pop(edx); // Restore EDX's value preserved above.
 mov(&State0, State); // Reset the state back to zero.

end StateMachine;

```

The `JMP` instruction at the beginning of the *StateMachine* procedure transfers control to the location pointed at by the *State* variable. The first time you call *StateMachine* it points at the *State0* label. Thereafter, each subsection of code sets the *State* variable to point at the appropriate successor code.

## 2.10 Spaghetti Code

One major problem with assembly language is that it takes several statements to realize a simple idea encapsulated by a single HLL statement. All too often an assembly language programmer will notice that s/he can save a few bytes or cycles by jumping into the middle of some programming structure. After a few such observations (and corresponding modifications) the code contains a whole sequence of jumps in and out of portions of the code. If you were to draw a line from each jump to its destination, the resulting listing would end up looking like someone dumped a bowl of spaghetti on your code, hence the term “spaghetti code”.

Spaghetti code suffers from one major drawback- it’s difficult (at best) to read such a program and figure out what it does. Most programs start out in a “structured” form only to become spaghetti code at the altar of efficiency. Alas, spaghetti code is rarely efficient. Since it’s difficult to figure out exactly what’s going on, it’s very difficult to determine if you can use a better algorithm to improve the system. Hence, spaghetti code may wind up less efficient than structured code.

While it’s true that producing some spaghetti code in your programs may improve its efficiency (e.g., destructuring your code, see “Efficient Implementation of IF Statements in Assembly Language” on page 749), doing so should always be a last resort after you’ve tried everything else and you still haven’t achieved what you need. Always start out writing your programs with straight-forward IFs and SWITCH statements. Start combining sections of code (via `JMP` instructions) once everything is working and well understood. Of course, you should never obliterate the structure of your code unless the gains are worth it.

A famous saying in structured programming circles is “After GOTOs, pointers are the next most dangerous element in a programming language.” A similar saying is “Pointers are to data structures what GOTOs are to control structures.” In other words, avoid excessive use of pointers. If pointers and gotos are bad, then the indirect jump must be the worst construct of all since it involves both GOTOs and pointers! Seriously though, the indirect jump instructions should be avoided for casual use. They tend to make a program harder to read. After all, an indirect jump can (theoretically) transfer control to any label within a program. Imagine how hard it would be to follow the flow through a program if you have no idea what a pointer contains and you come across an indirect jump using that pointer. Therefore, you should always exercise care when using jump indirect instructions.

## 2.11 Loops

Loops represent the final basic control structure (sequences, decisions, and loops) that make up a typical program. Like so many other structures in assembly language, you’ll find yourself using loops in places you’ve never dreamed of using loops. Most HLLs have implied loop structures hidden away. For example, consider the BASIC statement “IF A\$ = B\$ THEN 100”. This IF statement compares two strings and jumps to statement 100 if they are equal. In assembly language, you would need to write a loop to compare each character in A\$ to the corresponding character in B\$ and then jump to statement 100 if and only if all the characters matched. In BASIC, there is no loop to be seen in the program. In assembly language, this very

simple IF statement requires a loop to compare the individual characters in the string<sup>6</sup>. This is but a small example which shows how loops seem to pop up everywhere.

Program loops consist of three components: an optional initialization component, a loop termination test, and the body of the loop. The order with which these components are assembled can dramatically change the way the loop operates. Three permutations of these components appear over and over again. Because of their frequency, these loop structures are given special names in high-level languages: WHILE loops, REPEAT..UNTIL loops (do..while in C/C++), and infinite loops (e.g., FOREVER..ENDFOR in HLA).

### 2.11.1 While Loops

The most general loop is the WHILE loop. In HLA it takes the following form:

```
while(expression) do <<statements>> endwhile;
```

There are two important points to note about the WHILE loop. First, the test for termination appears at the beginning of the loop. Second as a direct consequence of the position of the termination test, the body of the loop may never execute. If the termination condition always exists, the loop body will always be skipped over.

Consider the following HLA WHILE loop:

```
mov(0, I);
while(I < 100) do

 inc(I);

endwhile;
```

The “mov( 0, I);” instruction is the initialization code for this loop. *I* is a loop control variable, because it controls the execution of the body of the loop. “I<100” is the loop termination condition. That is, the loop will not terminate as long as *I* is less than 100. The single instruction “inc( I);” is the loop body. This is the code that executes on each pass of the loop.

Note that an HLA WHILE loop can be easily synthesized using IF and JMP statements. For example, the HLA WHILE loop presented above can be replaced by:

```
mov(0, I);
WhileLp:
if(I < 100) then

 inc(i);
 jmp WhileLp;

endif;
```

More generally, any WHILE loop can be built up from the following:

```
<< optional initialization code>>

UniqueLabel:
if(not_termination_condition) then

 <<loop body>>
 jmp UniqueLabel;

endif;
```

6. Of course, the HLA Standard Library provides the *str:eq* routine that compares the strings for you, effectively hiding the loop even in an assembly language program.

Therefore, you can use the techniques from earlier in this chapter to convert IF statements to assembly language along with a single JMP instruction to produce a WHILE loop. The example we've been looking at in this section translates to the following "pure" 80x86 assembly code<sup>7</sup>:

```

mov(0, i);
WhileLp:
 cmp(i, 100);
 jnl WhileDone;
 inc(i);
 jmp WhileLp;

WhileDone:

```

---

## 2.11.2 Repeat..Until Loops

The REPEAT..UNTIL (do..while) loop tests for the termination condition at the end of the loop rather than at the beginning. In HLA, the REPEAT..UNTIL loop takes the following form:

```

<< optional initialization code >>
repeat

 <<loop body>>

until(termination_condition);

```

This sequence executes the initialization code, the loop body, then tests some condition to see if the loop should repeat. If the boolean expression evaluates to false, the loop repeats; otherwise the loop terminates. The two things to note about the REPEAT..UNTIL loop are that the termination test appears at the end of the loop and, as a direct consequence of this, the loop body always executes at least once.

Like the WHILE loop, the REPEAT..UNTIL loop can be synthesized with an IF statement and a JMP . You could use the following:

```

<< initialization code >>
SomeUniqueLabel:

 << loop body >>

if(not_the_termination_condition) then jmp SomeUniqueLabel; endif;

```

Based on the material presented in the previous sections, you can easily synthesize REPEAT..UNTIL loops in assembly language. The following is a simple example:

```

repeat

 stdout.put("Enter a number greater than 100: ");
 stdin.get(i);

until(i > 100);

// This translates to the following IF/JMP code:

RepeatLbl:

 stdout.put("Enter a number greater than 100: ");
 stdin.get(i);

```

---

7. Note that HLA will actually convert most WHILE statements to different 80x86 code than this section presents. The reason for the difference appears a little later in this text when we explore how to write more efficient loop code.

```

 if(i <= 100) then jmp RepeatLbl; endif;

// It also translates into the following "pure" assembly code:

RepeatLabel:

 stdout.put("Enter a number greater than 100: ");
 stdin.get(i);

 cmp(i, 100);
 jng RepeatLbl;

```

---

### 2.11.3 FOREVER..ENDFOR Loops

If WHILE loops test for termination at the beginning of the loop and REPEAT..UNTIL loops check for termination at the end of the loop, the only place left to test for termination is in the middle of the loop. The HLA FOREVER..ENDFOR loop, combined with the BREAK and BREAKIF statements, provide this capability. The FOREVER..ENDFOR loop takes the following form:

```

forever

 << loop body >>

endfor;

```

Note that there is no explicit termination condition. Unless otherwise provided for, the FOREVER..ENDFOR construct simply forms an infinite loop. Loop termination is typically handled by a BREAKIF statement. Consider the following HLA code that employs a FOREVER..ENDFOR construct:

```

forever

 stdin.get(character);
 breakif(character = '.');
 stdout.put(character);

endfor;

```

Converting a FOREVER loop to pure assembly language is trivial. All you need is a label and a JMP instruction. The BREAKIF statement in this example is really nothing more than an IF and a JMP instruction. The "pure" assembly language version of the code above looks something like the following:

```

foreverLabel:

 stdin.get(character);
 cmp(character, '.');
 je ForIsDone;
 stdout.put(character);
 jmp foreverLabel;

ForIsDone:

```

---

### 2.11.4 FOR Loops

The FOR loop is a special form of the WHILE loop that repeats the loop body a specific number of times. In HLA, the FOR loop takes the following form:

```

for(<<Initialization Stmt>>; <<Termination Expression>>; <<inc_Smt>>) do

 << statements >>

endfor;

```

This is completely equivalent to the following:

```

<< Initialization Stmt>>;
while(<<Termination Expression>>) do

 << statements >>

 <<inc_Smt>>

endwhile;

```

Traditionally, the FOR loop has been used to process arrays and other objects accessed in sequential numeric order. One normally initializes a loop control variable with the initialization statement and then uses the loop control variable as an index into the array (or other data type), e.g.,

```

for(mov(0, esi); esi < 7; inc(esi)) do

 stdout.put("Array Element = ", SomeArray[esi*4], nl);

endfor;

```

To convert this to “pure” assembly language, begin by translating the FOR loop into an equivalent WHILE loop:

```

mov(0, esi);
while(esi < 7) do

 stdout.put("Array Element = ", SomeArray[esi*4], nl);

 inc(esi);
endwhile;

```

Now, using the techniques from the section on WHILE loops (see “While Loops” on page 764), translate the code into pure assembly language:

```

mov(0, esi);
WhileLp:
cmp(esi, 7);
jnl EndWhileLp;

 stdout.put("Array Element = ", SomeArray[esi*4], nl);

 inc(esi);
 jmp WhileLp;

EndWhileLp:

```

---

## 2.11.5 The BREAK and CONTINUE Statements

The HLA BREAK and CONTINUE statements both translate into a single JMP instruction. The BREAK instruction exits the loop that immediately contains the BREAK statement; the CONTINUE statement restarts the loop that immediately contains the CONTINUE statement.

Converting a BREAK statement to “pure” assembly language is very easy. Just emit a JMP instruction that transfers control to the first statement following the ENDxxxx clause of the loop to exit. This is easily accomplished by placing a label after the associated END clause and jumping to that label. The following code fragments demonstrate this technique for the various loops:

```
// Breaking out of a forever loop:

forever
 <<stmts>>
 //break;
 jmp BreakFromForever;
 <<stmts>>
endfor;
BreakFromForever:

// Breaking out of a FOR loop;
for(<<initStmt>>; <<expr>>; <<incStmt>>) do
 <<stmts>>
 //break;
 jmp BrkFromFor;
 <<stmts>>
endfor;
BrkFromFor:

// Breaking out of a WHILE loop:

while(<<expr>>) do
 <<stmts>>
 //break;
 jmp BrkFromWhile;
 <<stmts>>
endwhile;
BrkFromWhile:

// Breaking out of a REPEAT..UNTIL loop:

repeat
 <<stmts>>
 //break;
 jmp BrkFromRpt;
 <<stmts>>
until(<<expr>>);
BrkFromRpt:
```

The CONTINUE statement is slightly more difficult to implement than the BREAK statement. The implementation still consists of a single JMP instruction, however the target label doesn't wind up going in the same spot for each of the different loops. The following figures show where the CONTINUE statement transfers control for each of the HLA loops:

**Figure 2.2** CONTINUE Destination for the FOREVER Loop

---

**Figure 2.3** CONTINUE Destination and the WHILE Loop

---

Note: CONTINUE forces the execution of the <<incStmt>> clause and then transfers control to the test for loop termination.

**Figure 2.4** CONTINUE Destination and the FOR Loop

---

**Figure 2.5** CONTINUE Destination and the REPEAT..UNTIL Loop

The following code fragments demonstrate how to convert the CONTINUE statement into an appropriate JMP instruction for each of these loop types.

**forever..continue..endfor**

```

// Conversion of forever loop w/continue
// to pure assembly:
forever
 <<stmts>>
 continue;
 <<stmts>>
endfor;

```

// Converted code:

```

foreverLbl:
 <<stmts>>
 jmp foreverLbl;
 <<stmts>>

```

**while..continue..endwhile**

```

// Conversion of while loop w/continue
// into pure assembly:

while(<<expr>>) do
 <<stmts>>
 continue;
 <<stmts>>
endwhile;

```

// Converted code:

```

whlLabel:
<<Code to evaluate expr>>
Jcc EndOfWhile; // Skip loop on expr failure.
 <<stmts>>
 jmp whlLabel; // Jump to start of loop on continue.
 <<stmts>>
 jmp whlLabel; // Repeat the code.
EndOfwhile:

```

**for..continue..endfor**

```

// Conversion for a for loop w/continue

```

```

// into pure assembly:

for(<<initStmt>>; <<expr>>; <<incStmt>>) do
 <<stmts>>
 continue;
 <<stmts>>
endfor;

// Converted code

<<initStmt>>
ForLpLbl:
<<Code to evaluate expr>>
Jcc EndOfFor; // Branch if expression fails.
 <<stmts>>
 jmp ContFor; // Branch to <<incStmt>> on continue.
 <<stmts>>

 ContFor:
 <<incStmt>>
 jmp ForLpLbl;
EndOfFor:

```

**repeat..continue..until**

```

repeat
 <<stmts>>
 continue;
 <<stmts>>
until(<<expr>>);

// Converted Code:

RptLpLbl:
 <<stmts>>
 jmp ContRpt; // Continue branches to loop termination test.
 <<stmts>>
 ContRpt:
 <<code to test expr>>
 Jcc RptLpLbl; // Jumps if expression evaluates false.

```

---

**2.11.6 Register Usage and Loops**

Given that the 80x86 accesses registers much faster than memory locations, registers are the ideal spot to place loop control variables (especially for small loops). However, there are some problems associated with using registers within a loop. The primary problem with using registers as loop control variables is that registers are a limited resource. Therefore, the following will not work properly:

```

mov(8, cx);
loop1:
 mov(4, cx);
 loop2:
 <<stmts>>
 dec(cx);
 jnz loop2;

 dec(cx);
 jnz loop1;

```

The intent here, of course, was to create a set of nested loops, that is, one loop inside another. The inner loop (*Loop2*) should repeat four times for each of the eight executions of the outer loop (*Loop1*). Unfortunately, both loops use the same register as a loop control variable.. Therefore, this will form an infinite loop since CX will be set to zero at the end of the first loop. Since CX is always zero upon encountering the second DEC instruction, control will always transfer to the LOOP1 label (since decrementing zero produces a non-zero result). The solution here is to save and restore the CX register or to use a different register in place of CX for the outer loop:

```

mov(8, cx);
loop1:
 push(cx);
 mov(4, cx);
 loop2:
 <<stmts>>
 dec(cx);
 jnz loop2;

 pop(cx);
 dec(cx);
 jnz loop1;

```

or:

```

mov(8, dx);
loop1:
 mov(4, cx);
 loop2:
 <<stmts>>
 dec(cx);
 jnz loop2;

 dec(dx);
 jnz loop1;

```

Register corruption is one of the primary sources of bugs in loops in assembly language programs, always keep an eye out for this problem.

## 2.12 Performance Improvements

The 80x86 microprocessors execute sequences of instructions at blinding speeds. Therefore, you'll rarely encounter a program that is slow which doesn't contain any loops. Since loops are the primary source of performance problems within a program, they are the place to look when attempting to speed up your software. While a treatise on how to write efficient programs is beyond the scope of this chapter, there are some things you should be aware of when designing loops in your programs. They're all aimed at removing unnecessary instructions from your loops in order to reduce the time it takes to execute one iteration of the loop.

### 2.12.1 Moving the Termination Condition to the End of a Loop

Consider the following flow graphs for the three types of loops presented earlier:

REPEAT..UNTIL loop:

```

Initialization code
 Loop body
 Test for termination
 Code following the loop

```

WHILE loop:

```

Initialization code
Loop termination test
 Loop body
 Jump back to test
Code following the loop

```

FOREVER..ENDFOR loop:

```

Initialization code
 Loop body, part one
 Loop termination test
 Loop body, part two
 Jump back to loop body part 1
Code following the loop

```

As you can see, the REPEAT..UNTIL loop is the simplest of the bunch. This is reflected in the assembly language code required to implement these loops. Consider the following REPEAT..UNTIL and WHILE loops that are identical:

// Example involving a WHILE loop:

```

mov(edi, esi);
sub(20, esi);
while(esi <= edi) do

 <<stmts>>
 inc(esi);

endwhile;

```

// Conversion of the code above into pure assembly language:

```

mov(edi, esi);
sub(20, esi);
whlLbl:
cmp(esi, edi);
jnle EndOfWhile;

 <<stmts>>
 inc(esi);
 <<stmts>>
 jmp whlLbl;

EndOfWhile:

```

//Example involving a REPEAT..UNTIL loop:

```

mov(edi, esi);
sub(20, esi);
repeat

 <<stmts>>
 inc(esi);

until(esi > edi);

```

// Conversion of the REPEAT..UNTIL loop into pure assembly:

```

rptLabel:
 <<stmts>>
 inc(esi);

```

```

 cmp(esi, edi);
 jng rptLabel;

```

As you can see by carefully studying the conversion to pure assembly language, testing for the termination condition at the end of the loop allowed us to remove a JMP instruction from the loop. This can be significant if this loop is nested inside other loops. In the preceding example there wasn't a problem with executing the body at least once. Given the definition of the loop, you can easily see that the loop will be executed exactly 20 times. This suggests that the conversion to a REPEAT..UNTIL loop is trivial and always possible. Unfortunately, it's not always quite this easy. Consider the following HLA code:

```

while(esi <= edi) do
 <<stmts>>
 inc(esi);
endwhile;

```

In this particular example, we haven't the slightest idea what ESI contains upon entry into the loop. Therefore, we cannot assume that the loop body will execute at least once. So we must test for loop termination before executing the body of the loop. The test can be placed at the end of the loop with the inclusion of a single JMP instruction:

```

 jmp WhlTest;
TopOfLoop:
 <<stmts>>
 inc(esi);
 WhlTest:
 cmp(esi, edi);
 jle TopOfLoop;

```

Although the code is as long as the original WHILE loop, the JMP instruction executes only once rather than on each repetition of the loop. Note that this slight gain in efficiency is obtained via a slight loss in readability. The second code sequence above is closer to spaghetti code than the original implementation. Such is often the price of a small performance gain. Therefore, you should carefully analyze your code to ensure that the performance boost is worth the loss of clarity. More often than not, assembly language programmers sacrifice clarity for dubious gains in performance, producing impossible to understand programs.

Note, by the way, that HLA translates its WHILE statement into a sequence of instructions that test the loop termination condition at the bottom of the loop using exactly the technique this section describes. Therefore, you do not have to worry about the HLA WHILE statement introducing slower code into your programs.

## 2.12.2 Executing the Loop Backwards

Because of the nature of the flags on the 80x86, loops which range from some number down to (or up to) zero are more efficient than any other. Compare the following HLA FOR loop and the code it generates:

```

for(mov(1, J); J <= 8; inc(J)) do
 <<stmts>>
endfor;

```

// Conversion to pure assembly (as well as using a repeat..until form):

```

mov(1, J);
ForLp:
 <<stmts>>
 inc(J);
 cmp(J, 8);
 jnge ForLp;

```

Now consider another loop that also has eight iterations, but runs its loop control variable from eight down to one rather than one up to eight:

```
mov(8, J);
LoopLbl:
 <<stmts>>
 dec(J);
 jnz LoopLbl;
```

Note that by running the loop from eight down to one we saved a comparison on each repetition of the loop.

Unfortunately, you cannot force all loops to run backwards. However, with a little effort and some coercion you should be able to work most FOR loops so they operate backwards. By saving the execution time of the CMP instruction on each iteration of the loop the code may run faster.

The example above worked out well because the loop ran from eight down to one. The loop terminated when the loop control variable became zero. What happens if you need to execute the loop when the loop control variable goes to zero? For example, suppose that the loop above needed to range from seven down to zero. As long as the upper bound is positive, you can substitute the JNS instruction in place of the JNZ instruction above to repeat the loop some specific number of times:

```
mov(7, J);
LoopLbl:
 <<stmts>>
 dec(J);
 jns LoopLbl;
```

This loop will repeat eight times with *J* taking on the values seven down to zero on each execution of the loop. When it decrements zero to minus one, it sets the sign flag and the loop terminates.

Keep in mind that some values may look positive but they are negative. If the loop control variable is a byte, then values in the range 128..255 are negative. Likewise, 16-bit values in the range 32768..65535 are negative. Therefore, initializing the loop control variable with any value in the range 129..255 or 32769..65535 (or, of course, zero) will cause the loop to terminate after a single execution. This can get you into a lot of trouble if you're not careful.

## 2.12.3 Loop Invariant Computations

A loop invariant computation is some calculation that appears within a loop that always yields the same result. You needn't do such computations inside the loop. You can compute them outside the loop and reference the value of the computation inside the loop. The following HLA code demonstrates a loop which contains an invariant computation:

```
for(mov(0, eax); eax < n; inc(eax)) do

 mov(eax, edx);
 add(j, edx);
 sub(2, edx);
 add(edx, k);

endfor;
```

Since *j* never changes throughout the execution of this loop, the sub-expression "j-2" can be computed outside the loop and its value used in the expression inside the loop:

```
mov(j, ecx);
sub(2, ecx);
for(mov(0, eax); eax < n; inc(eax)) do

 mov(eax, edx);
 add(ecx, edx);
 add(edx, k);
```

```
endfor;
```

Still, the value in ECX never changes inside this loop, so although we've eliminated a single instruction by computing the subexpression "j-2" outside the loop, there is still an invariant component to this calculation. Since we note that this invariant component executes  $n$  times in the loop, we can translate the code above to the following:

```
mov(j, ecx);
sub(2, ecx);
intmul(n, ecx); // Compute n*(j-2) and add this into k outside
add(ecx, k); // the loop.
for(mov(0, eax); eax < n; inc(eax)) do

 add(eax, k);

endifor;
```

As you can see, we've shrunk the loop body from four instructions down to one. Of course, if you're really interested in improving the efficiency of this particular loop, you'd be much better off (most of the time) computing  $k$  using the formula:

$$k = k + ((n + 1) \times temp) + \frac{(n + 2) \times (n + 2)}{2}$$

This computation for  $k$  is based on the formula:

$$\sum_{i=0}^n i = \frac{(n + 1) \times (n)}{2}$$

However, simple computations such as this one aren't always possible. Still, this demonstrates that a better algorithm is almost always better than the trickiest code you can come up with.

Removing invariant computations and unnecessary memory accesses from a loop (particularly an inner loop in a set of nested loops) can produce dramatic performance improvements in a program.

## 2.12.4 Unraveling Loops

For small loops, that is, those whose body is only a few statements, the overhead required to process a loop may constitute a significant percentage of the total processing time. For example, look at the following Pascal code and its associated 80x86 assembly language code:

```
FOR I := 3 DOWNT0 0 DO A [I] := 0;

mov(3, I);
LoopLbl:
 mov(I, ebx);
 mov(0, A[ebx*4]);
 dec(I);
 jns LoopLbl;
```

Each iteration of the loop requires four instructions. Only one instruction is performing the desired operation (moving a zero into an element of  $A$ ). The remaining three instructions control the repetition of the loop. Therefore, it takes 16 instructions to do the operation logically required by four.

While there are many improvements we could make to this loop based on the information presented thus far, consider carefully exactly what it is that this loop is doing-- it's simply storing four zeros into  $A[0]$  through  $A[3]$ . A more efficient approach is to use four MOV instructions to accomplish the same task. For example, if  $A$  is an array of dwords, then the following code initializes  $A$  much faster than the code above:

```
mov(0, A[0]);
mov(0, A[4]);
```

```
mov(0, A[8]);
mov(0, A[12]);
```

Although this is a trivial example, it shows the benefit of loop unraveling. If this simple loop appeared buried inside a set of nested loops, the 4:1 instruction reduction could possibly double the performance of that section of your program.

Of course, you cannot unravel all loops. Loops that execute a variable number of times cannot be unraveled because there is rarely a way to determine (at assembly time) the number of times the loop will execute. Therefore, unraveling a loop is a process best applied to loops that execute a known number of times (and the number of times is known at assembly time).

Even if you repeat a loop some fixed number of iterations, it may not be a good candidate for loop unraveling. Loop unraveling produces impressive performance improvements when the number of instructions required to control the loop (and handle other overhead operations) represent a significant percentage of the total number of instructions in the loop. Had the loop above contained 36 instructions in the body of the loop (exclusive of the four overhead instructions), then the performance improvement would be, at best, only 10% (compared with the 300-400% it now enjoys). Therefore, the costs of unraveling a loop, i.e., all the extra code which must be inserted into your program, quickly reaches a point of diminishing returns as the body of the loop grows larger or as the number of iterations increases. Furthermore, entering that code into your program can become quite a chore. Therefore, loop unraveling is a technique best applied to small loops.

Note that the superscalar x86 chips (Pentium and later) have *branch prediction hardware* and use other techniques to improve performance. Loop unrolling on such systems many actually *slow down* the code since these processors are optimized to execute short loops.

## 2.12.5 Induction Variables

Consider the following modification of the loop presented in the previous section:

```
FOR I := 0 TO 255 DO csetVar[I] := {};
```

Here the program is initializing each element of an array of character sets to the empty set. The straight-forward code to achieve this is the following:

```
mov(0, i);
FLp:

// Compute the index into the array (note that each element
// of a CSET array contains 16 bytes).

mov(i, ebx);
shl(4, ebx);

// Set this element to the empty set (all zero bits).

mov(0, csetVar[ebx]);
mov(0, csetVar[ebx+4]);
mov(0, csetVar[ebx+8]);
mov(0, csetVar[ebx+12]);

inc(i);
cmp(i, 256);
jb FLp;
```

Although unraveling this code will still produce a performance improvement, it will take 1024 instructions to accomplish this task, too many for all but the most time-critical applications. However, you can reduce the execution time of the body of the loop using *induction variables*. An induction variable is one whose value depends entirely on the value of some other variable. In the example above, the index into the

array *csetVar* tracks the loop control variable (it's always equal to the value of the loop control variable times 16). Since *i* doesn't appear anywhere else in the loop, there is no sense in performing all the computations on *i*. Why not operate directly on the array index value? The following code demonstrates this technique:

```
mov(0, ebx);
FLp:
 mov(0, csetVar[ebx]);
 mov(0, csetVar[ebx+4]);
 mov(0, csetVar[ebx+8]);
 mov(0, csetVar[ebx+12]);

 add(16, ebx);
 cmp(ebx, 256*16);
 jb FLp;
```

The induction that takes place in this example occurs when the code increments the loop control variable (moved into EBX for efficiency reasons) by 16 on each iteration of the loop rather than by one. Multiplying the loop control variable by 16 allows the code to eliminate multiplying the loop control variable by 16 on each iteration of the loop (i.e., this allows us to remove the SHL instruction from the previous code). Further, since this code no longer refers to the original loop control variable (*i*), the code can maintain the loop control variable strictly in the EBX register.

## 2.13 Hybrid Control Structures in HLA

The HLA high level language control structures have a few drawbacks: (1) they're not true assembly language instructions, (2) complex boolean expressions only support short circuit evaluation, and (3) they often introduce inefficient coding practices into a language that most people only use when they need to write high-performance code. On the other hand, while the 80x86 low level control structures let you write efficient code, the resulting code is very difficult to read and maintain. HLA provides a set of hybrid control structures that allow you to use pure assembly language statements to evaluate boolean expressions while using the high level control structures to delineate the statements controlled by the boolean expressions. The result is code that is much more readable than pure assembly language without being a whole lot less efficient.

HLA provides hybrid forms of the IF..ELSEIF..ELSE..ENDIF, WHILE..ENDWHILE, REPEAT..UNTIL, BREAKIF, EXITIF, and CONTINUEIF statements (i.e., those that involve a boolean expression). For example, a hybrid IF statement takes the following form:

```
if(#{ <<statements>> }#) then <<statements>> endif;
```

Note the use of #{ and }# quotes to surround a sequence of instructions within this statement. This is what differentiates the hybrid control structures from the standard high level language control structures. The remaining hybrid control structures take the following forms:

```
while(#{ <<statements>> }#) <<statements>> endwhile;
repeat <<statements>> until(#{ <<statements>> }#);
breakif(#{ <<statements>> }#);
exitif(#{ <<statements>> }#);
continueif(#{ <<statements>> }#);
```

The statements within the curly braces replace the normal boolean expression in an HLA high level control structure. These particular statements are special insofar as HLA defines two labels, *true* and *false*, within their context. HLA associates the label *true* with the code that would normally execute if a boolean expression were present and that expression's result was true. Similarly, HLA associates the label *false* with the code that would execute if a boolean expression in one of these statements evaluated false. As a simple example, consider the following two (equivalent) IF statements:

```
if(eax < ebx) then inc(eax); endif;

if
```

```

(#{
 cmp(eax, ebx);
 jnl false;
}#) then
 inc(eax);

endif;

```

The JNL that transfers control to the *false* label in this latter example will skip over the INC instruction if EAX is not less than EBX. Note that if EAX is less than EBX then control falls through to the INC instruction. This is roughly equivalent to the following pure assembly code:

```

cmp(eax, ebx);
jnl falseLabel;
 inc(eax);
falseLabel:

```

As a slightly more complex example, consider the statement

```
if(eax >= J && eax <= K) then sub(J, eax); endif;
```

The following hybrid IF statement accomplishes the above:

```

if
(#{
 cmp(eax, J);
 jnge false;
 cmp(eax, K);
 jnle false;
}#) then
 sub(J, eax);

endif;

```

As one final example of the hybrid IF statement, consider the following:

```

// if((eax > ebx) && (eax < ecx) || (eax = edx)) then mov(ebx, eax); endif;

if
(#{
 cmp(eax, edx);
 je true;
 cmp(eax, ebx);
 jng false;
 cmp(eax, ecx);
 jnl false;
}#) then
 mov(ebx, eax);

endif;

```

Since these examples are rather trivial, they don't really demonstrate how much more readable the code can be when using hybrid statements rather than pure assembly code. However, one thing you notice is that the use of hybrid statements eliminate the need to insert labels throughout your code. This is what makes your programs easier to read and understand.

For the IF statement, the *true* label corresponds to the THEN clause of the statement; the *false* label corresponds to the ELSEIF, ELSE, or ENDIF clause (whichever follows the THEN clause). For the WHILE loop, the *true* label corresponds to the body of the loop while the *false* label is attached to the first statement following the corresponding ENDWHILE. For the REPEAT..UNTIL statement, the *true* label is attached to the code following the UNTIL clause while the *false* label is attached to the first statement of the body of the loop. The BREAKIF, EXITIF, and CONTINUEIF statements associate the *false* label with the statement

immediately following one of these statements, they associate the *true* label with the code normally associated with a BREAK, EXIT, or CONTINUE statement.

---

## 2.14 Putting It All Together

In this chapter we've taken a look at the low-level, or "pure" assembly language, implementation of several common control structures. Although HLA's high level control structures are easy to use and quite a bit more readable than their low-level equivalents, sometimes efficiency demands a low-level implementation. This chapter presents the blueprints for such transformations.

While this chapter covers the principle high level control structures and their translation to assembly language, there are some additional control structures that this chapter does not consider. Iterators and the TRY..ENDTRY statement are two good examples. Fear not, however, the volume on Advanced Assembly Language Programming will tidy up those loose ends.

# Intermediate Procedures

# Chapter Three

## 3.1 Chapter Overview

This chapter picks up where the chapter “Introduction to Procedures” in Volume Three leaves off. That chapter presented a high level view of procedures, parameters, and local variables; this chapter takes a look at some of the low-level implementation details. This chapter begins by discussing the CALL instruction and how it affects the stack. Then it discusses activation records and how a program passes parameters to a procedure and how that procedure maintains local (automatic) variables. Next, this chapter presents an in-depth discussion of pass by value and pass by reference parameters. This chapter concludes by discussing procedure variables, procedural parameters, iterators, and the FOREACH..ENDFOR loop.

## 3.2 Procedures and the CALL Instruction

Most procedural programming languages implement procedures using the call/return mechanism. That is, some code calls a procedure, the procedure does its thing, and then the procedure returns to the caller. The call and return instructions provide the 80x86’s *procedure invocation mechanism*. The calling code calls a procedure with the CALL instruction, the procedure returns to the caller with the RET instruction. For example, the following 80x86 instruction calls the HLA Standard Library *stdout.newln* routine:

```
call stdout.newln;
```

*stdout.newln* prints a carriage return/line feed sequence to the video display and returns control to the instruction immediately following the “call stdout.newln;” instruction.

The HLA language lets you call procedures using a high level language syntax. Specifically, you may call a procedure by simply specifying the procedure’s name and (in the case of *stdout.newln*) an empty parameter list. That is, the following is completely equivalent to “call stdout.newln”:

```
stdout.newln();
```

The 80x86 CALL instruction does two things. First, it pushes the address of the instruction immediately following the CALL onto the stack; then it transfers control to the address of the specified procedure. The value that CALL pushes onto the stack is known as the *return address*. When the procedure wants to return to the caller and continue execution with the first statement following the CALL instruction, the procedure simply pops the return address off the stack and jumps (indirectly) to that address. Most procedures return to their caller by executing a RET (return) instruction. The RET instruction pops a return address off the stack and transfers control indirectly to the address it pops off the stack.

By default, the HLA compiler automatically places a RET instruction (along with a few other instructions) at the end of each HLA procedure you write. This is why you haven’t had to explicitly use the RET instruction up to this point. To disable the default code generation in an HLA procedure, specify the following options when declaring your procedures:

```
procedure ProcName; noframe; nodisplay;
begin ProcName;
 .
 .
 .
end ProcName;
```

The NOFRAME and NODISPLAY clauses are examples of procedure *options*. HLA procedures support four such options, specifically RETURNS (See “The HLA RETURNS Option in Procedures” on page 540.), the NOFRAME, NODISPLAY, and NOALIGNSTK. You’ll see the purpose of NOALIGNSTK a little later in this chapter. These procedure options may appear in any order following the procedure name (and parameters, if any). Note that NOFRAME and NODISPLAY (as well as NOALIGNSTK) may only

appear in an actual procedure declaration. You cannot specify these options in an external procedure prototype.

The `NOFRAME` option tells HLA that you don't want the compiler to automatically generate entry and exit code for the procedure. This tells HLA not to automatically generate the `RET` instruction (along with several other instructions).

The `NODISPLAY` option tells HLA that it should not allocate storage in procedure's local variable area for a *display*. The display is a mechanism you use to access non-local `VAR` objects in a procedure. Therefore, a display is only necessary if you nest procedures in your programs. This chapter will not consider the display or nested procedures; for more details on the display and nested procedures see the appropriate chapter in Volume Five. Until then, you can safely specify the `NODISPLAY` option on all your procedures. Note that you may specify the `NODISPLAY` option independently of the `NOFRAME` option. Indeed, for all of the procedures appearing in this text up to this point specifying the `NODISPLAY` option makes a lot of sense because none of those procedures have actually used the display. Procedures that have the `NODISPLAY` option are a tiny bit faster and a tiny bit shorter than those procedures that do not specify this option.

The following is an example of the minimal procedure:

```
procedure minimal; nodisplay; noframe; noalignstk;
begin minimal;

 ret();

end minimal;
```

If you call this procedure with the `CALL` instruction, *minimal* will simply pop the return address off the stack and return back to the caller. You should note that a `RET` instruction is absolutely necessary when you specify the `NOFRAME` procedure option<sup>1</sup>. If you fail to put the `RET` instruction in the procedure, the program will not return to the caller upon encountering the "end minimal;" statement. Instead, the program will fall through to whatever code happens to follow the procedure in memory. The following example program demonstrates this problem:

```
program missingRET;
#include("stdlib.hhf");

// This first procedure has the NOFRAME
// option but does not have a RET instruction.

procedure firstProc; noframe; nodisplay;
begin firstProc;

 stdout.put("Inside firstProc" nl);

end firstProc;

// Because the procedure above does not have a
// RET instruction, it will "fall through" to
// the following instruction. Note that there
// is no call to this procedure anywhere in
// this program.

procedure secondProc; noframe; nodisplay;
begin secondProc;

 stdout.put("Inside secondProc" nl);
```

1. Strictly speaking, this isn't true. But some mechanism that pops the return address off the stack and jumps to the return address is necessary in the procedure's body.

```

 ret ();

 end secondProc;

begin missingRET;

 // Call the procedure that doesn't have
 // a RET instruction.

 call firstProc;

end missingRET;

```

---

### Program 3.1 Effect of Missing RET Instruction in a Procedure

---

Although this behavior might be desirable in certain rare circumstances, it usually represents a defect in most programs. Therefore, if you specify the NOFRAME option, always remember to explicitly return from the procedure using the RET instruction.

---

## 3.3 Procedures and the Stack

Since procedures use the stack to hold the return address, you must exercise caution when pushing and popping data within a procedure. Consider the following simple (and defective) procedure:

```

procedure MessedUp; noframe; nodisplay;
begin MessedUp;

 push(eax);
 ret ();

end MessedUp;

```

At the point the program encounters the RET instruction, the 80x86 stack takes the form shown in Figure 3.1:

**Figure 3.1** Stack Contents Before RET in “MessedUp” Procedure

The RET instruction isn’t aware that the value on the top of stack is not a valid address. It simply pops whatever value is on the top of the stack and jumps to that location. In this example, the top of stack contains the saved EAX value. Since it is very unlikely that EAX contains the proper return address (indeed, there is about a one in four billion chance it is correct), this program will probably crash or exhibit some other undefined behavior. Therefore, you must take care when pushing data onto the stack within a procedure that you properly pop that data prior to returning from the procedure.

**Note:** if you do not specify the NOFRAME option when writing a procedure, HLA automatically generates code at the beginning of the procedure that pushes some data onto the stack. Therefore, unless you understand exactly what is going on and you’ve taken care of this data HLA pushes on the stack, you should never execute the bare RET instruction inside a procedure that does not have the NOFRAME option. Doing so will attempt to return to the location specified by this data (which is not a return address) rather than properly returning to the caller. In procedures that do not have the NOFRAME option, use the EXIT or EXITIF statements to return from the procedure (See “BEGIN..EXIT..EXITIF..END” on page 718.).

Popping extra data off the stack prior to executing the RET statement can also create havoc in your programs. Consider the following defective procedure:

```
procedure MessedUpToo; noframe; nodisplay;
begin MessedUpToo;

 pop(eax);
 ret();

end MessedUpToo;
```

Upon reaching the RET instruction in this procedure, the 80x86 stack looks something like that shown in Figure 3.2:

**Figure 3.2** Stack Contents Before RET in MessedUpToo

Once again, the RET instruction blindly pops whatever data happens to be on the top of the stack and attempts to return to that address. Unlike the previous example, where it was very unlikely that the top of stack contained a valid return address (since it contained the value in EAX), there is a small possibility that the top of stack in this example actually *does* contain a return address. However, this will not be the proper return address for the *MessedUpToo* procedure; instead, it will be the return address for the procedure that called *MessedUpToo*. To understand the effect of this code, consider the following program:

```

program extraPop;
#include("stdlib.hhf");

// Note that the following procedure pops
// excess data off the stack (in this case,
// it pops messedUpToo's return address).

procedure messedUpToo; noframe; nodisplay;
begin messedUpToo;

 stdout.put("Entered messedUpToo" nl);
 pop(eax);
 ret();

end messedUpToo;

procedure callsMU2; noframe; nodisplay;
begin callsMU2;

 stdout.put("calling messedUpToo" nl);
 messedUpToo();

 // Because messedUpToo pops extra data
 // off the stack, the following code
 // never executes (since the data popped
 // off the stack is the return address that
 // points at the following code.

 stdout.put("Returned from messedUpToo" nl);

```

```

 ret ();

 end callsMU2;

begin extraPop;

 stdout.put("Calling callsMU2" nl);
 callsMU2 ();
 stdout.put("Returned from callsMU2" nl);

end extraPop;

```

---

---

### Program 3.2 Effect of Popping Too Much Data Off the Stack

---

---

Since a valid return address is sitting on the top of the stack, you might think that this program will actually work (properly). However, note that when returning from the *MessedUpToo* procedure, this code returns directly to the main program rather than to the proper return address in the *EndSkipped* procedure. Therefore, all code in the *callsMU2* procedure that follows the call to *MessedUpToo* does not execute. When reading the source code, it may be very difficult to figure out why those statements are not executing since they immediately follow the call to the *MessUpToo* procedure. It isn't clear, unless you look very closely, that the program is popping an extra return address off the stack and, therefore, doesn't return back to *callsMU2* but, rather, returns directly to whomever calls *callsMU2*. Of course, in this example it's fairly easy to see what is going on (because this example is a demonstration of this problem). In real programs, however, determining that a procedure has accidentally popped too much data off the stack can be much more difficult. Therefore, you should always be careful about pushing and popping data in a procedure. You should always verify that there is a one-to-one relationship between the pushes in your procedures and the corresponding pops.

---

## 3.4 Activation Records

Whenever you call a procedure there is certain information the program associates with that procedure call. The return address is a good example of some information the program maintains for a specific procedure call. Parameters and automatic local variables (i.e., those you declare in the VAR section) are additional examples of information the program maintains for each procedure call. *Activation record* is the term we'll use to describe the information the program associates with a specific call to a procedure<sup>2</sup>.

Activation record is an appropriate name for this data structure. The program creates an activation record when calling (activating) a procedure and the data in the structure is organized in a manner identical to records (see "Records" on page 465). Perhaps the only thing unusual about an activation record (when comparing it to a standard record) is that the base address of the record is in the middle of the data structure, so you must access fields of the record at positive and negative offsets.

Construction of an activation record begins in the code that calls a procedure. The caller pushes the parameter data (if any) onto the stack. Then the execution of the CALL instruction pushes the return address onto the stack. At this point, construction of the activation record continues in the procedure itself. The procedure pushes registers and other important state information and then makes room in the activation record for local variables. The procedure must also update the EBP register so that it points at the base address of the activation record.

To see what a typical activation record looks like, consider the following HLA procedure declaration:

```

procedure ARDemo(i:uns32; j:int32; k:dword); nodisplay;
var
 a:int32;

```

---

2. Stack frame is another term many people use to describe the activation record.

```

r:real32;
c:char;
b:boolean;
w:word;
begin ARDemo;
.
.
.
end ARDemo;

```

Whenever an HLA program calls this *ARDemo* procedure, it begins by pushing the data for the parameters onto the stack. The calling code will push the parameters onto the stack in the order they appear in the parameter list, from left to right. Therefore, the calling code first pushes the value for the *i* parameter, then it pushes the value for the *j* parameter, and it finally pushes the data for the *k* parameter. After pushing the parameters, the program calls the *ARDemo* procedure. Immediately upon entry into the *ARDemo* procedure, the stack contains these four items arranged as shown in Figure 3.3

**Figure 3.3** Stack Organization Immediately Upon Entry into *ARDemo*

The first few instructions in *ARDemo* (note that it does not have the *NOFRAME* option) will push the current value of *EBP* onto the stack and then copy the value of *ESP* into *EBP*. Next, the code drops the stack pointer down in memory to make room for the local variables. This produces the stack organization shown in Figure 3.4

**Figure 3.4** Activation Record for ARDemo

To access objects in the activation record you must use offsets from the EBP register to the desired object. The two items of immediate interest to you are the parameters and the local variables. You can access the parameters at positive offsets from the EBP register, you can access the local variables at negative offsets from the EBP register as Figure 3.5 shows:

**Figure 3.5** Offsets of Objects in the ARDemo Activation Record

Intel specifically reserves the EBP (extended base pointer) for use as a pointer to the base of the activation record. This is why you should never use the EBP register for general calculations. If you arbitrarily

change the value in the EBP register you will lose access to the current procedure's parameters and local variables.

### 3.5 The Standard Entry Sequence

The caller of a procedure is responsible for pushing the parameters onto the stack. Of course, the CALL instruction pushes the return address onto the stack. It is the procedure's responsibility to construct the rest of the activation record. This is typically accomplished by the following "standard entry sequence" code:

```
push(ebp); // Save a copy of the old EBP value
mov(esp, ebp); // Get ptr to base of activation record into EBP
sub(NumVars, esp); // Allocate storage for local variables.
```

If the procedure doesn't have any local variables, the third instruction above, "sub( NumVars, esp );" isn't needed. *NumVars* represents the number of bytes of local variables needed by the procedure. This is a constant that should be an even multiple of four (so the ESP register remains aligned on a double word boundary). If the number of bytes of local variables in the procedure is not an even multiple of four, you should round the value up to the next higher multiple of four before subtracting this constant from ESP. Doing so will slightly increase the amount of storage the procedure uses for local variables but will not otherwise affect the operation of the procedure.

**Warning:** if the *NumVars* constant is not an even multiple of four, subtracting this value from ESP (which, presumably, contains a dword-aligned pointer) will virtually guarantee that all future stack accesses are misaligned since the program almost always pushes and pops dword values. This will have a very negative performance impact on the program. Worse still, many Windows API calls will fail if the stack is not dword-aligned upon entry into the Windows subsystem. Therefore, you must always ensure that your local variable allocation value is an even multiple of four.

Because of the problems with a misaligned stack, by default HLA will also emit a fourth instruction as part of the standard entry sequence. The HLA compiler actually emits the following standard entry sequence for the ARDemo procedure defined earlier:

```
push(ebp);
mov(esp, ebp);
sub(12, esp); // Make room for ARDemo's local variables.
and($FFFF_FFFC, esp); // Force dword stack alignment.
```

The AND instruction at the end of this sequence forces the stack to be aligned on a four-byte boundary (it reduces the value in the stack pointer by one, two, or three if the value in ESP is not an even multiple of four). Although the *ARDemo* entry code correctly subtracts 12 from ESP for the local variables (12 is both an even multiple of four and the number of bytes of local variables), this only leaves ESP double word aligned if it was double word aligned immediately upon entry into the procedure. Had the caller messed with the stack and left ESP containing a value that was not an even multiple of four, subtracting 12 from ESP would leave ESP containing an unaligned value. The AND instruction in the sequence above, however, guarantees that ESP is dword aligned regardless of ESP's value upon entry into the procedure. The few bytes and CPU cycles needed to execute this instruction pay off handsomely if ESP is not double word aligned.

Although it is always safe to execute the AND instruction in the standard entry sequence, it might not be necessary. If you always ensure that ESP contains a double word aligned value, the AND instruction in the standard entry sequence above is unnecessary. Therefore, if you've specified the NOFRAME procedure option, you don't have to include that instruction as part of the entry sequence.

If you haven't specified the NOFRAME option (i.e., you're letting HLA emit the instructions to construct the standard entry sequence for you), you can still tell HLA not to emit the extra AND instruction if you're sure the stack will be dword aligned whenever someone calls the procedure. To do this, use the NOALIGNSTK procedure option, e.g.,

```
procedure NASDemo(i:uns32; j:int32; k:dword); noalignstk;
```

```

var
 LocalVar:int32;
begin NASDemo;
 .
 .
end NASDemo;

```

HLA emits the following entry sequence for the procedure above:

```

push(ebp);
mov(esp, ebp);
sub(4, esp);

```

### 3.6 The Standard Exit Sequence

Before a procedure returns to its caller, it needs to clean up the activation record. Although it is possible to share the clean-up duties between the procedure and the procedure's caller, Intel has included some features in the instruction set that allows the procedure to efficiently handle all the clean up chores itself. Standard HLA procedures and procedure calls, therefore, assume that it is the procedure's responsibility to clean up the activation record (including the parameters) when the procedure returns to its caller.

If a procedure does not have any parameters, the calling sequence is very simple. It requires only three instructions:

```

mov(ebp, esp); // Deallocate locals and clean up stack.
pop(ebp); // Restore pointer to caller's activation record.
ret(); // Return to the caller.

```

If the procedure has some parameters, then a slight modification to the standard exit sequence is necessary in order to remove the parameter data from the stack. Procedures with parameters use the following standard exit sequence:

```

mov(ebp, esp); // Deallocate locals and clean up stack.
pop(ebp); // Restore pointer to caller's activation record.
ret(ParmBytes); // Return to the caller and pop the parameters.

```

The *ParmBytes* operand of the RET instruction is a constant that specifies the number of *bytes* of parameter data to remove from the stack after the return instruction pops the return address. For example, the ARDemo example code in the previous sections has three double word parameters. Therefore, the standard exit sequence would take the following form:

```

mov(ebp, esp);
pop(ebp);
ret(12);

```

If you've declared your parameters using HLA syntax (i.e., a parameter list follows the procedure declaration), then HLA automatically creates a local constant in the procedure, *\_parms\_*, that is equal to the number of bytes of parameters in that procedure. Therefore, rather than worrying about having to count the number of parameter bytes yourself, you can use the following standard exit sequence for any procedure that has parameters:

```

mov(ebp, esp);
pop(ebp);
ret(_parms_);

```

Note that if you do not specify a byte constant operand to the RET instruction, the 80x86 will not pop the parameters off the stack upon return. Those parameters will still be sitting on the stack when you execute the first instruction following the CALL to the procedure. Similarly, if you specify a value that is too

small, some of the parameters will be left on the stack upon return from the procedure. If the RET operand you specify is too large, the RET instruction will actually pop some of the caller's data off the stack, usually with disastrous consequences.

Note that if you wish to return early from a procedure that doesn't have the NOFRAME option, and you don't particularly want to use the EXIT or EXITIF statement, you must execute the standard exit sequence to return to the caller. A simple RET instruction is insufficient since local variables and the old EBP value are probably sitting on the top of the stack.

### 3.7 HLA Local Variables

Your program accesses local variables in a procedure by using negative offsets from the activation record base address (EBP). For example, consider the following HLA procedure (which admittedly, doesn't do much other than demonstrate the use of local variables):

```
procedure LocalVars; nodisplay;
var
 a:int32;
 b:int32;
begin LocalVars;

 mov(0, a);
 mov(a, eax);
 mov(eax, b);

end LocalVars;
```

The activation record for LocalVars looks like

**Figure 3.6** Activation Record for LocalVars Procedure

The HLA compiler emits code that is roughly equivalent to the following for the body of this procedure<sup>3</sup>:

```
mov(0, (type dword [ebp-4]));
mov([ebp-4], eax);
mov(eax, [ebp-8]);
```

3. Ignoring the code associated with the standard entry and exit sequences.

You could actually type these statements into the procedure yourself and they would work. Of course, using memory references like “[ebp-4]” and “[ebp-8]” rather than *a* or *b* makes your programs very difficult to read and understand. Therefore, you should always declare and use HLA symbolic names rather than offsets from EBP.

The standard entry sequence for this *LocalVars* procedure will be<sup>4</sup>

```
push(ebp);
mov(esp, ebp);
sub(8, esp);
```

This code subtracts eight from the stack pointer because there are eight bytes of local variables (two *dword* objects) in this procedure. Unfortunately, as the number of local variables increases, especially if those variables have different types, computing the number of bytes of local variables becomes rather tedious. Fortunately, for those who wish to write the standard entry sequence themselves, HLA automatically computes this value for you and creates a constant, `_vars_`, that specifies the number of bytes of local variables for you<sup>5</sup>. Therefore, if you intend to write the standard entry sequence yourself, you should use the `_vars_` constant in the SUB instruction when allocating storage for the local variables:

```
push(ebp);
mov(esp, ebp);
sub(_vars_, esp);
```

Now that you’ve seen how assembly language (and, indeed, most languages) allocate and deallocate storage for local variables, it’s easy to understand why automatic (local VAR) variables do not maintain their values between two calls to the same procedure. Since the memory associated with these automatic variables is on the stack, when a procedure returns to its caller the caller can push other data onto the stack obliterating the values of the local variable values previously held on the stack. Furthermore, intervening calls to other procedures (with their own local variables) may wipe out the values on the stack. Also, upon reentry into a procedure, the procedure’s local variables may correspond to different physical memory locations, hence the values of the local variables would not be in their proper locations.

One big advantage to automatic storage is that it efficiently shares a fixed pool of memory among several procedures. For example, if you call three procedures in a row,

```
ProcA();
ProcB();
ProcC();
```

The first procedure (*ProcA* in the code above) allocates its local variables on the stack. Upon return, *ProcA* deallocates that stack storage. Upon entry into *ProcB*, the program allocates storage for *ProcB*’s local variables *using the same memory locations just freed by ProcA*. Likewise, when *ProcB* returns and the program calls *ProcC*, *ProcC* uses the same stack space for its local variables that *ProcB* recently freed up. This memory reuse makes efficient use of the system resources and is probably the greatest advantage to using automatic (VAR) variables.

## 3.8 Parameters

Although there is a large class of procedures that are totally self-contained, most procedures require some input data and return some data to the caller. Parameters are values that you pass to and from a procedure. There are many facets to parameters. Questions concerning parameters include:

- *where* is the data coming from?
- *what* mechanism do you use to pass and return data?
- *how* much data are you passing?

4. This code assumes that ESP is *dword* aligned upon entry so the “AND( \$FFFF\_FFFC, ESP );” instruction is unnecessary.

5. HLA even rounds this constant up to the next even multiple of four so you don’t have to worry about stack alignment.

In this chapter we will look at the two most common parameter passing mechanisms: pass by value and pass by reference. We will also discuss three popular places to pass parameters: in the registers, on the stack, and in the code stream. The amount of parameter data has a direct bearing on where and how to pass it. The following sections take up these issues.

---

### 3.8.1 Pass by Value

A parameter passed by value is just that – the caller passes a value to the procedure. Pass by value parameters are input only parameters. That is, you can pass them to a procedure but the procedure cannot return values through them. In high level languages the idea of a pass by value parameter being an input only parameter makes a lot of sense. Given the procedure call:

```
CallProc(I);
```

If you pass *I* by value, *CallProc* does not change the value of *I*, regardless of what happens to the parameter inside *CallProc*.

Since you must pass a copy of the data to the procedure, you should only use this method for passing small objects like bytes, words, and double words. Passing arrays and strings by value is very inefficient (since you must create and pass a copy of the structure to the procedure).

---

### 3.8.2 Pass by Reference

To pass a parameter by reference you must pass the address of a variable rather than its value. In other words, you must pass a pointer to the data. The procedure must dereference this pointer to access the data. Passing parameters by reference is useful when you must modify the actual parameter or when you pass large data structures between procedures.

Passing parameters by reference can produce some peculiar results. The following Pascal procedure provides an example of one problem you might encounter:

```
program main(input,output);
var m:integer;

(*
** Note: this procedure passes i and j by reference.
*)

procedure bletch(var i,j:integer);
begin
 i := i+2;
 j := j-i;
 writeln(i,' ',j);
end;

.
.
.

begin {main}
 m := 5;
 bletch(m,m);
end.
```

This particular code sequence will print “00” regardless of *m*’s value. This is because the parameters *i* and *j* are pointers to the actual data and they both point at the same object (that is, they are aliases). Therefore, the statement “j:=j-i;” always produces zero since *i* and *j* refer to the same variable.

Pass by reference is usually less efficient than pass by value. You must dereference all pass by reference parameters on each access; this is slower than simply using a value. However, when passing a large data structure, pass by reference is faster because you do not have to copy a large data structure before calling the procedure.

### 3.8.3 Passing Parameters in Registers

Having touched on how to pass parameters to a procedure, the next thing to discuss is where to pass parameters. Where you pass parameters depends on the size and number of those parameters. If you are passing a small number of bytes to a procedure, then the registers are an excellent place to pass parameters to a procedure. If you are passing a single parameter to a procedure you should use the following registers for the accompanying data types:

| Data Size    | Pass in this Register |
|--------------|-----------------------|
| Byte:        | al                    |
| Word:        | ax                    |
| Double Word: | eax                   |
| Quad Word:   | edx:eax               |

This is not a hard and fast rule. If you find it more convenient to pass 16 bit values in the SI or BX register, do so. However, most programmers use the registers above to pass parameters.

If you are passing several parameters to a procedure in the 80x86's registers, you should probably use up the registers in the following order:

| First | Last                         |
|-------|------------------------------|
|       | eax, edx, esi, edi, ebx, ecx |

In general, you should avoid using EBP register. If you need more than six double words, perhaps you should pass your values elsewhere.

As an example, consider the following “`strfill(str,c);`” that copies the character *c* (passed by value in AL) to each character position in *s* (passed by reference in EDI) up to a zero terminating byte:

```
// strfill- Overwrites the data in a string with a character.
//
// EDI- pointer to zero terminated string (e.g., an HLA string)
// AL- character to store into the string.

procedure strfill; nodisplay;
begin strfill;

 push(edi); // Preserve this because it will be modified.
 while((type char [edi] <> #0) do

 mov(al, [edi]);
 inc(edi);

 endwhile;
 pop(edi);

end strfill;
```

To call the *strfill* procedure you would load the address of the string data into EDI and the character value into AL prior to the call. The following code fragment demonstrates a typical call to *strfill*:

```
mov(s, edi); // Get ptr to string data into edi (assumes s:string).
mov(' ', al);
strfill();
```

Don't forget that HLA string variables are pointers. This example assumes that *s* is a HLA string variable and, therefore, contains a pointer to a zero-terminated string. Therefore, the “`mov( s, edi );`” instruction loads the address of the zero terminated string into the EDI register (hence this code passes the address of the string data to *strfill*, that is, it passes the string by reference).

One way to pass parameters in the registers is to simply load the registers with the appropriate values prior to a call and then reference the values in those registers within the procedure. This is the traditional mechanism for passing parameters in registers in an assembly language program. HLA, being somewhat more high level than traditional assembly language, provides a formal parameter declaration syntax that lets you tell HLA you're passing certain parameters in the general purpose registers. This declaration syntax is the following:

```
parmName: parmType in reg
```

Where *parmName* is the parameter's name, *parmType* is the type of the object, and *reg* is one of the 80x86's general purpose eight, sixteen, or thirty-two bit registers. The size of the parameter's type must be equal to the size of the register or HLA will generate an error. Here is a concrete example:

```
procedure HasRegParms(count: uns32 in ecx; charVal:char in al);
```

One nice feature to this syntax is that you can call a procedure that has register parameters exactly like any other procedure in HLA using the high level syntax, e.g.,

```
HasRegParms(ecx, bl);
```

If you specify the same register as an actual parameter that you've declared for the formal parameter, HLA does not emit any extra code; it assumes that the parameter is already in the appropriate register. For example, in the call above the first actual parameter is the value in ECX; since the procedure's declaration specifies that that first parameter is in ECX HLA will not emit any code. On the other hand, the second actual parameter is in BL while the procedure will expect this parameter value in AL. Therefore, HLA will emit a “`mov( bl, al );`” instruction prior to calling the procedure so that the value is in the proper register upon entry to the procedure.

You can also pass parameters by reference in a register. Consider the following declaration:

```
procedure HasRefRegParm(var myPtr:uns32 in edi);
```

A call to this procedure always requires some memory operand as the actual parameter. HLA will emit the code to load the address of that memory object into the parameter's register (EDI in this case). Note that when passing reference parameters, the register must be a 32-bit general purpose register since addresses are 32-bits long. Here's an example of a call to *HasRefRegParm*:

```
HasRefRegParm(x);
```

HLA will emit either a “`mov( &x, edi );`” or “`lea( edi, x );`” instruction to load the address of *x* into the EDI registers prior to the CALL instruction<sup>6</sup>.

If you pass an anonymous memory object (e.g., “[edi]” or “[ecx]”) as a parameter to *HasRefRegParm*, HLA will not emit any code if the memory reference uses the same register that you declare for the parameter (i.e., “[edi]”). It will use a simple MOV instruction to copy the actual address into EDI if you specify an indirect addressing mode using a register other than EDI (e.g., “[ecx]”). It will use an LEA instruction to compute the effective address of the anonymous memory operand if you use a more complex addressing mode like “[edi+ecx\*4+2]”.

Within the procedure's code, HLA creates text equates for these register parameters that map their names to the appropriate register. In the *HasRegParms* example, any time you reference the *count* parameter, HLA substitutes “`ecx`” for *count*. Likewise, HLA substitutes “`al`” for *charVal* throughout the procedure's body. Since these names are aliases for the registers, you should take care to always remember that you cannot use ECX and AL independently of these parameters. It would be a good idea to place a comment next to

---

6. The choice of instructions is dictated by whether *x* is a static variable (MOV for static objects, LEA for other objects).

each use of these parameters to remind the reader that *count* is equivalent to ECX and *charVal* is equivalent to AL.

---

### 3.8.4 Passing Parameters in the Code Stream

Another place where you can pass parameters is in the code stream immediately after the CALL instruction. Consider the following *print* routine that prints a literal string constant to the standard output device:

```
call print;
byte "This parameter is in the code stream.",0;
```

Normally, a subroutine returns control to the first instruction immediately following the CALL instruction. Were that to happen here, the 80x86 would attempt to interpret the ASCII code for “This...” as an instruction. This would produce undesirable results. Fortunately, you can skip over this string when returning from the subroutine.

So how do you gain access to these parameters? Easy. The return address on the stack points at them. Consider the following implementation of *print*:

---

```
program printDemo;
#include("stdlib.hhf");

// print-
//
// This procedure writes the literal string
// immediately following the call to the
// standard output device. The literal string
// must be a sequence of characters ending with
// a zero byte (i.e., a C string, not an HLA
// string).

procedure print; noframe; nodisplay;
const

 // RtnAdrs is the offset of this procedure's
 // return address in the activation record.

 RtnAdrs:text := "(type dword [ebp+4])";

begin print;

 // Build the activation record (note the
 // "noframe" option above).

 push(ebp);
 mov(esp, ebp);

 // Preserve the registers this function uses.

 push(eax);
 push(ebx);

 // Copy the return address into the EBX
 // register. Since the return address points
 // at the start of the string to print, this
 // instruction loads EBX with the address of
 // the string to print.

 mov(RtnAdrs, ebx);
```

```

// Until we encounter a zero byte, print the
// characters in the string.

forever

 mov([ebx], al); // Get the next character.
 breakif(!al); // Quit if it's zero.
 stdout.putc(al); // Print it.
 inc(ebx); // Move on to the next char.

endfor;

// Skip past the zero byte and store the resulting
// address over the top of the return address so
// we'll return to the location that is one byte
// beyond the zero terminating byte of the string.

inc(ebx);
mov(ebx, RtnAdrs);

// Restore EAX and EBX.

pop(ebx);
pop(eax);

// Clean up the activation record and return.

pop(ebp);
ret();

end print;

begin printDemo;

// Simple test of the print procedure.

call print;
byte "Hello World!", 13, 10, 0 ;

end printDemo;

```

---

### Program 3.3 Print Procedure Implementation (Using Code Stream Parameters)

---

Besides showing how to pass parameters in the code stream, the *print* routine also exhibits another concept: *variable length parameters*. The string following the CALL can be any practical length. The zero terminating byte marks the end of the parameter list. There are two easy ways to handle variable length parameters. Either use some special terminating value (like zero) or you can pass a special length value that tells the subroutine how many parameters you are passing. Both methods have their advantages and disadvantages. Using a special value to terminate a parameter list requires that you choose a value that never appears in the list. For example, *print* uses zero as the terminating value, so it cannot print the NUL character (whose ASCII code is zero). Sometimes this isn't a limitation. Specifying a special length parameter is another mechanism you can use to pass a variable length parameter list. While this doesn't require any special codes or limit the range of possible values that can be passed to a subroutine, setting up the length parameter and maintaining the resulting code can be a real nightmare<sup>7</sup>.

Despite the convenience afforded by passing parameters in the code stream, there are some disadvantages to passing parameters there. First, if you fail to provide the exact number of parameters the procedure requires, the subroutine will get very confused. Consider the *print* example. It prints a string of characters up to a zero terminating byte and then returns control to the first instruction following the zero terminating byte. If you leave off the zero terminating byte, the *print* routine happily prints the following opcode bytes as ASCII characters until it finds a zero byte. Since zero bytes often appear in the middle of an instruction, the *print* routine might return control into the middle of some other instruction. This will probably crash the machine. Inserting an extra zero, which occurs more often than you might think, is another problem programmers have with the *print* routine. In such a case, the *print* routine would return upon encountering the first zero byte and attempt to execute the following ASCII characters as machine code. Once again, this usually crashes the machine. These are the some of the reasons why the HLA *stdout.put* code does *not* pass its parameters in the code stream. Problems notwithstanding, however, the code stream is an efficient place to pass parameters whose values do not change.

---

### 3.8.5 Passing Parameters on the Stack

Most high level languages use the stack to pass parameters because this method is fairly efficient. By default, HLA also passes parameters on the stack. Although passing parameters on the stack is slightly less efficient than passing those parameters in registers, the register set is very limited and you can only pass a few value or reference parameters through registers. The stack, on the other hand, allows you to pass a large amount of parameter data without any difficulty. This is the principal reason that most programs pass their parameters on the stack.

HLA passes parameters you specify in a high-level language form on the stack. For example, suppose you define *strfill* from the previous section as follows:

```
procedure strfill(s:string; chr:char);
```

Calls of the form “*strfill*( *s*, ‘ ’ );” will pass the value of *s* (which is an address) and a space character on the 80x86 stack. When you specify a call to *strfill* in this manner, HLA automatically pushes the parameters for you, so you don’t have to push them onto the stack yourself. Of course, if you choose to do so, HLA will let you manually push the parameters onto the stack prior to the call.

To manually pass parameters on the stack, push them immediately before calling the subroutine. The subroutine then reads this data from the stack memory and operates on it appropriately. Consider the following HLA procedure call:

```
CallProc(i, j, k);
```

HLA pushes parameters onto the stack in the order that they appear in the parameter list<sup>7</sup>. Therefore, the 80x86 code HLA emits for this subroutine call (assuming you’re passing the parameters by value) is

```
push(i);
push(j);
push(k);
call CallProc;
```

Upon entry into *CallProc*, the 80x86’s stack looks like that shown in Figure 3.7:

---

7. Especially if the parameter list changes frequently.

8. Assuming, of course, that you don’t instruct HLA otherwise. It is possible to tell HLA to reverse the order of the parameters on the stack. See the chapter on “Mixed Language Programming” for more details.

**Figure 3.7 Stack Layout Upon Entry into CallProc**

You could gain access to the parameters passed on the stack by removing the data from the stack as the following code fragment demonstrates:

```
// Note: to extract parameters off the stack by popping it is very important
// to specify both the nodisplay and noframe procedure options.

static
 RtnAdrs: dword;
 p1Parm: dword;
 p2Parm: dword;
 p3Parm: dword;

procedure CallProc(p1:dword; p2:dword; p3:dword); nodisplay; noframe;
begin CallProc;

 pop(RtnAdrs);
 pop(p3Parm);
 pop(p2Parm);
 pop(p1Parm);
 push(RtnAdrs);
 .
 .
 .
 ret();

end CallProc;
```

As you can see from this code, it first pops the return address off the stack and into the *RtnAdrs* variable; then it pops (in reverse order) the values of the *p1*, *p2*, and *p3* parameters; finally, it pushes the return address back onto the stack (so the RET instruction will operate properly). Within the *CallProc* procedure, you may access the *p1Parm*, *p2Parm*, and *p3Parm* variables to use the *p1*, *p2*, and *p3* parameter values.

There is, however, a better way to access procedure parameters. If your procedure includes the standard entry and exit sequences (see “The Standard Entry Sequence” on page 789 and “The Standard Exit Sequence” on page 790), then you may directly access the parameter values in the activation record by indexing off the EBP register. Consider the layout of the activation record for *CallProc* that uses the following declaration:

```
procedure CallProc(p1:dword; p2:dword; p3:dword); nodisplay; noframe;
begin CallProc;

 push(ebp); // This is the standard entry sequence.
 mov(esp, ebp); // Get base address of A.R. into EBP.
```

·  
·  
·

Take a look at the stack immediately after the execution of “`mov( esp, ebp );`” in *CallProc*. Assuming you’ve pushed three double word parameters onto the stack, it should look something like shown in Figure 3.8:

**Figure 3.8** Activation Record for CallProc After Standard Entry Sequence Execution

.Now you can access the parameters by indexing off the EBP register:

```
mov([ebp+16], eax); // Accesses the first parameter.
mov([ebp+12], ebx); // Accesses the second parameter.
mov([ebp+8], ecx); // Accesses the third parameter.
```

Of course, like local variables, you’d never really access the parameters in this way. You can use the formal parameter names (*p1*, *p2*, and *p3*) and HLA will substitute a suitable “[*ebp+displacement*]” memory address. Even though you shouldn’t actually access parameters using address expressions like “[*ebp+12*]” it’s important to understand their relationship to the parameters in your procedures.

Other items that often appear in the activation record are register values your procedure preserves. The most rational place to preserve registers in a procedure is in the code immediately following the standard entry sequence. In a standard HLA procedure (one where you do not specify the `NOFRAME` option), this simply means that the code that preserves the registers should appear first in the procedure’s body. Likewise, the code to restore those register values should appear immediately before the `END` clause for the procedure<sup>9</sup>.

### 3.8.5.1 Accessing Value Parameters on the Stack

Accessing parameters passed by value is no different than accessing a local `VAR` object. As long as you’ve declared the parameter in a formal parameter list and the procedure executes the standard entry sequence upon entry into the program, all you need do is specify the parameter’s name to reference the value of that parameter. The following is an example program whose procedure accesses a parameter the main program passes to it by value:

---

```
program AccessingValueParameters;
```

---

9. Note that if you use the `EXIT` statement to exit a procedure, you must duplicate the code to pop the register values and place this code immediately before the `EXIT` clause. This is a good example of a maintenance nightmare and is also a good reason why you should only have one exit point in your program.

```

#include("stdlib.hhf")

procedure ValueParm(theParameter: uns32); nodisplay;
begin ValueParm;

 mov(theParameter, eax);
 add(2, eax);
 stdout.put
 (
 "theParameter + 2 = ",
 (type uns32 eax),
 nl
);

end ValueParm;

begin AccessingValueParameters;

 ValueParm(10);
 ValueParm(135);

end AccessingValueParameters;

```

---

### Program 3.4 Demonstration of Value Parameters

---

Although you may access the value of *theParameter* using the anonymous address “[EBP+8]” within your code, there is absolutely no good reason for doing so. If you declare the parameter list using the HLA high level language syntax, you can access the value parameter by specifying its name within the procedure.

---

#### 3.8.5.2 Passing Value Parameters on the Stack

As Program 3.4 demonstrates, passing a value parameter to a procedure is very easy. Just specify the value in the actual parameter list as you would for a high level language call. Actually, the situation is a little more complicated than this. Passing value parameters is easy if you’re passing constant, register, or variable values. It gets a little more complex if you need to pass the result of some expression. This section deals with the different ways you can pass a parameter by value to a procedure.

Of course, you do not have to use the HLA high level language syntax to pass value parameters to a procedure. You can push these values on the stack yourself. Since there are many times it is more convenient or more efficient to manually pass the parameters, describing how to do this is a good place to start.

As noted earlier in this chapter, when passing parameters on the stack you push the objects in the order they appear in the formal parameter list (from left to right). When passing parameters by value, you should push the values of the actual parameters onto the stack. The following program demonstrates how to do this:

---

```

program ManuallyPassingValueParameters;
#include("stdlib.hhf")

procedure ThreeValueParms(p1:uns32; p2:uns32; p3:uns32); nodisplay;
begin ThreeValueParms;

 mov(p1, eax);
 add(p2, eax);
 add(p3, eax);
 stdout.put

```

```

 (
 "p1 + p2 + p3 = ",
 (type uns32 eax),
 nl
);

end ThreeValueParms;

static
 SecondParmValue:uns32 := 25;

begin ManuallyPassingValueParameters;

 pushd(10); // Value associated with p1.
 pushd(SecondParmValue); // Value associated with p2.
 pushd(15); // Value associated with p3.
 call ThreeValueParms;

end ManuallyPassingValueParameters;

```

---

### Program 3.5 Manually Passing Parameters on the Stack

---

Note that if you manually push the parameters onto the stack as this example does, you must use the CALL instruction to call the procedure. If you attempt to use a procedure invocation of the form “ThreeValueParms();” then HLA will complain about a mismatched parameter list. HLA won’t realize that you’ve manually pushed the parameters (as far as HLA is concerned, those pushes appear to preserve some other data).

Generally, there is little reason to manually push a parameter onto the stack if the actual parameter is a constant, a register value, or a variable. HLA’s high level syntax handles most such parameters for you. There are several instances, however, where HLA’s high level syntax won’t work. The first such example is passing the result of an arithmetic expression as a value parameter. Since arithmetic expressions don’t exist in HLA, you will have to manually compute the result of the expression and pass that value yourself. There are two possible ways to do this: calculate the result of the expression and manually push that result onto the stack, or compute the result of the expression into a register and pass the register as a parameter to the procedure. Program 3.6 demonstrates these two mechanisms.

---

```

program PassingExpressions;
#include("stdlib.hhf")

 procedure ExprParm(exprValue:uns32); nodisplay;
 begin ExprParm;

 stdout.put("exprValue = ", exprValue, nl);

 end ExprParm;

static
 Operand1: uns32 := 5;
 Operand2: uns32 := 20;

begin PassingExpressions;

 // ExprParm(Operand1 + Operand2);
 //

```

```

// Method one: Compute the sum and manually
// push the sum onto the stack.

mov(Operand1, eax);
add(Operand2, eax);
push(eax);
call ExprParm;

// Method two: Compute the sum in a register and
// pass the register using the HLA high level
// language syntax.

mov(Operand1, eax);
add(Operand2, eax);
ExprParm(eax);

end PassingExpressions;

```

---

### Program 3.6 Passing the Result of Some Arithmetic Expression as a Parameter

---

The examples up to this point in this section have made an important assumption: that the parameter you are passing is a double word value. The calling sequence changes somewhat if you're passing parameters that are not four-byte objects. Because HLA can generate relatively inefficient code when passing objects that are not four-bytes long, manually passing such objects is a good idea if you want to have the fastest possible code.

HLA requires that all value parameters be an even multiple of four bytes long<sup>10</sup>. If you pass an object that is less than four bytes long, HLA requires that you *pad* the parameter data with extra bytes so that you always pass an object that is at least four bytes in length. For parameters that are larger than four bytes, you must ensure that you pass an even multiple of four bytes as the parameter value, adding extra bytes at the high-order end of the object to pad it, as necessary.

Consider the following procedure prototype:

```
procedure OneByteParm(b:byte);
```

The activation record for this procedure looks like the following:

---

10. This only applies if you use the HLA high level language syntax to declare and access parameters in your procedures. Of course, if you manually push the parameters yourself and you access the parameters inside the procedure using an addressing mode like “[ebp+8]” then you can pass any sized object you choose.

**Figure 3.9 OneByteParm Activation Record**

As you can see, there are four bytes on the stack associated with the `b` parameter, but only one of the four bytes contains valid data (the L.O. byte). The remaining three bytes are just padding and the procedure should ignore these bytes. In particular, you should never assume that these extra bytes contain zeros or some other consistent value. Depending on the type of parameter you pass, HLA's automatic code generation may or may not push zero bytes as the extra data on the stack.

When passing a byte parameter to a procedure, HLA will automatically emit code that pushes four bytes on the stack. Because HLA's parameter passing mechanism guarantees not to disturb any register or other values, HLA often generates more code than is actually needed to pass a byte parameter. For example, if you decide to pass the `AL` register as the byte parameter, HLA will emit code that pushes the `EAX` register onto the stack. This single push instruction is a very efficient way to pass `AL` as a four-byte parameter object. On the other hand, if you decide to pass the `AH` register as the byte parameter, pushing `EAX` won't work because this would leave the value in `AH` at offset `EBP+9` in the activation record shown in Figure 3.9. Unfortunately, the procedure expects this value at offset `EBP+8` so simply pushing `EAX` won't do the job. If you pass `AH`, `BH`, `CH`, or `DH` as a byte parameter, HLA emits code like the following:

```
sub(4, esp); // Make room for the parameter on the stack.
mov(ah, [esp]); // Store AH into the L.O. byte of the parameter.
```

As you can clearly see, passing one of the "H" registers as a byte parameter is less efficient (two instructions) than passing one of the "L" registers. So you should attempt to use the "L" registers whenever possible if passing an eight-bit register as a parameter<sup>11</sup>. Note, by the way, that there is very little you can do about the difference in efficiency, even if you manually pass the parameters yourself.

If the byte parameter you decide to pass is a variable rather than a register, HLA generates decidedly worse code. For example, suppose you call `OneByteParm` as follows:

```
OneByteParm(uns8Var);
```

For this call, HLA will emit code similar to the following to push this single byte parameter:

```
push(eax);
push(eax);
mov(uns8Var, al);
mov(al, [esp+4]);
pop(eax);
```

11. Or better yet, pass the parameter directly in the register if you are writing the procedure yourself.

As you can plainly see, this is a lot of code to pass a single byte on the stack! HLA emits this much code because (1) it guarantees not to disturb any registers, and (2) it doesn't know whether *uns8Var* is the last variable in allocated memory. You can generate much better code if you don't have to enforce either of these two constraints.

If you've got a spare 32-bit register laying around (especially one of EAX, EBX, ECX or EDX) then you can pass a byte parameter on the stack using only two instructions. Move (or move with zero/sign extension) the byte value into the register and then push the register onto the stack. For the current call to *OneByteParm*, the calling sequence would look like the following:

```
mov(uns8Var, al);
push(eax);
call OneByteParm;
```

If only ESI or EDI were available, you could use code like this:

```
movzx(uns8Var, esi);
push(esi);
call OneByteParm;
```

Another trick you can use to pass the parameter with only a single push instruction is to coerce the byte variable to a double word object, i.e.,

```
push((type dword uns8Var));
call OneByteParm;
```

This last example is very efficient. Note that it pushes the first three bytes of whatever value happens to follow *uns8Var* in memory as the padding bytes. HLA doesn't use this technique because there is a (very tiny) chance that using this scheme will cause the program to fail. If it turns out that the *uns8Var* object is the last byte of a given page in memory and the next page of memory is unreadable, the PUSH instruction will cause a memory access exception. To be on the safe side, the HLA compiler does not use this scheme. However, if you always ensure that the actual parameter you pass in this fashion is not the last variable you declare in a static section, then you can get away with code that uses this technique. Since it is nearly impossible for the byte object to appear at the last accessible address on the stack, it is probably safe to use this technique with VAR objects.

When passing word parameters on the stack you must also ensure that you include padding bytes so that each parameter consumes an even multiple of four bytes. You can use the same techniques we use to pass bytes except, of course, there are two valid bytes of data to pass instead of one. For example, you could use either of the following two schemes to pass a word object *w* to a *OneWordParm* procedure:

```
mov(w, ax);
push(eax);
call OneWordParm;
```

```
push((type dword w));
call OneWordParm;
```

When passing large objects by value on the stack (e.g., records and arrays), you do not have to ensure that each element or field of the object consumes an even multiple of four bytes; all you need to do is ensure that the entire data structure consumes an even number of bytes on the stack. For example, if you have an array of 10 three-byte elements, the entire array will need two bytes of padding (10\*3 is 30 bytes which is not evenly divisible by four, but 10\*3 + 2 is 32 which is divisible by four). HLA does a fairly good job of passing large data objects by value to a procedure. For larger objects, you should use the HLA high level language procedure invocation syntax unless you have some special requirements. Of course, if you want efficient operation, you should try to avoid passing large data structures by value.

### 3.8.5.3 Accessing Reference Parameters on the Stack

Since HLA passes the address of the actual parameters for reference parameters, accessing the reference parameters within a procedure is slightly more difficult than accessing value parameters because you have to dereference the pointers to the reference parameters. Unfortunately, HLA's high level syntax for procedure declarations and invocations does not (and cannot) abstract this detail away for you. You will have to manually dereference these pointers yourself. This section describes how you do this.

Consider the following program:

---

---

```

program AccessingReferenceParameters;
#include("stdlib.hhf")

 procedure RefParm(var theParameter: uns32); nodisplay;
 begin RefParm;

 // Add two directly to the parameter passed by
 // reference to this procedure.

 mov(theParameter, eax);
 add(2, (type uns32 [eax]));

 // Fetch the value of the reference parameter
 // and print it's value.

 mov([eax], eax);
 stdout.put
 (
 "theParameter now equals ",
 (type uns32 eax),
 nl
);

 end RefParm;

static
 p1: uns32 := 10;
 p2: uns32 := 15;

begin AccessingReferenceParameters;

 RefParm(p1);
 RefParm(p2);

 stdout.put("On return, p1=", p1, " and p2=", p2, nl);

end AccessingReferenceParameters;

```

---

---

#### Program 3.7 Accessing a Reference Parameter

---

---

In this example the *RefParm* procedure has a single pass by reference parameter. Pass by reference parameters are always a pointer to the type specified by the parameter's declaration. Therefore, *theParameter* is actual an object of type "pointer to uns32" rather than an *uns32* value. In order to access the value associated with *theParameter*, this code has to load that double word address into a 32-bit register and access the data indirectly. The "mov( theParameter, eax);" instruction in the code above fetches this pointer into the

EAX register and then the procedure uses the “[eax]” addressing mode to access the actual value of *theParameter*.

Since this procedure accesses the data of the actual parameter, adding two to this data affects the values of the variables passed to the *RefParm* procedure from the main program. Of course, this should come as no surprise since this is the standard semantics for pass by reference parameters.

As you can see, accessing (small) pass by reference parameters is a little less efficient than accessing value parameters because you need extra instructions to load the address into a 32-bit pointer register. If you access reference parameters frequently, these extra instructions can really begin to add up, reducing the efficiency of your program. Furthermore, it's easy to forget to dereference a reference parameter and use the address of the value instead of the value in your calculations (this is especially true when passing double-word parameters, like the *uns32* parameter in the example above, to your procedures). Therefore, unless you really need to affect the value of the actual parameter, you should use pass by value to pass small objects to a procedure.

Passing large objects, like arrays and records, is where reference parameters become very efficient. When passing these objects by value, the calling code has to make a copy of the actual parameter; if the actual parameter is a large object, the copy process can be very inefficient. Since computing the address of a large object is just as efficient as computing the address of a small scalar object, there is no efficiency loss when passing large objects by reference. Within the procedure you must still dereference the pointer to access the object but the efficiency loss due to indirection is minimal when you contrast this with the cost of copying that large object. The following program demonstrates how to use pass by reference to initialize an array of records:

---

```

program accessingRefArrayParameters;
#include("stdlib.hhf")

const
 NumElements := 64;

type
 Pt: record
 x:uns8;
 y:uns8;
 endrecord;

 Pts: Pt [NumElements];

procedure RefArrayParm(var ptArray: Pts); nodisplay;
begin RefArrayParm;

 push(eax);
 push(ecx);
 push(edx);

 mov(ptArray, edx); // Get address of parameter into EDX.

 for(mov(0, ecx); ecx < NumElements; inc(ecx)) do

 // For each element of the array, set the "x" field
 // to (ecx div 8) and set the "y" field to (ecx mod 8).

 mov(cl, al);
 shr(3, al); // ECX div 8.
 mov(al, (type Pt [edx+ecx*2]).x);

```

```

 mov(cl, al);
 and(%111, al); // ECX mod 8.
 mov(al, (type Pt [edx+ecx*2]).y);

 endfor;
 pop(edx);
 pop(ecx);
 pop(eax);

end RefArrayParm;

static
 MyPts: Pts;

begin accessingRefArrayParameters;

 // Initialize the elements of the array.

 RefArrayParm(MyPts);

 // Display the elements of the array.

 for(mov(0, ebx); ebx < NumElements; inc(ebx)) do

 stdout.put
 (
 "RefArrayParm[",
 (type uns32 ebx):2,
 ".x=",
 MyPts.x[ebx*2],

 " RefArrayParm[",
 (type uns32 ebx):2,
 ".y=",
 MyPts.y[ebx*2],
 nl
);

 endfor;

end accessingRefArrayParameters;

```

---

### Program 3.8 Passing an Array of Records by Referencing

---

As you can see from this example, passing large objects by reference isn't particularly inefficient. Other than tying up the EDX register throughout the *RefArrayParm* procedure plus a single instruction to load EDX with the address of the reference parameter, the *RefArrayParm* procedure doesn't require many more instructions than the same procedure where you would pass the parameter by value.

---

#### 3.8.5.4 Passing Reference Parameters on the Stack

HLA's high level syntax often makes passing reference parameters a breeze. All you need to do is specify the name of the actual parameter you wish to pass in the procedure's parameter list. HLA will automatically emit some code that will compute the address of the specified actual parameter and push this address

onto the stack. However, like the code HLA emits for value parameters, the code HLA generates to pass the address of the actual parameter on the stack may not be the most efficient that is possible. Therefore, if you want to write fast code, you may want to manually write the code to pass reference parameters to a procedure. This section discusses how to do exactly that.

Whenever you pass a static object as a reference parameter, HLA generates very efficient code to pass the address of that parameter to the procedure. As an example, consider the following code fragment:

```
procedure HasRefParm(var d:dword);
.
.
.
static
 FourBytes:dword;

var
 v: dword;
.
.
.
HasRefParm(FourBytes);
.
.
.
```

For the call to the *HasRefParm* procedure, HLA emits the following instruction sequence:

```
pushd(&FourBytes);
call HasRefParm;
```

You really aren't going to be able to do substantially better than this if you are passing your reference parameters on the stack. So if you're passing static objects as reference parameters, HLA generates fairly good code and you should stick with the high level syntax for the procedure call.

Unfortunately, when passing automatic (VAR) objects or indexed variables as reference parameters, HLA needs to compute the address of the object at run-time. This generally requires the use of the LEA instruction. Unfortunately, the LEA instruction requires the use of a 32-bit register and HLA promises not to disturb the values in any registers when it automatically generates code for you<sup>12</sup>. Therefore, HLA needs to preserve the value in whatever register it uses when it computes an address via LEA to pass a parameter by reference. The following example shows you the code that HLA actually emits:

```
// Call to the HasRefParm procedure:

 HasRefParm(v);

// HLA actually emits the following code for the above call:

 push(eax);
 push(eax);
 lea(eax, v);
 mov(eax, [esp+4]);
 pop(eax);
 call HasRefParm;
```

As you can see, this is quite a bit of code, especially if you have a 32-bit register available and you don't need to preserve that register's value. Here's a better code sequence given the availability of EAX:

```
 lea(eax, v);
 push(eax);
 call HasRefParm;
```

---

12. This isn't entirely true. You'll see the exception in the chapter on Classes and Objects.

Remember, when passing an actual parameter by reference, you must compute the address of that object and push the address onto the stack. For simple static objects you can use the address-of operator (“&”) to easily compute the address of the object and push it onto the stack; however, for indexed and automatic objects, you will probably need to use the LEA instruction to compute the address of the object. Here are some examples that demonstrate this using the *HasRefParm* procedure from the previous examples:

```

static
 i: int32;
 Ary: int32[16];
 iptr: pointer to int32 := &i;

var
 v: int32;
 AV: int32[10];
 vptr: pointer to int32;
 .
 .
 .
 lea(eax, v);
 mov(eax, vptr);
 .
 .
 .
// HasRefParm(i);

 push(&i); // Simple static object, so just use "&".
 call HasRefParm;

// HasRefParm(Ary[ebx]); // Pass element of Ary by reference.

 lea(eax, Ary[ebx*4]); // Must use LEA for indexed addresses.
 push(eax);
 call HasRefParm;

// HasRefParm(*iptr); -- Pass object pointed at by iptr

 push(iptr); // Pass address (iptr's value) on stack.
 call HasRefParm;

// HasRefParm(v);

 lea(eax, v); // Must use LEA to compute the address
 push(eax); // of automatic vars passed on stack.
 call HasRefParm;

// HasRefParm(AV[esi]); -- Pass element of AV by reference.

 lea(eax, AV[esi*4]); // Must use LEA to compute address of the
 push(eax); // desired element.
 call HasRefParm;

// HasRefParm(*vptr); -- Pass address held by vptr...

 push(vptr); // Just pass vptr's value as the specified
 call HasRefParm; // address.

```

### 3.8.5.5 Passing Formal Parameters as Actual Parameters

The examples in the previous two sections show how to pass static and automatic variables as parameters to a procedure, either by value or by reference. There is one situation that these sections don't handle properly: the case when you are passing a formal parameter in one procedure as an actual parameter to another procedure. The following simple example demonstrates the different cases that can occur for pass by value and pass by reference parameters:

```

procedure p1(val v:dword; var r:dword);
begin p1;
 .
 .
 .
end p1;

procedure p2(val v2:dword; var r2:dword);
begin p2;

 p1(v2, r2); // (1) First call to p1.
 p1(r2, v2); // (2) Second call to p1.

end p2;

```

In the statement labelled (1) above, procedure *p2* calls procedure *p1* and passes its two formal parameters as parameters to *p1*. Note that this code passes the first parameter of both procedures by value and it passes the second parameter of both procedures by reference. Therefore, in statement (1), the program passes the parameter into *p2* by value and passes it on to *p1* by value; likewise, the program passes *r2* in by reference and it passes the value onto *p2* by reference.

Since *p2*'s caller passes *v2* in by value and *p2* passes this parameter to *p1* by value, all the code needs to do is make a copy of *v2*'s value and pass this on to *p1*. The code to do this is nothing more than a single push instruction, e.g.,

```

push(v2);
<< code to handle r2 >>
call p1;

```

As you can see, this code is identical to passing an automatic variable by value. *Indeed, it turns out that the code you need to write to pass a value parameter to another procedure is identical to the code you would write to pass a local, automatic, variable to that other procedure.*

Passing *r2* in statement (1) above requires a little more thought. You do not take the address of *r2* using the LEA instruction as you would a value parameter or an automatic variable. When passing *r2* on through to *p1*, the author of this code probably expects the *r* formal parameter to contain the address of the variable whose address *p2*'s caller passed into *p2*. In plain English, this means that *p2* must pass the address of *r2*'s actual parameter on through to *p1*. Since the *r2* parameter is actually a double word value containing the address of the corresponding actual parameter, this means that the code must pass the dword value of *r2* on to *p1*. The complete code for statement (1) above looks like the following:

```

push(v2); // Pass the value passed in through v2 to p1.
push(r2); // Pass the address passed in through r2 to p1.
call p1;

```

The important thing to note in this example is that passing a formal reference parameter (*r2*) as an actual reference parameter (*r*) does not involve taking the address of the formal parameter (*r2*). *P2*'s caller has already done this; *p2* need only pass this address on through to *p1*.

In the second call to *p1* in the example above (2), the code swaps the actual parameters so that the call to *p1* passes *r2* by value and *v2* by reference. Specifically, *p1* expects *p2* to pass it the value of the *dword* object associated with *r2*; likewise, it expects *p2* to pass it the address of the value associated with *v2*.

To pass the value of the object associated with *r2*, your code must dereference the pointer associated with *r2* and directly pass the value. Here is the code HLA automatically generates to pass *r2* as the first parameter to *p1* in statement (2):

```
sub(4, esp); // Make room on stack for parameter.
push(eax); // Preserve EAX's value.
mov(r2, eax); // Get address of object passed in to p2.
mov([eax], eax); // Dereference to get the value of this object.
mov(eax, [esp+4]); // Put value of parameter into its location on stack.
pop(eax); // Restore original EAX value.
```

As usual, HLA generates a little more code than may be necessary because it won't destroy the value in the EAX register. You can write more efficient code if a register is available to use in this sequence. If EAX is unused, you could trim this down to the following:

```
mov(r2, eax); // Get the pointer to the actual object.
pushd([eax]); // Push the value of the object onto the stack.
```

Since you can treat value parameters exactly like local (automatic) variables, you use the same code to pass *v2* by reference to *p1* as you would to pass a local variable in *p2* to *p1*. Specifically, you use the LEA instruction to compute the address of the value in the *v2*. The code HLA automatically emits for statement (2) above preserves all registers and takes the following form (same as passing an automatic variable by reference):

```
push(eax); // Make room for the parameter.
push(eax); // Preserve EAX's value.
lea(eax, v2); // Compute address of v2's value.
mov(eax, [esp+4]); // Store away address as parameter value.
pop(eax); // Restore EAX's value
```

Of course, if you have a register available, you can improve on this code. Here's the complete code that corresponds to statement (2) above:

```
mov(r2, eax); // Get the pointer to the actual object.
pushd([eax]); // Push the value of the object onto the stack.
lea(eax, v2); // Push the address of V2 onto the stack.
push(eax);
call p1;
```

---

### 3.8.5.6 HLA Hybrid Parameter Passing Facilities

Like control structures, HLA provides a high level language syntax for procedure calls that is convenient to use and easy to read. However, this high level language syntax is sometimes inefficient and may not provide the capabilities you need (for example, you cannot specify an arithmetic expression as a value parameter as you can in high level languages). HLA lets you overcome these limitations by writing low-level ("pure") assembly language code. Unfortunately, the low-level code is harder to read and maintain than procedure calls that use the high level syntax. Furthermore, it's quite possible that HLA generates perfectly fine code for certain parameters and only one or two parameters present a problem. Fortunately, HLA provides a hybrid syntax for procedure calls that allows you to use both high-level and low-level syntax as appropriate for a given actual parameter. This lets you use the high level syntax where appropriate and then drop down into pure assembly language to pass those special parameters that HLA's high level language syntax cannot handle efficiently (if at all).

Within an actual parameter list (using the high level language syntax), if HLA encounters "{ followed by a sequence of statements and a closing "}", HLA will substitute the instructions between the braces in place of the code it would normally generate for that parameter. For example, consider the following code fragment:

```

procedure HybridCall(i:uns32; j:uns32);
begin HybridCall;
.
.
.
end HybridCall;
.
.
.
HybridCall
(
 5,
 #{
 mov(i, eax);
 add(j, eax);
 push(eax);
 }#
);

```

The call to *HybridCall* immediately above is equivalent to the following “pure” assembly language code:

```

pushd(5);
mov(i, eax);
add(j, eax);
push(eax);
call HybridCall;

```

As a second example, consider the example from the previous section:

```

procedure p2(val v2:dword; var r2:dword);
begin p2;

 p1(v2, r2); // (1) First call to p1.
 p1(r2, v2); // (2) Second call to p1.

end p2;

```

HLA generates exceedingly mediocre code for the second call to *p1* in this example. If efficiency is important in the context of this procedure call, and you have a free register available, you might want to rewrite this code as follows:

```

procedure p2(val v2:dword; var r2:dword);
begin p2;

 p1(v2, r2); // (1) First call to p1.
 p1 // (2) Second call to p1.
 (// This code assumes EAX is free.
 #{
 mov(r2, eax);
 pushd([eax]);
 }#,
 #{
 lea(eax, v2);
 push(eax);
 }#
);

end p2;

```

### 3.8.5.7 Mixing Register and Stack Based Parameters

You can mix register parameters and standard (stack-based) parameters in the same high level procedure declaration, e.g.,

```
procedure HasBothRegAndStack(var dest:dword in edi; count:un32);
```

When constructing the activation record, HLA ignores the parameters you pass in registers and only processes those parameters you pass on the stack. Therefore, a call to the *HasBothRegAndStack* procedure will push only a single parameter onto the stack (*count*). It will pass the *dest* parameter in the EDI register. When this procedure returns to its caller, it will only remove four bytes of parameter data from the stack.

## 3.9 Procedure Pointers

The x86 CALL instruction is very similar to the JMP instruction. In particular, it allows the same three basic forms as the JMP instruction: direct calls (to a procedure name), indirect calls through a 32-bit general purpose register, and indirect calls through a double word pointer variable. The CALL instruction allows the following (low-level) syntax supporting these three types of procedure invocations:

```
call Procname; // Direct call to procedure "Procname".
call(Reg32); // Indirect call to procedure whose address appears
 // in the Reg32 general-purpose 32-bit register.
call(dwordVar); // Indirect call to the procedure whose address appears
 // in the dwordVar double word variable.
```

HLA treats procedure names like static objects. Therefore, you can compute the address of a procedure by using the address-of (“&”) operator along with the procedure’s name or by using the LEA instruction. For example, “&Procname” is the address of the very first instruction of the *Procname* procedure. Therefore, all three of the following code sequences wind up calling the *Procname* procedure:

```
call Procname;
.
.
.
mov(&Procname, eax);
call(eax);
.
.
.
lea(eax, Procname);
call(eax);
```

Since the address of a procedure fits in a 32-bit object, you can store such an address into a *dword* variable; in fact, you can initialize a *dword* variable with the address of a procedure using code like the following:

```
procedure p;
begin p;
end p;
.
.
.
static
 ptrToP: dword := &p;
.
.
```

```
call(ptrToP); // Calls the "p" procedure if ptrToP has not changed.
```

Because the use of procedure pointers occurs frequently in assembly language programs, HLA provides a special syntax for declaring procedure pointer variables and for calling procedures indirectly through such pointer variables. To declare a procedure pointer in an HLA program, you can use a variable declaration like the following:

```
static
 procPtr: procedure;
```

Note that this syntax uses the keyword `PROCEDURE` as a data type. It follows the variable name and a colon in one of the variable declaration sections (`STATIC`, `READONLY`, `STORAGE`, or `VAR`). This sets aside exactly four bytes of storage for the *procPtr* variable. To call the procedure whose address is held by *procPtr*, you can use either of the following two forms:

```
call(procPtr); // Low-level syntax.
procPtr(); // High-level language syntax.
```

Note that the high level syntax for an indirect procedure call is identical to the high level syntax for a direct procedure call. HLA can figure out whether to use a direct call or an indirect call by the type of the identifier. If you've specified a variable name, HLA assumes it needs to use an indirect call; if you specify a procedure name, HLA uses a direct call.

Like all pointer objects, you should not attempt to indirectly call a procedure through a pointer variable unless you've initialized that variable with the address appropriately. There are two ways to initialize a procedure pointer variable: `STATIC` and `READONLY` objects allow an initializer, or you can compute the address of a routine (as a 32-bit value) and store that 32-bit address directly into the procedure pointer at run-time. The following code fragment demonstrates both ways you can initialize a procedure pointer.

```
static
 ProcPtr: procedure := &p; // Initialize ProcPtr with the address of p.
 .
 .
 ProcPtr(); // First invocation calls p.

 mov(&q, ProcPtr); // Reload ProcPtr with the address of q.
 .
 .
 ProcPtr(); // This invocation calls the "q" procedure.
```

Procedure pointer variable declarations also allow the declaration of parameters. To declare a procedure pointer with parameters, you must use a declaration like the following:

```
static
 p:procedure(i:int32; c:char);
```

This declaration states that *p* is a 32-bit pointer that contains the address of a procedure having two parameters. If desired, you could also initialize this variable *p* with the address of some procedure by using a static initializer, e.g.,

```
static
 p:procedure(i:int32; c:char) := &SomeProcedure;
```

Note that *SomeProcedure* must be a procedure whose parameter list exactly matches *p*'s parameter list (i.e., two value parameters, the first is an *int32* parameter and the second is a *char* parameter). To indirectly call this procedure, you could use either of the following sequences:

```
push(<< Value for i >>);
push(<< Value for c >>);
call(p);
```

```
-or-
 p(<<Value for i>>, <<Value for c>>);
```

The high level language syntax has the same features and restrictions as the high level syntax for a direct procedure call. The only difference is the actual CALL instruction HLA emits at the end of the calling sequence.

Although all of the examples in this section have used STATIC variable declarations, don't get the idea that you can only declare simple procedure pointers in the STATIC or other variable declaration sections. You can declare procedure pointer types in the TYPE section. You can declare procedure pointers as fields of a RECORD. Assuming you create a type name for a procedure pointer in the TYPE section, you can even create arrays of procedure pointers. The following code fragments demonstrate some of the possibilities:

```
type
 pptr: procedure;
 prec: record
 p:pptr;
 // other fields...
 endrecord;
static
 p1:pptr;
 p2:pptr[2]
 p3:prec;
 .
 .
 .
 p1();
 p2[ebx*4]();
 p3.p();
```

One very important thing to keep in mind when using procedure pointers is that HLA does not (and cannot) enforce strict type checking on the pointer values you assign to a procedure pointer variable. In particular, if the parameter lists do not agree between the declarations of the pointer variable and the procedure whose address you assign to the pointer variable, the program will probably crash if you attempt to call the mismatched procedure indirectly through the pointer using the high level syntax. Like the low-level "pure" procedure calls, it is your responsibility to ensure that the proper number and types of parameters are on the stack prior to the call.

### 3.10 Procedural Parameters

One place where procedure pointers are quite invaluable is in parameter lists. Selecting one of several procedures to call by passing the address of some procedure, selected from a set of procedures, is not an uncommon operation. Therefore, HLA lets you declare procedure pointers as parameters.

There is nothing special about a procedure parameter declaration. It looks exactly like a procedure variable declaration except it appears within a parameter list rather than within a variable declaration section. The following are some typical procedure prototypes that demonstrate how to declare such parameters:

```
procedure p1(procparm: procedure); forward;
procedure p2(procparm: procedure(i:int32)); forward;
procedure p3(val procparm: procedure); forward;
```

The last example above is identical to the first. It does point out, though, that you generally pass procedural parameters by value. This may seem counter-intuitive since procedure pointers are addresses and you will need to pass an address as the actual parameter; however, a pass by reference procedure parameter means something else entirely. consider the following (legal!) declaration:

```
procedure p4(var procPtr:procedure); forward;
```

This declaration tells HLA that you are passing a procedure variable *by reference* to *p4*. The address HLA expects must be the address of a procedure pointer variable, not a procedure.

When passing a procedure pointer by value, you may specify either a procedure variable (whose value HLA passes to the actual procedure) or a procedure pointer constant. A procedure pointer constant consists of the address-of operator (“&”) immediately followed by a procedure name. Passing procedure constants is probably the most convenient way to pass procedural parameters. For example, the following calls to the *Plot* routine might plot out the function passed as a parameter from  $-2\pi$  to  $+2\pi$ .

```
Plot(&sineFunc);
Plot(&cosFunc);
Plot(&tanFunc);
```

Note that you cannot pass a procedure as a parameter by simply specifying the procedure’s name. I.e., “Plot( sineFunc );” will not work. Simply specifying the procedure name doesn’t work because HLA will attempt to directly call the procedure whose name you specify (remember, a procedure name inside a parameter list invokes instruction composition). However, since you don’t specify a parameter list, or at least an empty pair of parentheses, after the parameter/procedure’s name, HLA generates a syntax error message. Moral of the story: don’t forget to preface procedure parameter constant names with the address-of operator.

### 3.11 Untyped Reference Parameters

Sometimes you will want to write a procedure to which you pass a generic memory object by reference without regard to the type of that memory object. A classic example is a procedure that zeros out some data structure. Such a procedure might have the following prototype:

```
procedure ZeroMem(var mem:byte; count:uns32);
```

This procedure would zero out *count* bytes starting at the address the first parameter specifies. The problem with this procedure prototype is that HLA will complain if you attempt to pass anything other than a byte object as the first parameter. Of course, you can overcome this problem using type coercion like the following, but if you call this procedure several times with lots of different data types, then the following coercion operator is rather tedious to use:

```
ZeroMem((type byte MyDataObject), @size(MyDataObject));
```

Of course, you can always use hybrid parameter passing or manually push the parameters yourself, but these solutions are even more work than using the type coercion operation. Fortunately, HLA provides a far more convenient solution: untyped reference parameters.

Untyped reference parameters are exactly that – pass by reference parameters on which HLA doesn’t bother to compare the type of the actual parameter against the type of the formal parameter. With an untyped reference parameter, the call to *ZeroMem* above would take the following form:

```
ZeroMem(MyDataObject, @size(MyDataObject));
```

*MyDataObject* could be any type and multiple calls to *ZeroMem* could pass different typed objects without any objections from HLA.

To declare an untyped reference parameter, you specify the parameter using the normal syntax except that you use the reserved word VAR in place of the parameter’s type. This VAR keyword tells HLA that any variable object is legal for that parameter. Note that you must pass untyped reference parameters by reference, so the VAR keyword must precede the parameter’s declaration as well. Here’s the correct declaration for the *ZeroMem* procedure using an untyped reference parameter:

```
procedure ZeroMem(var mem:var; count:uns32);
```

With this declaration, HLA will compute the address of whatever memory object you pass as an actual parameter to *ZeroMem* and pass this on the stack.

## 3.12 Iterators and the FOREACH Loop

One nifty feature HLA provides is support for *true* iterators<sup>13</sup>. An iterator is a special type of procedure or function that you use in conjunction with the HLA FOREACH..ENDFOR loop. Combined, these two language features (iterators and the FOREACH..ENDFOR loop) provide a very powerful user-defined looping construct.

The HLA FOREACH..ENDFOR statement uses the following basic syntax:

```
foreach iteratorID(optional_parameters) do

 << loop body >>

endfor;
```

The FOREACH statement calls the specified iterator. If the iterator *succeeds*, then the FOREACH statement executes the loop body; if the iterator *fails*, then control transfers to the first statement following the ENDFOR clause. On each iteration of the loop body, the program re-enters the iterator code and, once again, the iterator returns success or failure to determine whether to repeat the loop body.

At first glance, you might get the impression that the FOREACH loop is nothing more than a WHILE loop and an iterator is a function that returns true (success) or false (failure). However, this is not an accurate picture of how the FOREACH loop operates. First of all, the FOREACH loop does not CALL the iterator on each iteration of the loop; it *re-enters* the iterator. Specifically, control does not (necessarily) begin with the first statement of the iterator whenever control returns to the top of the FOREACH loop. The second big difference between a FOREACH/iterator loop and a WHILE/function loop is that the iterator procedure maintains its activation record in memory for the duration of the FOREACH loop. A function you would call from a WHILE loop, by contrast, builds and destroys the function's activation record on each iteration of the loop. This means that the iterator's local (automatic) variables maintain their values until the FOREACH loop terminates. This has important ramifications, especially for recursive iterator functions.

An iterator declaration looks very similar to a procedure declaration. Indeed, about the only syntactical difference is the use of the reserved word ITERATOR rather than PROCEDURE. The following is an example of a simple iterator:

```
iterator range(start:uns32; last:uns32); nodisplay;
begin range;

 mov(start, eax);
 while(eax <= last) do

 push(eax);
 yield();
 pop(eax);
 inc(eax);

 endwhile;

end range;
```

The only thing special about this iterator declaration, other than the use of the ITERATOR reserved word, is that it calls a special procedure named *yield*. In a few paragraphs you'll see the purpose of the call to the *yield* procedure.

A typical FOREACH loop that calls the *range* iterator might look like the following:

---

13. HLA's iterators are based on the control structure by the same name from the CLU programming language. Those things that C/C++ programmers refer to as iterators are more properly called *cursors*. While it is certainly possible to write cursors in HLA, it is important to note that HLA's iterators are quite a bit more powerful than C/C++'s iterators.

```

foreach range(1, 10) do
 stdout.put("Iteration = ", (type uns32 eax), nl);
endfor;

```

Here's how the iterator and the FOREACH loop work together. Upon first encountering the FOREACH statement, the program makes an *initial call* to the *range* iterator. Except for a few extra parameters HLA pushes on the stack, this call is exactly like a standard procedure call. Upon entry into the iterator, the *start* parameter has the initial value one and the *last* parameter has the initial value ten. The iterator loads *start* into EAX and compares this against the value in *last* (ten). Since EAX's value is less than or equal to ten, the program enters the loop's body. The loop body pushes EAX's value onto the stack and then calls the *yield* procedure. The *yield* procedure transfers control to the body of the FOREACH loop that called the *range* iterator in the first place. Calling *yield* is how the iterator returns success to the FOREACH loop. Within the body of the FOREACH loop, above, the code prints out the value of the EAX register as an unsigned integer. During the first iteration of the loop, EAX contains one so the loop body prints this value.

At the bottom of the FOREACH loop, the program *re-enters* the iterator. When the FOREACH loop re-enters the iterator, it transfers control to the first statement following the call to the *yield* function. Intuitively, you can view the FOREACH loop body as a procedure that the iterator calls whenever you call the *yield* function<sup>14</sup>. Whenever the program encounters the ENDFOR clause, it returns to the iterator, executing the first statement beyond the *yield* call. In the current example, this pops the value of EAX off the stack (preserved before the call to *yield*), the loop increments EAX and repeats as long as EAX is less than ten.

When the *range* iterator increments EAX to 11, the WHILE loop in the iterator terminates and control falls off the bottom of the iterator. This is how an iterator returns failure to the calling FOREACH loop. At that point control transfers to the first statement following the ENDFOR in the FOREACH..ENDFOR loop.

By the way, the *range* iterator, combined with the FOREACH loop above, creates a relatively inefficient implementation of the following loop:

```

for(mov(1, eax); eax < 10; inc(eax)) do
 stdout.put("Iteration = ", (type uns32 eax), nl);
endfor;

```

However, don't get the impression from this example that iterators are particularly inefficient. Iterators are not a good choice for something like *range*. However, there are many iterators you can write that are just as efficient as other means of loop control and computation.

An important point to remember when using iterators is that the iterator's activation record remains on the stack as long as the iterator returns success. The program only removes the activation record when the iterator fails. For example, the *range* iterator takes advantage of this fact since it refers to the value of its *last* parameter on each re-entry from the FOREACH loop. The fact that parameters and local (automatic) variables maintain their values for the duration of the FOREACH loop is very important to many algorithms that use iterators, especially recursive algorithms.

One side effect of having an iterator maintain its activation record until it fails is that the value of ESP changes considerably between the statement immediately before the FOREACH statement and the first statement in the body of the FOREACH loop. This is because the program "pushes" the activation record onto the stack upon encountering the FOREACH loop and doesn't "pop" this activation record off the stack until the FOREACH loop fails. Therefore, code like the following will not work as expected:

```

pushd(10);
foreach range(1, 25) do
 pop(ebx);
 push(ebx);
 stdout.put("eax=", eax, " ebx=", ebx, nl);

```

---

14. In fact, this is exactly how HLA implements iterators and the FOREACH loop. See the chapter on Advanced Procedures for more details.

```
endfor;
pop(ebx);
```

The problem with this code is that the FOREACH loop pushes a whole lot of data onto the stack after the PUSHED instruction pushes the value 10 onto the stack. Therefore, the POP instruction inside the loop does not pop the value 10 from the stack. Instead, it pops some data pushed on the stack by the iterator (specifically, it pops the return address that transfers control to the first instruction following the *yield* call). Therefore, you cannot use the stack to transfer data into or out of a FOREACH loop<sup>15</sup>.

Another problem with the stack and the FOREACH loop occurs if you try to prematurely exit a FOREACH loop before the iterator returns failure. Whenever an iterator fails, it cleans up the stack and restores ESP to the value it had upon encountering the FOREACH statement. However, statements like BREAK, BREAKIF, EXIT, EXITIF, JMP and any other flow of control transfer instructions will not clean up the stack if they transfer control out of a FOREACH loop. For example, the following code will leave the activation record for the *range* iterator sitting on the stack:

```
foreach range(2, 5) do

 jmp ExitFor;

endifor;
ExitFor:
```

Depending on the iterator and the code that calls the iterator, prematurely exiting a FOREACH loop without having the iterator return failure and leaving this junk sitting on the stack may have an adverse effect on the operation of your program. Clearly if you've pushed data onto the stack prior to the FOREACH loop, you will not be able to pop that data off unless you manually clean up the stack yourself (this involves saving the value of ESP prior to the FOREACH statement and restoring this value at the *ExitFor* label, above). Also, don't forget that prematurely exiting a FOREACH loop without letting the iterator finish may wind up grabbing some system resources that the iterator would normally free just before returning failure (e.g., calling *free* and closing files).

The Volume on Advanced Procedures will go into the details concerning the low-level implementation of iterators. Until then, keep in mind that iterators build their activation records differently than standard procedures. Until you read that chapter, you should not attempt to call an iterator directly (i.e., outside a FOREACH loop) nor should you use the "noframe" option with an iterator. See the chapter on Advanced Procedures for more details on the implementation of iterators.

### 3.13 Sample Programs

This section presents two sample programs. The first demonstrates the use of iterators using a fibonacci number iterator. The second demonstrates the use of procedural parameters.

#### 3.13.1 Generating the Fibonacci Sequence Using an Iterator

The following program generates the Fibonacci sequence  $f_1, f_2, f_3, \dots, f_{count}$  where *count* is a parameter. This simple example displays all the fibonacci numbers the iterator generates.

```
program iterDemo;
#include("stdlib.hhf")

 // Basic (recursive version) algorithm for
 // the fibonacci sequence.
```

15. Not that it's a good idea to transfer data into or out of any loop using the stack. Such code tends to have lots of errors due to extra pushes or pops appearing in the program.

```

//
// int fib(int N)
// {
// if(N<=2)
// return 1;
// else
// return fib(N-1) + fib(N-2)
// }
//
// Iterator (iterative) that computes all the fibonacci
// numbers between fib(1) and fib(count).

iterator fib(count:uns32); nodisplay;
var
 lastVal: uns32;
 BeforeLastVal: uns32;

begin fib;

 if(count > 0) then

 mov(0, BeforeLastVal);
 mov(1, eax);
 mov(eax, lastVal);

 // Handle fib(1) as a special case.

 yield();
 dec(count);

 // Okay, handle fib(2)..fib(count) here.

 while(@nz) do

 // Compute fib(n) = fib(n-1) + fib(n-2).
 // and then copy fib(n-1) {lastVal} to
 // fib(n-2) {BeforeLastVal} and store the
 // current result into lastVal so we'll
 // have the n-1 and n-2 values on the next
 // call.

 mov(lastVal, eax);
 add(BeforeLastVal, eax);
 mov(lastVal, BeforeLastVal);
 mov(eax, lastVal);

 // Yield fib(n) to the FOREACH loop.

 yield();

 // Repeat this iterator the specified number
 // of times.

 dec(count);

 endwhile;

 endif;

end fib;

```

```

static
 iteration:uns32;

begin iterDemo;

 // Display the fibonacci sequence for the first
 // ten fibonacci numbers.

 mov(1, iteration);
 foreach fib(10) do

 stdout.put("fib(", iteration, ") = ", (type uns32 eax), nl);
 inc(iteration);

 endfor;

end iterDemo;

```

---

### 3.13.2 Outer Product Computation with Procedural Parameters

The following program generates an *addition table*, a *subtraction table*, or a *multiplication table* based on user inputs. These tables are computed using an *outer product* calculation and procedural parameters. An outer product is simply the process of computing all the values for the elements of a matrix by using the row and column indices as inputs to some function (e.g., addition, subtraction, or multiplication).

```

program funcTable;
#include("stdlib.hhf")

static
 size: uns32;
 ftbl: array.dArray(uns32, 2);

 // GenerateTable-
 //
 // This function computes the "Outer Product". That is,
 // take the cartesian product of the indices into
 // the rows and columns of this array [(0,0), (0,1), ... (0,size-1),
 // (1,0), (1,1), ..., (size-1,size-1)], then feed the left and
 // right values of each coordinate to the "func" procedure passed
 // as a parameter. Whatever result the function returns, store that
 // into element (l,r) of the ftbl array.

 procedure GenerateTable(func:procedure(l:uns32; r:uns32)); nodisplay;
 begin GenerateTable;

 push(eax);
 push(ebx);
 push(ecx);
 push(edi);

 for(mov(0, ebx); ebx < size; inc(ebx)) do

 for(mov(0, ecx); ecx < size; inc(ecx)) do

 array.index(edi, ftbl, ebx, ecx);
 func(ebx, ecx);
 endfor;
 endfor;
 end GenerateTable;

```

```

 mov(eax, [edi]);

 endfor;

endfor;

pop(edi);
pop(ecx);
pop(ebx);
pop(eax);

end GenerateTable;

// The following functions compute the various
// values used to fill the table (obviously,
// "+" = addFunc, "-" = subFunc, and "*" = mulFunc).

procedure addFunc(left:uns32; right:uns32); nodisplay;
begin addFunc;

 mov(left, eax);
 add(right, eax);

end addFunc;

procedure subFunc(left:uns32; right:uns32); nodisplay;
begin subFunc;

 mov(left, eax);
 sub(right, eax);

end subFunc;

procedure mulFunc(left:uns32; right:uns32); nodisplay;
begin mulFunc;

 mov(left, eax);
 intmul(right, eax);

end mulFunc;

begin funcTable;

stdout.put("Function table generator: " nl);
stdout.put("----- " nl nl);

// Get the size of the function table from the user:

forever

 try

 stdout.put("Enter the size of the matrix: ");
 stdin.getu32();
 bound(eax, 1, 20);
 unprotected break;

 exception(ex.ConversionError)

```

```

 stdout.put("Illegal character, re-enter" nl);

exception(ex.ValueOutOfRange)

 stdout.put("Value out of range (1..20), please re-enter" nl);

exception(ex.BoundInstr)

 stdout.put("Value out of range (1..20), please re-enter" nl);

 endtry;

endfor;

// Allocate storage for the function table:

mov(eax, size);
array.daAlloc(ftbl, size, size);

// Get the function from the user:

stdout.put("What type of table do you want to generate?" nl nl);
stdout.put("+" Addition" nl);
stdout.put("-" Subtraction" nl);
stdout.put("*" Multiplication" nl);
stdout.newln();
repeat

 stdout.put("Choice? (+, -, *): ");
 stdin.FlushInput();
 stdin.getc();

until(al in { '+', '-', '*' });

// Fill in the entries in the table:

if(al = '+') then

 GenerateTable(&addFunc);

elseif(al = '-') then

 GenerateTable(&subFunc);

elseif(al = '*') then

 GenerateTable(&mulFunc);

endif;

// Display the column labels across the top:

stdout.put(nl nl " ");
for(mov(0, ebx); ebx < size; inc(ebx) do

 stdout.put((type uns32 ebx):5);

endfor;

```

```

stdout.newln();
stdout.put(" ");
for(mov(0, ebx); ebx < size; inc(ebx)) do

 stdout.put("-----");

endfor;
stdout.newln();

// Display the row labels and fill in the table.
// Note that this code prints the result as int32
// rather than uns32 because the subFunc function
// returns negative values.

for(mov(0, ebx); ebx < size; inc(ebx)) do

 stdout.put((type uns32 ebx):4, ": ");
 for(mov(0, ecx); ecx < size; inc(ecx)) do

 array.index(edi, ftbl, ebx, ecx);
 stdout.puti32size([edi], 5, ' ');

 endfor;
 stdout.newln();

endfor;

end funcTable;

```

---

### 3.14 Putting It All Together

In this chapter you saw the low level implementation of procedures and calls to procedures. You learned more about passing parameters by value and reference and you also learned a little more about local variables. This chapter discussed activations records and HLA procedure options. Finally, this chapter wraps up with a discussion of iterators and the FOREACH loop

Your journey through procedures is hardly complete, however. The next volume presents new ways to pass parameters, discusses nested procedures, and explains the low-level implementation of iterators. For more details, see the next volume in this series.

# Advanced Arithmetic

# Chapter Four

## 4.1 Chapter Overview

This chapter deals with those arithmetic operations for which assembly language is especially well suited and high level languages are, in general, poorly suited. It covers three main topics: extended precision arithmetic, arithmetic on operands whose sizes are different, and decimal arithmetic.

By far, the most extensive subject this chapter covers is multi-precision arithmetic. By the conclusion of this chapter you will know how to apply arithmetic and logical operations to integer operands of any size. If you need to work with integer values outside the range  $\pm 2$  billion (or with unsigned values beyond four billion), no sweat; this chapter will show you how to get the job done.

Operands whose sizes are not the same also present some special problems in arithmetic operations. For example, you may want to add a 128-bit unsigned integer to a 256-bit signed integer value. This chapter discusses how to convert these two operands to a compatible format so the operation may proceed.

Finally, this chapter discusses decimal arithmetic using the BCD (binary coded decimal) features of the 80x86 instruction set and the FPU. This lets you use decimal arithmetic in those few applications that absolutely require base 10 operations (rather than binary).

## 4.2 Multiprecision Operations

One big advantage of assembly language over high level languages is that assembly language does not limit the size of integer operations. For example, the C programming language defines a maximum of three different integer sizes: short int, int, and long int. On the PC, these are often 16 or 32 bit integers. Although the 80x86 machine instructions limit you to processing eight, sixteen, or thirty-two bit integers with a single instruction, you can always use more than one instruction to process integers of any size you desire. If you want to add 256 bit integer values together, no problem, it's relatively easy to accomplish this in assembly language. The following sections describe how extended various arithmetic and logical operations from 16 or 32 bits to as many bits as you please.

### 4.2.1 Multiprecision Addition Operations

The 80x86 ADD instruction adds two eight, sixteen, or thirty-two bit numbers<sup>1</sup>. After the execution of the add instruction, the 80x86 carry flag is set if there is an overflow out of the H.O. bit of the sum. You can use this information to do multiprecision addition operations. Consider the way you manually perform a multidigit (multiprecision) addition operation:

Step 1: Add the least significant digits together:

|      |          |                 |
|------|----------|-----------------|
| 289  |          | 289             |
| +456 | produces | +456            |
| ---- |          | ----            |
|      |          | 5 with carry 1. |

Step 2: Add the next significant digits plus the carry:

|                    |          |      |
|--------------------|----------|------|
| 1 (previous carry) |          | 289  |
| 289                |          | 289  |
| +456               | produces | +456 |
| ----               |          | ---- |

1. As usual, 32 bit arithmetic is available only on the 80386 and later processors.

5 45 with carry 1.

Step 3: Add the most significant digits plus the carry:

|      |          |                    |
|------|----------|--------------------|
|      |          | 1 (previous carry) |
| 289  |          | 289                |
| +456 | produces | +456               |
| ---- |          | ----               |
| 45   |          | 745                |

The 80x86 handles extended precision arithmetic in an identical fashion, except instead of adding the numbers a digit at a time, it adds them together a byte, word, or dword at a time. Consider the three double word (96 bit) addition operation in Figure 4.1.

Step 1: Add the least significant words together:

Step 2: Add the middle words together:

Step 3: Add the most significant words together:

**Figure 4.1 Adding Two 96-bit Objects Together**

As you can see from this figure, the idea is to break up a larger operation into a sequence of smaller operations. Since the x86 processor family is capable of adding together, at most, 32 bits at a time, the operation must proceed in blocks of 32-bits or less. So the first step is to add the two L.O. double words together much as we would add the two L.O. digits of a decimal number together in the manual algorithm. There is nothing special about this operation, you can use the ADD instruction to achieve this.

The second step involves adding together the second pair of double words in the two 96-bit values. Note that in step two, the calculation must also add in the carry out of the previous addition (if any). If there was a carry out of the L.O. addition, the ADD instruction sets the carry flag to one; conversely, if there was no carry out of the L.O. addition, the earlier ADD instruction clears the carry flag. Therefore, in this second

addition, we really need to compute the sum of the two double words plus the carry out of the first instruction. Fortunately, the x86 chips provide an instruction that does exactly this: the ADC (add with carry) instruction. The ADC instruction uses the same syntax as the ADD instruction and performs almost the same operation:

```
adc(source, dest); // dest := dest + source + C
```

As you can see, the only difference between the ADD and ADC instruction is that the ADC instruction adds in the value of the carry flag along with the source and destination operands. It also sets the flags the same way the ADD instruction does (including setting the carry flag if there is an unsigned overflow). This is exactly what we need to add together the middle two double words of our 96-bit sum.

In step three of Figure 4.1, the algorithm adds together the H.O. double words of the 96-bit value. Once again, this addition operation also requires the addition of the carry out of the sum of the middle two double words; hence the ADC instruction is needed here, as well. To sum it up, the ADD instruction adds the L.O. double words together. The ADC (add with carry) instruction adds all other double word pairs together. At the end of the extended precision addition sequence, the carry flag indicates unsigned overflow (if set), a set overflow flag indicates signed overflow, and the sign flag indicates the sign of the result. The zero flag doesn't have any real meaning at the end of the extended precision addition (it simply means that the sum of the H.O. two double words is zero, this does not indicate that the whole result is zero).

For example, suppose that you have two 64-bit values you wish to add together, defined as follows:

```
static
X: qword;
Y: qword;
```

Suppose, also, that you want to store the sum in a third variable, *Z*, that is likewise defined with the *qword* directive. The following x86 code will accomplish this task:

```
mov((type dword X), eax); // Add together the L.O. 32 bits
add((type dword Y), eax); // of the numbers and store the
mov(eax, (type dword Z)); // result into the L.O. dword of Z.

mov((type dword X[4]), eax); // Add together (with carry) the
adc((type dword Y[4]), eax); // H.O. 32 bits and store the result
mov(eax, (type dword Z[4])); // into the H.O. dword of Z.
```

Remember, these variables are declared with the *qword* directive. Therefore the compiler will not accept an instruction of the form "mov( X, eax );" because this instruction would attempt to load a 64 bit value into a 32 bit register. Therefore this code uses the coercion operator to coerce symbols *X*, *Y*, and *Z* to 32 bits. The first three instructions add the L.O. double words of *X* and *Y* together and store the result at the L.O. double word of *Z*. The last three instructions add the H.O. double words of *X* and *Y* together, along with the carry out of the L.O. word, and store the result in the H.O. double word of *Z*. Remember, address expressions of the form "X[4]" access the H.O. double word of a 64 bit entity. This is due to the fact that the x86 address space addresses bytes and it takes four consecutive bytes to form a double word.

You can extend this to any number of bits by using the ADC instruction to add in the higher order words in the values. For example, to add together two 128 bit values, you could use code that looks something like the following:

```
type
tBig: dword[4]; // Storage for four dwords is 128 bits.

static
BigVal1: tBig;
BigVal2: tBig;
BigVal3: tBig;
.
.
.
mov(BigVal1[0], eax); // Note there is no need for (type dword BigValx)
add(BigVal2[0], eax); // because the base type of BitValx is dword.
```

```

mov(eax, BigVal3[0]);

mov(BigVal1[4], eax);
adc(BigVal2[4], eax);
mov(eax, BigVal3[4]);

mov(BigVal1[8], eax);
adc(BigVal2[8], eax);
mov(eax, BigVal3[8]);

mov(BigVal1[12], eax);
adc(BigVal2[12], eax);
mov(eax, BigVal3[12]);

```

---

## 4.2.2 Multiprecision Subtraction Operations

Like addition, the 80x86 performs multi-byte subtraction the same way you would manually, except it subtracts whole bytes, words, or double words at a time rather than decimal digits. The mechanism is similar to that for the ADD operation. You use the SUB instruction on the L.O. byte/word/double word and the SBB (subtract with borrow) instruction on the high order values. The following example demonstrates a 64 bit subtraction using the 32 bit registers on the x86:

```

static
Left: qword;
Right: qword;
Diff: qword;
.
.
.
mov((type dword Left), eax);
sub((type dword Right), eax);
mov(eax, (type dword Diff));

mov((type dword Left[4]), eax);
sbb((type dword Right[4]), eax);
mov((type dword Diff[4]), eax);

```

The following example demonstrates a 128-bit subtraction:

```

type
tBig: dword[4]; // Storage for four dwords is 128 bits.

static
BigVal1: tBig;
BigVal2: tBig;
BigVal3: tBig;
.
.
.

// Compute BigVal3 := BigVal1 - BigVal2

mov(BigVal1[0], eax); // Note there is no need for (type dword BigValx)
sub(BigVal2[0], eax); // because the base type of BitValx is dword.
mov(eax, BigVal3[0]);

mov(BigVal1[4], eax);
sbb(BigVal2[4], eax);
mov(eax, BigVal3[4]);

```

```

mov(BigVal1[8], eax);
sbb(BigVal2[8], eax);
mov(eax, BigVal3[8]);

mov(BigVal1[12], eax);
sbb(BigVal2[12], eax);
mov(eax, BigVal3[12]);

```

---

## 4.2.3 Extended Precision Comparisons

Unfortunately, there isn't a "compare with borrow" instruction that can be used to perform extended precision comparisons. Since the CMP and SUB instructions perform the same operation, at least as far as the flags are concerned, you'd probably guess that you could use the SBB instruction to synthesize an extended precision comparison; however, you'd only be partly right. There is, however, a better way.

Consider the two unsigned values \$2157 and \$1293. The L.O. bytes of these two values do not affect the outcome of the comparison. Simply comparing \$21 with \$12 tells us that the first value is greater than the second. In fact, the only time you ever need to look at both bytes of these values is if the H.O. bytes are equal. In all other cases comparing the H.O. bytes tells you everything you need to know about the values. Of course, this is true for any number of bytes, not just two. The following code compares two signed 64 bit integers:

```

// This sequence transfers control to location "IsGreater" if
// QwordValue > QwordValue2. It transfers control to "IsLess" if
// QwordValue < QwordValue2. It falls through to the instruction
// following this sequence if QwordValue = QwordValue2. To test for
// inequality, change the "IsGreater" and "IsLess" operands to "NotEqual"
// in this code.

mov((type dword QWordValue[4]), eax); // Get H.O. dword
cmp(eax, (type dword QWordValue2[4]));
jg IsGreater;
jl IsLess;

mov((type dword QWordValue[0]), eax); // If H.O. dwords were equal,
cmp(eax, (type dword QWordValue2[0])); // then we must compare the
jg IsGreater; // L.O. dwords.
jl IsLess;

// Fall through to this point if the two values were equal.

```

To compare unsigned values, simply use the JA and JB instructions in place of JG and JL.

You can easily synthesize any possible comparison from the sequence above, the following examples show how to do this. These examples demonstrate signed comparisons, substitute JA, JAE, JB, and JBE for JG, JGE, JL, and JLE (respectively) if you want unsigned comparisons.

```

static
 QW1: qword;
 QW2: qword;

const
 QW1d: text := "(type dword QW1)";
 QW2d: text := "(type dword QW2)";

// 64 bit test to see if QW1 < QW2 (signed).
// Control transfers to "IsLess" label if QW1 < QW2. Control falls
// through to the next statement if this is not true.

```

```

mov(QW1d[4], eax); // Get H.O. dword
cmp(eax, QW2d[4]);
jg NotLess;
jl IsLess;

mov(QW1d[0], eax); // Fall through to here if the H.O. dwords are equal.

jg NotLessEQ;
jl IsLessEQ;

mov(QW1d[0], eax); // Fall through to here if the H.O. dwords are equal.
cmp(eax, QW2d[0]);
jle IsLessEQ;
NotLessEQ:

// 64 bit test to see if QW1 > QW2 (signed). Jumps to "IsGtr" if this condition
// is true.

mov(QW1d[4], eax); // Get H.O. dword
cmp(eax, QW2d[4]);
jg IsGtr;
jl NotGtr;

mov(QW1d[0], eax); // Fall through to here if the H.O. dwords are equal.
cmp(eax, QW2d[0]);
jg IsGtr;
NotGtr:

// 64 bit test to see if QW1 >= QW2 (signed). Jumps to "IsGtrEQ" if this
// is the case.

mov(QW1d[4], eax); // Get H.O. dword
cmp(eax, QW2d[4]);
jg IsGtrEQ;
jl NotGtrEQ;

mov(QW1d[0], eax); // Fall through to here if the H.O. dwords are equal.
cmp(eax, QW2d[0]);
jge IsGtrEQ;
NotGtrEQ:

// 64 bit test to see if QW1 = QW2 (signed or unsigned). This code branches
// to the label "IsEqual" if QW1 = QW2. It falls through to the next instruction
// if they are not equal.

mov(QW1d[4], eax); // Get H.O. dword
cmp(eax, QW2d[4]);
jne NotEqual;

mov(QW1d[0], eax); // Fall through to here if the H.O. dwords are equal.

```

```

 cmp(eax, QW2d[0]);
 je IsEqual;
NotEqual:

// 64 bit test to see if QW1 <> QW2 (signed or unsigned). This code branches
// to the label "NotEqual" if QW1 <> QW2. It falls through to the next
// instruction if they are equal.

 mov(QW1d[4], eax); // Get H.O. dword
 cmp(eax, QW2d[4]);
 jne NotEqual;

 mov(QW1d[0], eax); // Fall through to here if the H.O. dwords are equal.
 cmp(eax, QW2d[0]);
 jne NotEqual;

// Fall through to this point if they are equal.

```

You cannot directly use the HLA high level control structures if you need to perform an extended precision comparison. However, you may use the HLA hybrid control structures and bury the appropriate comparison into this statements. Doing so will probably make your code easier to read. For example, the following *if..then..else..endif* statement checks to see if *QW1 > QW2* using a 64-bit extended precision unsigned comparison:

```

if
(#{
 mov(QW1d[4], eax);
 cmp(eax, QW2d[4]);
 jg true;

 mov(QW1d[0], eax);
 cmp(eax, QW2d[0]);
 jng false;
}#) then

 << code to execute if QW1 > QW2 >>

else

 << code to execute if QW1 <= QW2 >>

endif;

```

If you need to compare objects that are larger than 64 bits, it is very easy to generalize the code above. Always start the comparison with the H.O. double words of the objects and work you way down towards the L.O. double words of the objects as long as the corresponding double words are equal. The following example compares two 128-bit values to see if the first is less than or equal (unsigned) to the second:

```

type
 t128: dword[4];

static
 Big1: t128;
 Big2: t128;
 .
 .
 .
 if
 (#{
 mov(Big1[12], eax);

```

```

 cmp(eax, Big2[12]);
 jb true;
 mov(Big1[8], eax);
 cmp(eax, Big2[8]);
 jb true;
 mov(Big1[4], eax);
 cmp(eax, Big2[4]);
 jb true;
 mov(Big1[0], eax);
 cmp(eax, Big2[0]);
 jnbe false;
}#) then

 << Code to execute if Big1 <= Big2 >>

else

 << Code to execute if Big1 > Big2 >>

endif;

```

---

## 4.2.4 Extended Precision Multiplication

Although a 16x16 or 32x32 multiply is usually sufficient, there are times when you may want to multiply larger values together. You will use the x86 single operand MUL and IMUL instructions for extended precision multiplication.

Not surprisingly (in view of how we achieved extended precision addition using ADC and SBB), you use the same techniques to perform extended precision multiplication on the x86 that you employ when manually multiplying two values. Consider a simplified form of the way you perform multi-digit multiplication by hand:

1) Multiply the first two digits together (5\*3):

```

 123
 45

 15

```

2) Multiply 5\*2:

```

 123
 45

 15
 10

```

3) Multiply 5\*1:

```

 123
 45

 15
 10
 5

```

4) Multiply 4\*3:

```

 123
 45

 15
 10
 5
 12

```

5) Multiply 4\*2:

```

123
 45

 15
 10
 5
 12
 8

```

6) Multiply 4\*1:

```

123
 45

 15
 10
 5
 12
 8
 4

```

7) Add all the partial products together:

```

123
 45

 15
 10
 5
 12
 8
 4

5535

```

The 80x86 does extended precision multiplication in the same manner except that it works with bytes, words, and double words rather than digits. Figure 4.2 shows how this works

1) Multiply the L.O. words

2) Multiply D \* A

3) Multiply C times B

4) Multiply C \* A

## 5) Compute sum of partial products

---

**Figure 4.2 Extended Precision Multiplication**

---

Probably the most important thing to remember when performing an extended precision multiplication is that you must also perform a multiple precision addition at the same time. Adding up all the partial products requires several additions that will produce the result. The following listing demonstrates the proper way to multiply two 64 bit values on a 32 bit processor:

Note: *Multiplier* and *Multiplicand* are 64 bit variables declared in the data segment via the *qword* type. *Product* is a 128 bit variable declared in the data segment via the *qword[2]* type.

---

```

program testMUL64;
#include("stdlib.hhf")

type
 t128:dword[4];

procedure MUL64(Multiplier:qword; Multiplicand:qword; var Product:t128);
const
 mp:text := "(type dword Multiplier)";
 mc:text := "(type dword Multiplicand)";
 prd:text := "(type dword [edi])";

begin MUL64;

 mov(Product, edi);

 // Multiply the L.O. dword of Multiplier times Multiplicand.

 mov(mp, eax);
 mul(mc, eax); // Multiply L.O. dwords.
 mov(eax, prd); // Save L.O. dword of product.
 mov(edx, ecx); // Save H.O. dword of partial product result.

 mov(mp, eax);
 mul(mc[4], eax); // Multiply mp(L.O.) * mc(H.O.)
 add(ecx, eax); // Add to the partial product.
 adc(0, edx); // Don't forget the carry!
 mov(eax, ebx); // Save partial product for now.

```

```

mov(edx, ecx);

// Multiply the H.O. word of Multiplier with Multiplicand.

mov(mp[4], eax); // Get H.O. dword of Multiplier.
mul(mc, eax); // Multiply by L.O. word of Multiplicand.
add(ebx, eax); // Add to the partial product.
mov(eax, prd[4]); // Save the partial product.
adc(edx, ecx); // Add in the carry!

mov(mp[4], eax); // Multiply the two H.O. dwords together.
mul(mc[4], eax);
add(ecx, eax); // Add in partial product.
adc(0, edx); // Don't forget the carry!
mov(eax, prd[8]); // Save the partial product.
mov(edx, prd[12]);

end MUL64;

static
 op1: qword;
 op2: qword;
 rslt: t128;

begin testMUL64;

 // Initialize the qword values (note that static objects
 // are initialized with zero bits).

 mov(1234, (type dword op1));
 mov(5678, (type dword op2));
 MUL64(op1, op2, rslt);

 // The following only prints the L.O. qword, but
 // we know the H.O. qword is zero so this is okay.

 stdout.put("rslt=");
 stdout.putu64((type qword rslt));

end testMUL64;

```

---

### Program 4.1 Extended Precision Multiplication

---

One thing you must keep in mind concerning this code, it only works for unsigned operands. To multiply two signed values you must note the signs of the operands before the multiplication, take the absolute value of the two operands, do an unsigned multiplication, and then adjust the sign of the resulting product based on the signs of the original operands. Multiplication of signed operands appears in the exercises.

This example was fairly straight-forward since it was possible to keep the partial products in various registers. If you need to multiply larger values together, you will need to maintain the partial products in temporary (memory) variables. Other than that, the algorithm that Program 4.1 uses generalizes to any number of double words.

## 4.2.5 Extended Precision Division

You cannot synthesize a general n-bit/m-bit division operation using the DIV and IDIV instructions. Such an operation must be performed using a sequence of shift and subtract instructions and is extremely messy. However, a less general operation, dividing an n-bit quantity by a 32 bit quantity is easily synthesized using the DIV instruction. This section presents both methods for extended precision division.

Before describing how to perform a multi-precision division operation, you should note that some operations require an extended precision division even though they may look calculable with a single DIV or IDIV instruction. Dividing a 64-bit quantity by a 32-bit quantity is easy, as long as the resulting quotient fits into 32 bits. The DIV and IDIV instructions will handle this directly. However, if the quotient does not fit into 32 bits then you have to handle this problem as an extended precision division. The following sequence will accomplish this for you:

```
static
dividend: dword[2] := [$1234, 4]; // = $4_0000_1234.
divisor: dword := 2; // dividend/divisor = $2_0000_091A
quotient: dword[2];
remainder:dword;
.
.
.
mov(divisor, ebx);
mov(dividend[4], eax);
xor(edx, edx); // Zero extend for unsigned division.
div(ebx, edx:eax);
mov(eax, quotient[4]); // Save H.O. dword of the quotient (2).
mov(dividend[0], eax); // Note that this code does *NOT* zero extend
div(ebx, edx:eax); // EAX into EDX before this DIV instr.
mov(eax, quotient[0]); // Save L.O. dword of the quotient ($91a).
mov(edx, remainder); // Save away the remainder.
```

Since it is perfectly legal to divide a value by one, it is certainly possible that the resulting quotient after a division could require as many bits as the dividend. That is why the *quotient* variable in this example is the same size (64 bits) as the *dividend* variable. Regardless of the size of the dividend and divisor operands, the remainder is always no larger than the size of the division operation (32 bits in this case). Hence the *remainder* variable in this example is just a double word.

Before analyzing this code to see how it works, let's take a brief look at why a single 64/32 division will *not* work for this particular example even though the DIV instruction does indeed calculate the result for a 64/32 division. The naive approach, assuming that the x86 is capable of this operation, would look something like the following:

```
// This code does *NOT* work!

mov(dividend[0], eax); // Get dividend into edx:eax
mov(dividend[4], edx);
div(divisor, edx:eax); // Divide edx:eax by divisor.
```

Although this code is syntactically correct and will compile, if you attempt to run this code it will raise an *ex.DivideError*<sup>2</sup> exception. The reason, if you'll remember how the DIV instruction works, is that the quotient must fit into 32 bits; since the quotient turns out to be \$2\_0000\_091A, it will not fit into the EAX register, hence the resulting exception.

Now let's take another look at the former code that correctly computes the 64/32 quotient. This code begins by computing the 32/32 quotient of *dividend[4]/divisor*. The quotient from this division (2) becomes the H.O. double word of the final quotient. The remainder from this division (0) becomes the extension in EDX for the second half of the division operation. The second half divides *edx:dividend[0]* by *divisor* to

---

2. Windows may translate this to an *ex.IntoInstr* exception.

produce the L.O. double word of the quotient and the remainder from the division. Note that the code does not zero extend EAX into EDX prior to the second DIV instruction. EDX already contains valid bits and this code must not disturb them.

The 64/32 division operation above is actually just a special case of the more general division operation that lets you divide an arbitrary sized value by a 32-bit divisor. To achieve this, you begin by moving the H.O. double word of the dividend into EAX and zero extending this into EDX. Next, you divide this value by the divisor. Then, without modifying EDX along the way, you store away the partial quotients, load EAX with the next lower double word in the dividend, and divide it by the divisor. You repeat this operation until you've processed all the double words in the dividend. At that time the EDX register will contain the remainder. The following program demonstrates how to divide a 128 bit quantity by a 32 bit divisor, producing a 128 bit quotient and a 32 bit remainder:

---

```

program testDiv128;
#include("stdlib.hhf")

type
 t128:dword[4];

procedure div128
(
 Dividend: t128;
 Divisor: dword;
 var QuotAdrs: t128;
 var Remainder: dword
); nodisplay;

const
 Quotient: text := "(type dword [edi])";

begin div128;

 push(eax);
 push(edx);
 push(edi);

 mov(QuotAdrs, edi); // Pointer to quotient storage.

 mov(Dividend[12], eax); // Begin division with the H.O. dword.
 xor(edx, edx); // Zero extend into EDX.
 div(Divisor, edx:eax); // Divide H.O. dword.
 mov(eax, Quotient[12]); // Store away H.O. dword of quotient.

 mov(Dividend[8], eax); // Get dword #2 from the dividend
 div(Divisor, edx:eax); // Continue the division.
 mov(eax, Quotient[8]); // Store away dword #2 of the quotient.

 mov(Dividend[4], eax); // Get dword #1 from the dividend.
 div(Divisor, edx:eax); // Continue the division.
 mov(eax, Quotient[4]); // Store away dword #1 of the quotient.

 mov(Dividend[0], eax); // Get the L.O. dword of the dividend.
 div(Divisor, edx:eax); // Finish the division.
 mov(eax, Quotient[0]); // Store away the L.O. dword of the quotient.

 mov(Remainder, edi); // Get the pointer to the remainder's value.
 mov(edx, [edi]); // Store away the remainder value.

 pop(edi);

```

```

 pop(edx);
 pop(eax);

end div128;

static
 op1: t128 := [$2222_2221, $4444_4444, $6666_6666, $8888_8888];
 op2: dword := 2;
 quo: t128;
 rmndr: dword;

begin testDiv128;

 div128(op1, op2, quo, rmndr);

 stdout.put
 (
 nl
 nl
 "After the division: " nl
 nl
 "Quotient = $",
 quo[12], "_",
 quo[8], "_",
 quo[4], "_",
 quo[0], nl

 "Remainder = ", (type uns32 rmndr)
);

end testDiv128;

```

---

#### Program 4.2 Unsigned 128/32 Bit Extended Precision Division

---

You can extend this code to any number of bits by simply adding additional MOV / DIV / MOV instructions to the sequence. Like the extended multiplication the previous section presents, this extended precision division algorithm works only for unsigned operands. If you need to divide two signed quantities, you must note their signs, take their absolute values, do the unsigned division, and then set the sign of the result based on the signs of the operands.

If you need to use a divisor larger than 32 bits you're going to have to implement the division using a shift and subtract strategy. Unfortunately, such algorithms are very slow. In this section we'll develop two division algorithms that operate on an arbitrary number of bits. The first is slow but easier to understand, the second is quite a bit faster (in general).

As for multiplication, the best way to understand how the computer performs division is to study how you were taught to perform long division by hand. Consider the operation 3456/12 and the steps you would take to manually perform this operation:

|                                                                                                                                                                                                |                                                                                                                                                                                                            |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\begin{array}{r} 12 \overline{) 3456} \\ \underline{24} \phantom{00} \\ 105 \phantom{00} \end{array}$ <p>(1) 12 goes into 34 two times.</p>                                                   | $\begin{array}{r} 2 \\ 12 \overline{) 3456} \\ \underline{24} \phantom{00} \\ 105 \phantom{00} \end{array}$ <p>(2) Subtract 24 from 35 and drop down the 105.</p>                                          |
| $\begin{array}{r} 2 \\ 12 \overline{) 3456} \\ \underline{24} \phantom{00} \\ 105 \\ \underline{96} \\ 96 \end{array}$ <p>(3) 12 goes into 105 eight times.</p>                                | $\begin{array}{r} 28 \\ 12 \overline{) 3456} \\ \underline{24} \phantom{00} \\ 105 \\ \underline{96} \\ 96 \end{array}$ <p>(4) Subtract 96 from 105 and drop down the 96.</p>                              |
| $\begin{array}{r} 28 \\ 12 \overline{) 3456} \\ \underline{24} \phantom{00} \\ 105 \\ \underline{96} \\ 96 \\ \underline{96} \\ 0 \end{array}$ <p>(5) 12 goes into 96 exactly eight times.</p> | $\begin{array}{r} 288 \\ 12 \overline{) 3456} \\ \underline{24} \phantom{00} \\ 105 \\ \underline{96} \\ 96 \\ \underline{96} \\ 0 \end{array}$ <p>(6) Therefore, 12 goes into 3456 exactly 288 times.</p> |

**Figure 4.3 Manual Digit-by-digit Division Operation**

---

This algorithm is actually easier in binary since at each step you do not have to guess how many times 12 goes into the remainder nor do you have to multiply 12 by your guess to obtain the amount to subtract. At each step in the binary algorithm the divisor goes into the remainder exactly zero or one times. As an example, consider the division of 27 (11011) by three (11):

|                                                                                                                                          |                                                      |
|------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------|
| $\begin{array}{r} 11 \overline{) 11011} \\ \underline{11} \phantom{0000} \\ 00 \phantom{0000} \end{array}$                               | <p>11 goes into 11 one time.</p>                     |
| $\begin{array}{r} 1 \\ 11 \overline{) 11011} \\ \underline{11} \phantom{0000} \\ 00 \phantom{0000} \end{array}$                          | <p>Subtract out the 11 and bring down the zero.</p>  |
| $\begin{array}{r} 1 \\ 11 \overline{) 11011} \\ \underline{11} \phantom{0000} \\ 00 \phantom{0000} \\ \underline{00} \\ 00 \end{array}$  | <p>11 goes into 00 zero times.</p>                   |
| $\begin{array}{r} 10 \\ 11 \overline{) 11011} \\ \underline{11} \phantom{0000} \\ 00 \phantom{0000} \\ \underline{00} \\ 01 \end{array}$ | <p>Subtract out the zero and bring down the one.</p> |

$$\begin{array}{r}
 10 \\
 11 \overline{) 11011} \\
 \underline{11} \\
 00 \\
 \underline{00} \\
 01 \\
 00
 \end{array}$$

11 goes into 01 zero times.

$$\begin{array}{r}
 100 \\
 11 \overline{) 11011} \\
 \underline{11} \\
 00 \\
 \underline{00} \\
 01 \\
 \underline{00} \\
 11
 \end{array}$$

Subtract out the zero and bring down the one.

$$\begin{array}{r}
 100 \\
 11 \overline{) 11011} \\
 \underline{11} \\
 00 \\
 \underline{00} \\
 01 \\
 \underline{00} \\
 11 \\
 \underline{11} \\
 11
 \end{array}$$

11 goes into 11 one time.

$$\begin{array}{r}
 1001 \\
 11 \overline{) 11011} \\
 \underline{11} \\
 00 \\
 \underline{00} \\
 01 \\
 \underline{00} \\
 11 \\
 \underline{11} \\
 00
 \end{array}$$

This produces the final result of 1001.

**Figure 4.4 Longhand Division in Binary**

---

There is a novel way to implement this binary division algorithm that computes the quotient and the remainder at the same time. The algorithm is the following:

```

Quotient := Dividend;
Remainder := 0;
for i:= 1 to NumberBits do

 Remainder:Quotient := Remainder:Quotient SHL 1;
 if Remainder >= Divisor then

 Remainder := Remainder - Divisor;
 Quotient := Quotient + 1;

 endif

```

endfor

*NumberBits* is the number of bits in the *Remainder*, *Quotient*, *Divisor*, and *Dividend* variables. Note that the "Quotient := Quotient + 1;" statement sets the L.O. bit of *Quotient* to one since this algorithm previously shifts *Quotient* one bit to the left. The following program implements this algorithm

---

```

program testDiv128b;
#include("stdlib.hhf")

type
 t128:dword[4];

// div128-
//
// This procedure does a general 128/128 division operation
// using the following algorithm:
// (all variables are assumed to be 128 bit objects)
//
// Quotient := Dividend;
// Remainder := 0;
// for i:= 1 to NumberBits do
//
// Remainder:Quotient := Remainder:Quotient SHL 1;
// if Remainder >= Divisor then
//
// Remainder := Remainder - Divisor;
// Quotient := Quotient + 1;
//
// endif
// endfor
//

procedure div128
(
 Dividend: t128;
 Divisor: t128;
 var QuotAdrs: t128;
 var RmndrAdrs: t128
); nodisplay;

const
 Quotient: text := "Dividend"; // Use the Dividend as the Quotient.

var
 Remainder: t128;

begin div128;

 push(eax);
 push(ecx);
 push(edi);

 mov(0, eax); // Set the remainder to zero.
 mov(eax, Remainder[0]);
 mov(eax, Remainder[4]);
 mov(eax, Remainder[8]);
 mov(eax, Remainder[12]);

```

```

mov(128, ecx); // Count off 128 bits in ECX.
repeat

 // Compute Remainder:Quotient := Remainder:Quotient SHL 1:

 shl(1, Dividend[0]); // See the section on extended
 rcl(1, Dividend[4]); // precision shifts to see how
 rcl(1, Dividend[8]); // this code shifts 256 bits to
 rcl(1, Dividend[12]); // the left by one bit.
 rcl(1, Remainder[0]);
 rcl(1, Remainder[4]);

### Program 4.3 Extended Precision Division

---

---

This code looks simple but there are a few problems with it. First, it does not check for division by zero (it will produce the value \$FFFF\_FFFF\_FFFF\_FFFF if you attempt to divide by zero), it only handles unsigned values, and it is very slow. Handling division by zero is very simple, just check the divisor against zero prior to running this code and return an appropriate error code if the divisor is zero. Dealing with signed values is the same as the earlier division algorithm, this problem appears as a programming exercise. The performance of this algorithm, however, leaves a lot to be desired. It's around an order of magnitude or two worse than the DIV/IDIV instructions on the x86 and they are among the slowest instructions on the CPU.

There is a technique you can use to boost the performance of this division by a fair amount: check to see if the divisor variable uses only 32 bits. Often, even though the divisor is a 128 bit variable, the value itself fits just fine into 32 bits (i.e., the H.O. double words of Divisor are zero). In this special case, that occurs frequently, you can use the DIV instruction which is much faster.

---

## 4.2.6 Extended Precision NEG Operations

Although there are several ways to negate an extended precision value, the shortest way for smaller values (96 bits or less) is to use a combination of NEG and SBB instructions. This technique uses the fact that NEG subtracts its operand from zero. In particular, it sets the flags the same way the SUB instruction would if you subtracted the destination value from zero. This code takes the following form (assuming you want to negate the 64-bit value in EDX:EAX):

```

neg(edx);
neg(eax);
sbb(0, edx);

```

The SBB instruction decrements EDX if there is a borrow out of the L.O. word of the negation operation (which always occurs unless EAX is zero).

To extend this operation to additional bytes, words, or double words is easy; all you have to do is start with the H.O. memory location of the object you want to negate and work towards the L.O. byte. The following code computes a 128 bit negation:

```

static
 Value: dword[4];
 .
 .
 .
 neg(Value[12]); // Negate the H.O. double word.
 neg(Value[8]); // Neg previous dword in memory.
 sbb(0, Value[12]); // Adjust H.O. dword.

 neg(Value[4]); // Negate the second dword in the object.
 sbb(0, Value[8]); // Adjust third dword in object.
 sbb(0, Value[12]); // Adjust the H.O. dword.

 neg(Value); // Negate the L.O. dword.
 sbb(0, Value[4]); // Adjust second dword in object.

```

```
sbb(0, Value[8]); // Adjust third dword in object.
sbb(0, Value[12]); // Adjust the H.O. dword.
```

Unfortunately, this code tends to get really large and slow since you need to propagate the carry through all the H.O. words after each negate operation. A simpler way to negate larger values is to simply subtract that value from zero:

```
static
 Value: dword[5]; // 160-bit value.
 .
 .
 .
 mov(0, eax);
 sub(Value, eax);
 mov(eax, Value);

 mov(0, eax);
 sbb(Value[4], eax);
 mov(eax, Value[4]);

 mov(0, eax);
 sbb(Value[8], eax);
 mov(eax, Value[8]);

 mov(0, eax);
 sbb(Value[12], eax);
 mov(eax, Value[12]);

 mov(0, eax);
 sbb(Value[16], eax);
 mov(eax, Value[16]);
```

---

## 4.2.7 Extended Precision AND Operations

Performing an n-byte AND operation is very easy – simply AND the corresponding bytes between the two operands, saving the result. For example, to perform the AND operation where all three operands are 64 bits long, you could use the following code:

```
mov((type dword source1), eax);
and((type dword source2), eax);
mov(eax, (type dword dest));

mov((type dword source1[4]), eax);
and((type dword source2[4]), eax);
mov(eax, (type dword dest[4]));
```

This technique easily extends to any number of words, all you need to is logically AND the corresponding bytes, words, or double words together in the operands. Note that this sequence sets the flags according to the value of the last AND operation. If you AND the H.O. double words last, this sets all but the zero flag correctly. If you need to test the zero flag after this sequence, you will need to logically OR the two resulting double words together (or otherwise compare them both against zero).

---

## 4.2.8 Extended Precision OR Operations

Multi-byte logical OR operations are performed in the same way as multi-byte AND operations. You simply OR the corresponding bytes in the two operand together. For example, to logically OR two 96 bit values, use the following code:

```
mov((type dword source1), eax);
or((type dword source2), eax);
mov(eax, (type dword dest));

mov((type dword source1[4]), eax);
or((type dword source2[4]), eax);
mov(eax, (type dword dest[4]));

mov((type dword source1[8]), eax);
or((type dword source2[8]), eax);
mov(eax, (type dword dest[8]));
```

As for the previous example, this does not set the zero flag properly for the entire operation. If you need to test the zero flag after a multiprecision OR, you must logically OR the resulting double words together.

---

## 4.2.9 Extended Precision XOR Operations

Extended precision XOR operations are performed in a manner identical to AND/OR – simply XOR the corresponding bytes in the two operands to obtain the extended precision result. The following code sequence operates on two 64 bit operands, computes their exclusive-or, and stores the result into a 64 bit variable.

```
mov((type dword source1), eax);
xor((type dword source2), eax);
mov(eax, (type dword dest));

mov((type dword source1[4]), eax);
xor((type dword source2[4]), eax);
mov(eax, (type dword dest[4]));
```

The comment about the zero flag in the previous two sections applies here.

---

## 4.2.10 Extended Precision NOT Operations

The NOT instruction inverts all the bits in the specified operand. An extended precision NOT is performed by simply executing the NOT instruction on all the affected operands. For example, to perform a 64 bit NOT operation on the value in (edx:eax), all you need to do is execute the instructions:

```
not(eax);
not(edx);
```

Keep in mind that if you execute the NOT instruction twice, you wind up with the original value. Also note that exclusive-ORing a value with all ones (\$FF, \$FFFF, or \$FFFF\_FFFF) performs the same operation as the NOT instruction.

---

## 4.2.11 Extended Precision Shift Operations

Extended precision shift operations require a shift and a rotate instruction. Consider what must happen to implement a 64 bit SHL using 32 bit operations:

- 1) A zero must be shifted into bit zero.
- 2) Bits zero through 30 are shifted into the next higher bit.
- 3) Bit 31 is shifted into bit 32.
- 4) Bits 32 through 62 must be shifted into the next higher bit.
- 5) Bit 63 is shifted into the carry flag.

**Figure 4.5 64-bit Shift Left Operation**

The two instructions you can use to implement this 32 bit shift are SHL and RCL. For example, to shift the 64 bit quantity in (EDX:EAX) one position to the left, you'd use the instructions:

```
shl(1, eax);
rcl(1, eax);
```

Note that you can only shift an extended precision value one bit at a time. You cannot shift an extended precision operand several bits using the CL register. Nor can you specify a constant value greater than one using this technique.

To understand how this instruction sequence works, consider the operation of these instructions on an individual basis. The SHL instruction shifts a zero into bit zero of the 64 bit operand and shifts bit 31 into the carry flag. The RCL instruction then shifts the carry flag into bit 32 and then shifts bit 63 into the carry flag. The result is exactly what we want.

To perform a shift left on an operand larger than 64 bits you simply add additional RCL instructions. An extended precision shift left operation always starts with the least significant word and each succeeding RCL instruction operates on the next most significant word. For example, to perform a 96 bit shift left operation on a memory location you could use the following instructions:

```
shl(1, (type dword Operand[0]));
rcl(1, (type dword Operand[4]));
rcl(1, (type dword Operand[8]));
```

If you need to shift your data by two or more bits, you can either repeat the above sequence the desired number of times (for a constant number of shifts) or you can place the instructions in a loop to repeat them some number of times. For example, the following code shifts the 96 bit value *Operand* to the left the number of bits specified in ECX:

```
ShiftLoop:
 shl(1, (type dword Operand[0]));
 rcl(1, (type dword Operand[4]));
 rcl(1, (type dword Operand[8]));
 dec(ecx);
 jnz ShiftLoop;
```

You implement SHR and SAR in a similar way, except you must start at the H.O. word of the operand and work your way down to the L.O. word:

```
// Double precision SAR:

sar(1, (type dword Operand[8]));
rcr(1, (type dword Operand[4]));
rcr(1, (type dword Operand[0]));

// Double precision SHR:

shr(1, (type dword Operand[8]));
rcr(1, (type dword Operand[4]));
rcr(1, (type dword Operand[0]));
```

There is one major difference between the extended precision shifts described here and their 8/16/32 bit counterparts – the extended precision shifts set the flags differently than the single precision operations. This is because the rotate instructions affect the flags differently than the shift instructions. Fortunately, the carry is the flag most often tested after a shift operation and the extended precision shift operations (i.e., rotate instructions) properly set this flag.

The SHLD and SHRD instructions let you efficiently implement multiprecision shifts of several bits. These instructions have the following syntax:

```
shld(constant, Operand1, Operand2);
shld(cl, Operand1, Operand2);
shrd(constant, Operand1, Operand2);
shrd(cl, Operand1, Operand2);
```

The SHLD instruction does the following:

**Figure 4.6** SHLD Operation

*Operand<sub>1</sub>* must be a 16 or 32 bit register. *Operand<sub>2</sub>* can be a register or a memory location. Both operands must be the same size. The immediate operand can be a value in the range zero through n-1, where n is the number of bits in the two operands; it specifies the number of bits to shift.

The SHLD instruction shifts bits in *Operand<sub>2</sub>* to the left. The H.O. bits shift into the carry flag and the H.O. bits of *Operand<sub>1</sub>* shift into the L.O. bits of *Operand<sub>2</sub>*. Note that this instruction does not modify the value of *Operand<sub>1</sub>*, it uses a temporary copy of *Operand<sub>1</sub>* during the shift. The immediate operand specifies the number of bits to shift. If the count is n, then SHLD shifts bit n-1 into the carry flag. It also shifts the H.O. n bits of *Operand<sub>1</sub>* into the L.O. n bits of *Operand<sub>2</sub>*. The SHLD instruction sets the flag bits as follows:

- If the shift count is zero, the SHLD instruction doesn't affect any flags.
- The carry flag contains the last bit shifted out of the H.O. bit of the *Operand<sub>2</sub>*.
- If the shift count is one, the overflow flag will contain one if the sign bit of *Operand<sub>2</sub>* changes during the shift. If the count is not one, the overflow flag is undefined.
- The zero flag will be one if the shift produces a zero result.

- The sign flag will contain the H.O. bit of the result.

The SHRD instruction is similar to SHLD except, of course, it shifts its bits right rather than left. To get a clear picture of the SHRD instruction, consider Figure 4.7

**Figure 4.7** SHRD Operation

The SHRD instruction sets the flag bits as follows:

- If the shift count is zero, the SHRD instruction doesn't affect any flags.
- The carry flag contains the last bit shifted out of the L.O. bit of the *Operand<sub>2</sub>*.
- If the shift count is one, the overflow flag will contain one if the H.O. bit of *Operand<sub>2</sub>* changes. If the count is not one, the overflow flag is undefined.
- The zero flag will be one if the shift produces a zero result.
- The sign flag will contain the H.O. bit of the result.

Consider the following code sequence:

```
static
ShiftMe: dword[3] := [$1234, $5678, $9012];
.
.
.
mov(ShiftMe[4], eax)
shld(6, eax, ShiftMe[8]);
mov(ShiftMe[0], eax);
shld(6, eax, ShiftMe[4]);
shl(6, ShiftMe[0]);
```

The first SHLD instruction above shifts the bits from *ShiftMe+4* into *ShiftMe+8* without affecting the value in *ShiftMe+4*. The second SHLD instruction shifts the bits from *SHIFTME* into *SHIFTME+4*. Finally, the SHL instruction shifts the L.O. double word the appropriate amount. There are two important things to note about this code. First, unlike the other extended precision shift left operations, this sequence works from the H.O. double word down to the L.O. double word. Second, the carry flag does not contain the carry out of the H.O. shift operation. If you need to preserve the carry flag at that point, you will need to push the flags after the first SHLD instruction and pop the flags after the SHL instruction.

You can do an extended precision shift right operation using the SHRD instruction. It works almost the same way as the code sequence above except you work from the L.O. double word to the H.O. double word. The solution is left as an exercise at the end of this chapter.

### 4.2.12 Extended Precision Rotate Operations

The RCL and RCR operations extend in a manner almost identical to that for SHL and SHR . For example, to perform 96 bit RCL and RCR operations, use the following instructions:

```
rcl(1, (type dword Operand[0]));
rcl(1, (type dword Operand[4]));
rcl(1, (type dword Operand[8]));

rcr(1, (type dword Operand[8]));
rcr(1, (type dword Operand[4]));
rcr(1, (type dword Operand[0]));
```

The only difference between this code and the code for the extended precision shift operations is that the first instruction is a RCL or RCR rather than a SHL or SHR instruction.

Performing an extended precision ROL or ROR instruction isn't quite as simple an operation. You can use the BT, SHLD, and SHRD instructions to implement an extended precision ROL or ROR instruction. The following code shows how to use the SHLD instruction to do an extended precision ROL:

```
// Compute ROL(4, EDX:EAX);

mov(edx, ebx);
shld, 4, eax, edx);
shld(4, ebx, eax);
bt(0, eax); // Set carry flag, if desired.
```

An extended precision ROR instruction is similar; just keep in mind that you work on the L.O. end of the object first and the H.O. end last.

### 4.2.13 Extended Precision I/O

Once you have the ability to compute using extended precision arithmetic, the next problem is how do you get those extended precision values into your program and how do you display those extended precision values to the user? HLA's Standard Library provides routines for unsigned decimal, signed decimal, and hexadecimal I/O for values that are eight, 16, 32, or 64 bits in length. So as long as you're working with values whose size is less than or equal to 64 bits in length, you can use the Standard Library code. If you need to input or output values that are greater than 64 bits in length, you will need to write your own procedures to handle the operation. This section discusses the strategies you will need to write such routines.

The examples in this section work specifically with 128-bit values. The algorithms are perfectly general and extend to any number of bits (indeed, the 128-bit algorithms in this section are really nothing more than an extension of the algorithms the HLA Standard Library uses for 64-bit values). If you need a set of 128-bit unsigned I/O routines, you will probably be able to use the following code as-is. If you need to handle larger values, simple modifications to the following code is all that should be necessary.

The following examples all assume a common data type for 128-bit values. The HLA type declaration for this data type is one of the following depending on the type of value

```
type
bits128: dword[4];
uns128: bits128;
int128: bits128;
```

---

### 4.2.13.1 Extended Precision Hexadecimal Output

Extended precision hexadecimal output is very easy. All you have to do is output each double word component of the extended precision value from the H.O. double word to the L.O. double word using a call to the *stdout.putd* routine. The following procedure does exactly this to output a *bits128* value:

```
procedure putb128(b128: bits128); nodisplay;
begin putb128;

 stdout.putd(b128[12]);
 stdout.putd(b128[8]);
 stdout.putd(b128[4]);
 stdout.putd(b128[0]);

end putb128;
```

Since HLA provides the *stdout.putq* procedure, you can shorten the code above by calling *stdout.putq* just twice:

```
procedure putb128(b128: bits128); nodisplay;
begin putb128;

 stdout.putq((type qword b128[8]));
 stdout.putq((type qword b128[0]));

end putb128;
```

Note that this code outputs the two quad words with the H.O. quad word output first and L.O. quad word output second.

---

### 4.2.13.2 Extended Precision Unsigned Decimal Output

Decimal output is a little more complicated than hexadecimal output because the H.O. bits of a binary number affect the L.O. digits of the decimal representation (this was not true for hexadecimal values which is why hexadecimal output is so easy). Therefore, we will have to create the decimal representation for a binary number by extracting one decimal digit at a time from the number.

The most commonly employed solution for unsigned decimal output is to successively divide the value by ten until the result becomes zero. The remainder after the first division is a value in the range 0..9 and this value corresponds to the L.O. digit of the decimal number. Successive divisions by ten (and their corresponding remainder) extract successive digits to the left in the number.

Iterative solutions to this problem generally allocate storage for a string of characters large enough to hold the entire number. Then the code extracts the decimal digits in a loop and places them in the string one by one. At the end of the conversion process, the routine prints the characters in the string in reverse order (remember, the divide algorithm extracts the L.O. digits first and the H.O. digits last, the opposite of the way you need to print them).

In this section, we will employ a recursive solution because it is a little more elegant. The recursive solution begins by dividing the value by 10 and saving the remainder in a local variable. If the quotient was not zero, the routine recursively calls itself to print any leading digits first. On return from the recursive call (which prints all the leading digits), the recursive algorithm prints the digit associated with the remainder to complete the operation. Here's how the operation works when printing the decimal value "123":

- (1) Divide 123 by 10. Quotient is 12, remainder is 3.
- (2) Save the remainder (3) in a local variable and recursively call the routine with the quotient.
- (3) [Recursive Entry 1] Divide 12 by 10. Quotient is 1, remainder is 2.
- (4) Save the remainder (2) in a local variable and recursively call the routine with the quotient.

- (5) [Recursive Entry 2] Divide 1 by 10. Quotient is 0, remainder is 1.
- (6) Save the remainder (1) in a local variable. Since the Quotient is zero, don't call the routine recursively.
- (7) Output the remainder value saved in the local variable (1). Return to the caller (Recursive Entry 1).
- (8) [Return to Recursive Entry 1] Output the remainder value saved in the local variable in recursive entry 1 (2). Return to the caller (original invocation of the procedure).
- (9) [Original invocation] Output the remainder value saved in the local variable in the original call (3). Return to the original caller of the output routine.

The only operation that requires extended precision calculation through this entire algorithm is the "divide by 10" requirement. Everything else is simple and straight-forward. We are in luck with this algorithm, since we are dividing an extended precision value by a value that easily fits into a double word, we can use the fast (and easy) extended precision division algorithm that uses the DIV instruction (see "Extended Precision Division" on page 838). The following program implements a 128-bit decimal output routine utilizing this technique.

```

program out128;

#include("stdlib.hhf");

// 128-bit unsigned integer data type:

type
 uns128: dword[4];

// DivideBy10-
//
// Divides "divisor" by 10 using fast
// extended precision division algorithm
// that employs the DIV instruction.
//
// Returns quotient in "quotient"
// Returns remainder in eax.
// Trashes EBX, EDX, and EDI.

procedure DivideBy10(dividend:uns128; var quotient:uns128); nodisplay;
begin DivideBy10;

 mov(quotient, edi);
 xor(edx, edx);
 mov(dividend[12], eax);
 mov(10, ebx);
 div(ebx, edx:eax);
 mov(eax, [edi+12]);

 mov(dividend[8], eax);
 div(ebx, edx:eax);
 mov(eax, [edi+8]);

 mov(dividend[4], eax);
 div(ebx, edx:eax);
 mov(eax, [edi+4]);

 mov(dividend[0], eax);
 div(ebx, edx:eax);
 mov(eax, [edi+0]);

```

```

 mov(edx, eax);

end DivideBy10;

// Recursive version of putul28.
// A separate "shell" procedure calls this so that
// this code does not have to preserve all the registers
// it uses (and DivideBy10 uses) on each recursive call.

procedure recursivePutul28(b128:uns128); nodisplay;
var
 remainder: byte;

begin recursivePutul28;

 // Divide by ten and get the remainder (the char to print).

 DivideBy10(b128, b128);
 mov(al, remainder); // Save away the remainder (0..9).

 // If the quotient (left in b128) is not zero, recursively
 // call this routine to print the H.O. digits.

 mov(b128[0], eax); // If we logically OR all the dwords
 or(b128[4], eax); // together, the result is zero if and
 or(b128[8], eax); // only if the entire number is zero.
 or(b128[12], eax);
 if(@nz) then

 recursivePutul28(b128);

 endif;

 // Okay, now print the current digit.

 mov(remainder, al);
 or('0', al); // Converts 0..9 -> '0..'9'.
 stdout.putc(al);

end recursivePutul28;

// Non-recursive shell to the above routine so we don't bother
// saving all the registers on each recursive call.

procedure putul28(b128:uns128); nodisplay;
begin putul28;

 push(eax);
 push(ebx);
 push(edx);
 push(edi);

 recursivePutul28(b128);

 pop(edi);
 pop(edx);
 pop(ebx);
 pop(eax);

```

```

end putu128;

// Code to test the routines above:

static
 b0: uns128 := [0, 0, 0, 0]; // decimal = 0
 b1: uns128 := [1234567890, 0, 0, 0]; // decimal = 1234567890
 b2: uns128 := [$8000_0000, 0, 0, 0]; // decimal = 2147483648
 b3: uns128 := [0, 1, 0, 0]; // decimal = 4294967296

 // Largest uns128 value
 // (decimal=340,282,366,920,938,463,463,374,607,431,768,211,455) :

 b4: uns128 := [$FFFF_FFFF, $FFFF_FFFF, $FFFF_FFFF, $FFFF_FFFF];

begin out128;

 stdout.put("b0 = ");
 putu128(b0);
 stdout.newln();

 stdout.put("b1 = ");
 putu128(b1);
 stdout.newln();

 stdout.put("b2 = ");
 putu128(b2);
 stdout.newln();

 stdout.put("b3 = ");
 putu128(b3);
 stdout.newln();

 stdout.put("b4 = ");
 putu128(b4);
 stdout.newln();

end out128;

```

---

---

Program 4.4    128-bit Extended Precision Decimal Output Routine

---

---

### 4.2.13.3 Extended Precision Signed Decimal Output

Once you have an extended precision unsigned decimal output routine, writing an extended precision signed decimal output routine is very easy. The basic algorithm takes the following form:

- Check the sign of the number. If it is positive, call the unsigned output routine to print it.
- If the number is negative, print a minus sign. Then negate the number and call the unsigned output routine to print it.

To check the sign of an extended precision integer, of course, you simply test the H.O. bit of the number. To negate a large value, the best solution is to probably subtract that value from zero. Here's a quick version of *puti128* that uses the *putu128* routine from the previous section.

```

procedure puti128(i128: int128); nodisplay;
begin puti128;

 if((type int32 i128[12]) < 0) then

 stdout.put('-');

 // Extended Precision Negation:

 push(eax);
 mov(0, eax);
 sub(i128[0], eax);
 mov(eax, i128[0]);

 mov(0, eax);
 sbb(i128[4], eax);
 mov(eax, i128[4]);

 mov(0, eax);
 sbb(i128[8], eax);
 mov(eax, i128[8]);

 mov(0, eax);
 sbb(i128[12], eax);
 mov(eax, i128[12]);
 pop(eax);

 endif;
 putu128((type uns128 i128));

end puti128;

```

---

#### 4.2.13.4 Extended Precision Formatted I/O

The code in the previous two sections prints signed and unsigned integers using the minimum number of necessary print positions. To create nicely formatted tables of values you will need the equivalent of a *puti128Size* or *putu128Size* routine. Once you have the "unformatted" versions of these routines, implementing the formatted versions is very easy.

The first step is to write an "i128Size" and a "u128Size" routine that computes the minimum number of digits needed to display the value. The algorithm to accomplish this is very similar to the numeric output routines. In fact, the only difference is that you initialize a counter to zero upon entry into the routine (e.g., the non-recursive shell routine) and you increment this counter rather than outputting a digit on each recursive call. (Don't forget to increment the counter inside "i128Size" if the number is negative; you must allow for the output of the minus sign.) After the calculation is complete, these routines should return the size of the operand in the EAX register.

Once you have the "i128Size" and "u128Size" routines, writing the formatted output routines is very easy. Upon initial entry into *puti128Size* or *putu128Size*, these routines call the corresponding "size" routine to determine the number of print positions for the number to display. If the value that the "size" routine returns is greater than the absolute value of the minimum size parameter (passed into *puti128Size* or *putu128Size*) all you need to do is call the put routine to print the value, no other formatting is necessary. If the absolute value of the parameter size is greater than the value *i128Size* or *u128Size* returns, then the program must compute the difference between these two values and print that many spaces (or other filler character) before printing the number (if the parameter size value is positive) or after printing the number (if the parameter size value is negative). The actual implementation of these two routines is left as an exercise at

the end of the volume. If you have any further questions about how to do this, you can take a look at the HLA Standard Library code for routines like *stdout.putu32Size*.

### 4.2.13.5 Extended Precision Input Routines

There are a couple of fundamental differences between the extended precision output routines and the extended precision input routines. First of all, numeric output generally occurs without possibility of error<sup>3</sup>; numeric input, on the other hand, must handle the very real possibility of an input error such as illegal characters and numeric overflow. Also, HLA's Standard Library and run-time system encourages a slightly different approach to input conversion. This section discusses those issues that differentiate input conversion from output conversion.

Perhaps the biggest difference between input and output conversion is the fact that output conversion is *unbracketed*. That is, when converting a numeric value to a string of characters for output, the output routine does not concern itself with character preceding the output string nor does it concern itself with the characters following the numeric value in the output stream. Numeric output routines convert their data to a string and print that string without considering the context (i.e., the characters before and after the string representation of the numeric value). Numeric input routines cannot be so cavalier; the contextual information surrounding the numeric string is very important.

A typical numeric input operation consists of reading a string of characters from the user and then translating this string of characters into an internal numeric representation. For example, a statement like `"stdin.get(i32);"` typically reads a line of text from the user and converts a sequence of digits appearing at the beginning of that line of text into a 32-bit signed integer (assuming *i32* is an *int32* object). Note, however, that the *stdin.get* routine skips over certain characters in the string that may appear before the actual numeric characters. For example, *stdin.get* automatically skips any leading spaces in the string. Likewise, the input string may contain additional data beyond the end of the numeric input (for example, it is possible to read two integer values from the same input line), therefore the input conversion routine must somehow determine where the numeric data ends in the input stream. Fortunately, HLA provides a simple mechanism that lets you easily determine the start and end of the input data: the *Delimiters* character set.

The *Delimiters* character set is a variable, internal to HLA, that contains the set of legal characters that may precede or follow a legal numeric value. By default, this character set includes the end of string marker (a zero byte), a tab character, a line feed character, a carriage return character, a space, a comma, a colon, and a semicolon. Therefore, HLA's numeric input routines will automatically ignore any characters in this set that occur on input before a numeric string. Likewise, characters from this set may legally follow a numeric string on input (conversely, if any non-delimiter character follows the numeric string, HLA will raise an *ex.ConversionError* exception).

The *Delimiters* character set is a private variable inside the HLA Standard Library. Although you do not have direct access to this object, the HLA Standard Library does provide two accessor functions, *conv.setDelimiters* and *conv.getDelimiters* that let you access and modify the value of this character set. These two functions have the following prototypes (found in the "conv.hhf" header file):

```
procedure conv.setDelimiters(Delims:cset);
procedure conv.getDelimiters(var Delims:cset);
```

The *conv.SetDelimiters* procedure will copy the value of the *Delims* parameter into the internal *Delimiters* character set. Therefore, you can use this procedure to change the character set if you want to use a different set of delimiters for numeric input. The *conv.getDelimiters* call returns a copy of the internal *Delimiters* character set in the variable you pass as a parameter to the *conv.getDelimiters* procedure. We will use the value returned by *conv.getDelimiters* to determine the end of numeric input when writing our own extended precision numeric input routines.

When reading a numeric value from the user, the first step will be to get a copy of the *Delimiters* character set. The second step is to read and discard input characters from the user as long as those characters are

---

3. Technically speaking, this isn't entirely true. It is possible for a device error (e.g., disk full) to occur. The likelihood of this is so low that we can effectively ignore this possibility.

members of the *Delimiters* character set. Once a character is found that is not in the *Delimiters* set, the input routine must check this character and verify that it is a legal numeric character. If not, the program should raise an *ex.IllegalChar* exception if the character's value is outside the range \$00..\$7f or it should raise the *ex.ConversionError* exception if the character is not a legal numeric character. Once the routine encounters a numeric character, it should continue reading characters as long as they valid numeric characters; while reading the characters the conversion routine should be translating them to the internal representation of the numeric data. If, during conversion, an overflow occurs, the procedure should raise the *ex.ValueOutOfRange* exception.

Conversion to numeric representation should end when the procedure encounters the first delimiter character at the end of the string of digits. However, it is very important that the procedure does not consume the delimiter character that ends the string. That is, the following is incorrect:

```
static
 Delimiters: cset;
 .
 .
 .
conv.getDelimiters(Delimiters);

// Skip over leading delimiters in the string:

while(stdin.getc() in Delimiters) do /* getc did the work */ endwhile;
while(al in {'0'..'9'}) do

 // Convert character in AL to numeric representation and
 // accumulate result...

 stdin.getc();

endwhile;
if(al not in Delimiters) then

 raise(ex.ConversionError);

endif;
```

The first WHILE loop reads a sequence of delimiter characters. When this first WHILE loop ends, the character in AL is not a delimiter character. So far, so good. The second WHILE loop processes a sequence of decimal digits. First, it checks the character read in the previous WHILE loop to see if it is a decimal digit; if so, it processes that digit and reads the next character. This process continues until the call to *stdin.getc* (at the bottom of the loop) reads a non-digit character. After the second WHILE loop, the program checks the last character read to ensure that it is a legal delimiter character for a numeric input value.

The problem with this algorithm is that it consumes the delimiter character after the numeric string. For example, the colon symbol is a legal delimiter in the default *Delimiters* character set. If the user types the input "123:456" and executes the code above, this code will properly convert "123" to the numeric value one hundred twenty-three. However, the very next character read from the input stream will be the character "4" not the colon character (":"). While this may be acceptable in certain circumstances, Most programmers expect numeric input routines to consume only leading delimiter characters and the numeric digit characters. They do not expect the input routine to consume any trailing delimiter characters (e.g., many programs will read the next character and expect a colon as input if presented with the string "123:456"). Since *stdin.getc* consumes an input character, and there is no way to "put the character back" onto the input stream, some other way of reading input characters from the user, that doesn't consume those characters, is needed<sup>4</sup>.

The HLA Standard Library comes to the rescue by providing the *stdin.peekc* function. Like *stdin.getc*, the *stdin.peekc* routine reads the next input character from HLA's internal buffer. There are two major differ-

---

4. The HLA Standard Library routines actually buffer up input lines in a string and process characters out of the string. This makes it easy to "peek" ahead one character when looking for a delimiter to end the input value. Your code can also do this, however, the code in this chapter will use a different approach.

ences between *stdin.peekc* and *stdin.getc*. First, *stdin.peekc* will not force the input of a new line of text from the user if the current input line is empty (or you've already read all the text from the input line). Instead, *stdin.peekc* simply returns zero in the AL register to indicate that there are no more characters on the input line. Since #0 is (by default) a legal delimiter character for numeric values, and the end of line is certainly a legal way to terminate numeric input, this works out rather well. The second difference between *stdin.getc* and *stdin.peekc* is that *stdin.peekc* does not consume the character read from the input buffer. If you call *stdin.peekc* several times in a row, it will always return the same character; likewise, if you call *stdin.getc* immediately after *stdin.peekc*, the call to *stdin.getc* will generally return the same character as returned by *stdin.peekc* (the only exception being the end of line condition). So although we cannot put characters back onto the input stream after we've read them with *stdin.getc*, we can peek ahead at the next character on the input stream and base our logic on that character's value. A corrected version of the previous algorithm might be the following:

```
static
 Delimiters: cset;
 .
 .
 .
conv.getDelimiters(Delimiters);

// Skip over leading delimiters in the string:

while(stdin.peekc() in Delimiters) do

 // If at the end of the input buffer, we must explicitly read a
 // new line of text from the user. stdin.peekc does not do this
 // for us.

 if(al = #0) then

 stdin.ReadLn();

 else

 stdin.getc(); // Remove delimiter from the input stream.

 endif;

endwhile;
while(stdin.peekc in {'0'..'9'}) do

 stdin.getc(); // Remove the input character from the input stream.

 // Convert character in AL to numeric representation and
 // accumulate result...

endwhile;
if(al not in Delimiters) then

 raise(ex.ConversionError);

endif;
```

Note that the call to *stdin.peekc* in the second WHILE does not consume the delimiter character when the expression evaluates false. Hence, the delimiter character will be the next character read after this algorithm finishes.

The only remaining comment to make about numeric input is to point out that the HLA Standard Library input routines allow arbitrary underscores to appear within a numeric string. The input routines ignore these underscore characters. This allows the user to input strings like "FFFF\_F012" and "1\_023\_596" which are a little more readable than "FFFFFF012" or "1023596". To allow underscores (or any

other symbol you choose) within a numeric input routine is quite simple; just modify the second WHILE loop above as follows:

```

while(stdin.peekc in {'0'..'9', '_'}) do

 stdin.getc(); // Read the character from the input stream.

 // Ignore underscores while processing numeric input.

 if(al <> '_') then

 // Convert character in AL to numeric representation and
 // accumulate result...

 endif;

endwhile;

```

---

### 4.2.13.6 Extended Precision Hexadecimal Input

As was the case for numeric output, hexadecimal input is the easiest numeric input routine to write. The basic algorithm for hexadecimal string to numeric conversion is the following:

- Initialize the extended precision value to zero.
- For each input character that is a valid hexadecimal digit, do the following:
  - Convert the hexadecimal character to a value in the range 0..15 (\$0..\$F).
  - If the H.O. four bits of the extended precision value are non-zero, raise an exception.
  - Multiply the current extended precision value by 16 (i.e., shift left four bits).
  - Add the converted hexadecimal digit value to the accumulator.
- Check the last input character to ensure it is a valid delimiter. Raise an exception if it is not.

The following program implements this extended precision hexadecimal input routine for 128-bit values.

---

```

program Xin128;

#include("stdlib.hhf");

// 128-bit unsigned integer data type:

type
 b128: dword[4];

procedure getb128(var inValue:b128); nodisplay;
const
 HexChars := {'0'..'9', 'a'..'f', 'A'..'F', '_'};
var
 Delimiters: cset;
 LocalValue: b128;

begin getb128;

 push(eax);
 push(ebx);

```

```

// Get a copy of the HLA standard numeric input delimiters:

conv.getDelimiters(Delimiters);

// Initialize the numeric input value to zero:

xor(eax, eax);
mov(eax, LocalValue[0]);
mov(eax, LocalValue[4]);
mov(eax, LocalValue[8]);
mov(eax, LocalValue[12]);

// By default, #0 is a member of the HLA Delimiters
// character set. However, someone may have called
// conv.setDelimiters and removed this character
// from the internal Delimiters character set. This
// algorithm depends upon #0 being in the Delimiters
// character set, so let's add that character in
// at this point just to be sure.

cs.unionChar(#0, Delimiters);

// If we're at the end of the current input
// line (or the program has yet to read any input),
// for the input of an actual character.

if(stdin.peekc() = #0) then

 stdin.ReadLn();

endif;

// Skip the delimiters found on input. This code is
// somewhat convoluted because stdin.peekc does not
// force the input of a new line of text if the current
// input buffer is empty. We have to force that input
// ourselves in the event the input buffer is empty.

while(stdin.peekc() in Delimiters) do

 // If we're at the end of the line, read a new line
 // of text from the user; otherwise, remove the
 // delimiter character from the input stream.

 if(al = #0) then

 stdin.ReadLn(); // Force a new input line.

 else

 stdin.getc(); // Remove the delimiter from the input buffer.

 endif;

endwhile;

// Read the hexadecimal input characters and convert
// them to the internal representation:

```

```

while(stdin.peekc() in HexChars) do

 // Actually read the character to remove it from the
 // input buffer.

 stdin.getc();

 // Ignore underscores, process everything else.

 if(al <> '_') then

 if(al in '0'..'9') then

 and($f, al); // '0'..'9' -> 0..9

 else

 and($f, al); // 'a'/'A'..'f'/'F' -> 1..6
 add(9, al); // 1..6 -> 10..15

 endif;

 // Conversion algorithm is the following:
 //
 // (1) LocalValue := LocalValue * 16.
 // (2) LocalValue := LocalValue + al
 //
 // Note that "* 16" is easily accomplished by
 // shifting LocalValue to the left four bits.
 //
 // Overflow occurs if the H.O. four bits of LocalValue
 // contain a non-zero value prior to this operation.

 // First, check for overflow:

 test($F0, (type byte LocalValue[15]));
 if(@nz) then

 raise(ex.ValueOutOfRange);

 endif;

 // Now multiply LocalValue by 16 and add in
 // the current hexadecimal digit (in EAX).

 mov(LocalValue[8], ebx);
 shld(4, ebx, LocalValue[12]);
 mov(LocalValue[4], ebx);
 shld(4, ebx, LocalValue[8]);
 mov(LocalValue[0], ebx);
 shld(4, ebx, LocalValue[4]);
 shl(4, ebx);
 add(eax, ebx);
 mov(ebx, LocalValue[0]);

 endif;

endwhile;

// Okay, we've encountered a non-hexadecimal character.

```

```

// Let's make sure it's a valid delimiter character.
// Raise the ex.ConversionError exception if it's invalid.

if(al not in Delimiters) then

 raise(ex.ConversionError);

endif;

// Okay, this conversion has been a success. Let's store
// away the converted value into the output parameter.

mov(inValue, ebx);
mov(LocalValue[0], eax);
mov(eax, [ebx]);

mov(LocalValue[4], eax);
mov(eax, [ebx+4]);

mov(LocalValue[8], eax);
mov(eax, [ebx+8]);

mov(LocalValue[12], eax);
mov(eax, [ebx+12]);

pop(ebx);
pop(eax);

end getb128;

// Code to test the routines above:

static
 b1:b128;

begin Xin128;

 stdout.put("Input a 128-bit hexadecimal value: ");
 getb128(b1);
 stdout.put
 (
 "The value is: $",
 b1[12], ' ',
 b1[8], ' ',
 b1[4], ' ',
 b1[0],
 nl
);

end Xin128;

```

---

---

### Program 4.5 Extended Precision Hexadecimal Input

---

---

Extending this code to handle objects that are not 128 bits long is very easy. There are only three changes necessary: you must zero out the whole object at the beginning of the `getb128` routine; when check-

ing for overflow (the "test( \$F, (type byte LocalValue[15]);" instruction) you must test the H.O. four bits of the new object you're processing; and you must modify the code that multiplies LocalValue by 16 (via SHLD) so that it multiplies your object by 16 (i.e., shifts it to the left four bits).

---

### 4.2.13.7 Extended Precision Unsigned Decimal Input

The algorithm for extended precision unsigned decimal input is nearly identical to that for hexadecimal input. In fact, the only difference (beyond only accepting decimal digits) is that you multiply the extended precision value by 10 rather than 16 for each input character (in general, the algorithm is the same for any base; just multiply the accumulating value by the input base). The following code demonstrates how to write a 128-bit unsigned decimal input routine.

---

```

program Uin128;

#include("stdlib.hhf");

// 128-bit unsigned integer data type:

type
 u128: dword[4];

procedure getu128(var inValue:u128); nodisplay;
var
 Delimiters: cset;
 LocalValue: u128;
 PartialSum: u128;

begin getu128;

 push(eax);
 push(ebx);
 push(ecx);
 push(edx);

 // Get a copy of the HLA standard numeric input delimiters:

 conv.getDelimiters(Delimiters);

 // Initialize the numeric input value to zero:

 xor(eax, eax);
 mov(eax, LocalValue[0]);
 mov(eax, LocalValue[4]);
 mov(eax, LocalValue[8]);
 mov(eax, LocalValue[12]);

 // By default, #0 is a member of the HLA Delimiters
 // character set. However, someone may have called
 // conv.setDelimiters and removed this character
 // from the internal Delimiters character set. This
 // algorithm depends upon #0 being in the Delimiters
 // character set, so let's add that character in
 // at this point just to be sure.

 cs.unionChar(#0, Delimiters);

```

```

// If we're at the end of the current input
// line (or the program has yet to read any input),
// for the input of an actual character.

if(stdin.peekc() = #0) then

 stdin.ReadLn();

endif;

// Skip the delimiters found on input. This code is
// somewhat convoluted because stdin.peekc does not
// force the input of a new line of text if the current
// input buffer is empty. We have to force that input
// ourselves in the event the input buffer is empty.

while(stdin.peekc() in Delimiters) do

 // If we're at the end of the line, read a new line
 // of text from the user; otherwise, remove the
 // delimiter character from the input stream.

 if(al = #0) then

 stdin.ReadLn(); // Force a new input line.

 else

 stdin.getc(); // Remove the delimiter from the input buffer.

 endif;

endwhile;

// Read the decimal input characters and convert
// them to the internal representation:

while(stdin.peekc() in '0'..'9') do

 // Actually read the character to remove it from the
 // input buffer.

 stdin.getc();

 // Ignore underscores, process everything else.

 if(al <> '_') then

 and($f, al); // '0'..'9' -> 0..9
 mov(eax, PartialSum[0]); // Save to add in later.

 // Conversion algorithm is the following:
 //
 // (1) LocalValue := LocalValue * 10.
 // (2) LocalValue := LocalValue + al
 //
 // First, multiply LocalValue by 10:

```

```

mov(10, eax);
mul(LocalValue[0], eax);
mov(eax, LocalValue[0]);
mov(edx, PartialSum[4]);

mov(10, eax);
mul(LocalValue[4], eax);
mov(eax, LocalValue[4]);
mov(edx, PartialSum[8]);

mov(10, eax);
mul(LocalValue[8], eax);
mov(eax, LocalValue[8]);
mov(edx, PartialSum[12]);

mov(10, eax);
mul(LocalValue[12], eax);
mov(eax, LocalValue[12]);

// Check for overflow. This occurs if EDX
// contains a none zero value.

if(edx /* <> 0 */) then

 raise(ex.ValueOutOfRange);

endif;

// Add in the partial sums (including the
// most recently converted character).

mov(PartialSum[0], eax);
add(eax, LocalValue[0]);

mov(PartialSum[4], eax);
adc(eax, LocalValue[4]);

mov(PartialSum[8], eax);
adc(eax, LocalValue[8]);

mov(PartialSum[12], eax);
adc(eax, LocalValue[12]);

// Another check for overflow. If there
// was a carry out of the extended precision
// addition above, we've got overflow.

if(@c) then

 raise(ex.ValueOutOfRange);

endif;

endif;

endwhile;

// Okay, we've encountered a non-decimal character.
// Let's make sure it's a valid delimiter character.
// Raise the ex.ConversionError exception if it's invalid.

```

```

 if(al not in Delimiters) then
 raise(ex.ConversionError);
 endif;

 // Okay, this conversion has been a success. Let's store
 // away the converted value into the output parameter.

 mov(inValue, ebx);
 mov(LocalValue[0], eax);
 mov(eax, [ebx]);

 mov(LocalValue[4], eax);
 mov(eax, [ebx+4]);

 mov(LocalValue[8], eax);
 mov(eax, [ebx+8]);

 mov(LocalValue[12], eax);
 mov(eax, [ebx+12]);

 pop(edx);
 pop(ecx);
 pop(ebx);
 pop(eax);

end getu128;

// Code to test the routines above:

static
 b1:u128;

begin Uin128;

 stdout.put("Input a 128-bit decimal value: ");
 getu128(b1);
 stdout.put
 (
 "The value is: $",
 b1[12], ' ',
 b1[8], ' ',
 b1[4], ' ',
 b1[0],
 nl
);

end Uin128;

```

---

---

### Program 4.6 Extended Precision Unsigned Decimal Input

---

---

As for hexadecimal input, extending this decimal input to some number of bits beyond 128 is fairly easy. All you need do is modify the code that zeros out the LocalValue variable and the code that multiplies

LocalValue by ten (overflow checking is done in this same code, so there are only two spots in this code that require modification).

---

### 4.2.13.8 Extended Precision Signed Decimal Input

Once you have an unsigned decimal input routine, writing a signed decimal input routine is easy. The following algorithm describes how to accomplish this:

- Consume any delimiter characters at the beginning of the input stream.
- If the next input character is a minus sign, consume this character and set a flag noting that the number is negative.
- Call the unsigned decimal input routine to convert the rest of the string to an integer.
- Check the return result to make sure it's H.O. bit is clear. Raise the `ex.ValueOutOfRange` exception if the H.O. bit of the result is set.
- If the sign flag was set in step two above, negate the result.

The actual code is left as a programming exercise at the end of this volume.

---

## 4.3 Operating on Different Sized Operands

Occasionally you may need to compute some value on a pair of operands that are not the same size. For example, you may need to add a word and a double word together or subtract a byte value from a word value. The solution is simple: just extend the smaller operand to the size of the larger operand and then do the operation on two similarly sized operands. For signed operands, you would sign extend the smaller operand to the same size as the larger operand; for unsigned values, you zero extend the smaller operand. This works for any operation, although the following examples demonstrate this for the addition operation.

To extend the smaller operand to the size of the larger operand, use a sign extension or zero extension operation (depending upon whether you're adding signed or unsigned values). Once you've extended the smaller value to the size of the larger, the addition can proceed. Consider the following code that adds a byte value to a word value:

```
static
 var1: byte;
 var2: word;
 .
 .
 .
// Unsigned addition:

 movzx(var1, ax);
 add(var2, ax);

// Signed addition:

 movsx(var1, ax);
 add(var2, ax);
```

In both cases, the byte variable was loaded into the AL register, extended to 16 bits, and then added to the word operand. This code works out really well if you can choose the order of the operations (e.g., adding the eight bit value to the sixteen bit value). Sometimes, you cannot specify the order of the operations. Perhaps the sixteen bit value is already in the AX register and you want to add an eight bit value to it. For unsigned addition, you could use the following code:

```
 mov(var2, ax); // Load 16 bit value into AX
 . // Do some other operations leaving
 . // a 16-bit quantity in AX.
 add(var1, al); // Add in the eight-bit value
 adc(0, ah); // Add carry into the H.O. word.
```

The first ADD instruction in this example adds the byte at *var1* to the L.O. byte of the value in the accumulator. The ADC instruction above adds the carry out of the L.O. byte into the H.O. byte of the accumulator. Care must be taken to ensure that this ADC instruction is present. If you leave it out, you may not get the correct result.

Adding an eight bit signed operand to a sixteen bit signed value is a little more difficult. Unfortunately, you cannot add an immediate value (as above) to the H.O. word of AX. This is because the H.O. extension byte can be either \$00 or \$FF. If a register is available, the best thing to do is the following:

```
mov(ax, bx); // BX is the available register.
movsx(var1, ax);
add(bx, ax);
```

If an extra register is not available, you might try the following code:

```
push(ax); // Save word value.
movsx(var1, ax); // Sign extend 8-bit operand to 16 bits.
add([esp], ax); // Add in previous word value
add(2, esp); // Pop junk from stack
```

Another alternative is to store the 16 bit value in the accumulator into a memory location and then proceed as before:

```
mov(ax, temp);
movsx(var1, ax);
add(temp, ax);
```

All the examples above added a byte value to a word value. By zero or sign extending the smaller operand to the size of the larger operand, you can easily add any two different sized variables together.

As a last example, consider adding an eight bit signed value to a quadword (64 bit) value:

```
static
QVal:qword;
BVal:int8;
.
.
.
movsx(BVal, eax);
cdq();
add((type dword QVal), eax);
adc((type dword QVal[4]), edx);
```

## 4.4 Decimal Arithmetic

The 80x86 CPUs use the binary numbering system for their native internal representation. The binary numbering system is, by far, the most common numbering system in use in computer systems today. In days long since past, however, there were computer systems that were based on the decimal (base 10) numbering system rather than the binary numbering system. Consequently, their arithmetic system was decimal based rather than binary. Such computer systems were very popular in systems targeted for business/commercial systems<sup>5</sup>. Although systems designers have discovered that binary arithmetic is almost always better than decimal arithmetic for general calculations, the myth still persists that decimal arithmetic is better for money calculations than binary arithmetic. Therefore, many software systems still specify the use of decimal arithmetic in their calculations (not to mention that there is lots of legacy code out there whose algorithms are

5. In fact, until the release of the IBM 360 in the middle 1960's, most scientific computer systems were binary based while most commercial/business systems were decimal based. IBM pushed their system\360 as a single purpose solution for both business and scientific applications. Indeed, the model designation (360) was derived from the 360 degrees on a compass so as to suggest that the system\360 was suitable for computations "at all points of the compass" (i.e., business and scientific).

only stable if they use decimal arithmetic). Therefore, despite the fact that decimal arithmetic is generally inferior to binary arithmetic, the need for decimal arithmetic still persists.

Of course, the 80x86 is not a decimal computer; therefore we have to play tricks in order to represent decimal numbers using the native binary format. The most common technique, even employed by most so-called decimal computers, is to use the *binary coded decimal*, or BCD representation. The BCD representation (see “Nibbles” on page 46) uses four bits to represent the 10 possible decimal digits. The binary value of those four bits is equal to the corresponding decimal value in the range 0..9. Of course, with four bits we can actually represent 16 different values. The BCD format ignores the remaining six bit combinations.

**Table 1: Binary Code Decimal (BCD) Representation**

| BCD Representation | Decimal Equivalent |
|--------------------|--------------------|
| 0000               | 0                  |
| 0001               | 1                  |
| 0010               | 2                  |
| 0011               | 3                  |
| 0100               | 4                  |
| 0101               | 5                  |
| 0110               | 6                  |
| 0111               | 7                  |
| 1000               | 8                  |
| 1001               | 9                  |
| 1010               | Illegal            |
| 1011               | Illegal            |
| 1100               | Illegal            |
| 1101               | Illegal            |
| 1110               | Illegal            |
| 1111               | Illegal            |

Since each BCD digit requires four bits, we can represent a two-digit BCD value with a single byte. This means that we can represent the decimal values in the range 0..99 using a single byte (versus 0..255 if we treat the value as an unsigned binary number). Clearly it takes a bit more memory to represent the same value in BCD as it does to represent the same value in binary. For example, with a 32-bit value you can represent BCD values in the range 0..99,999,999 (eight significant digits) but you can represent values in the range 0..4,294,967,295 (better than nine significant digits) using the binary representation.

Not only does the BCD format waste memory on a binary computer (since it uses more bits to represent a given integer value), but decimal arithmetic is slower. For these reasons, you should avoid the use of decimal arithmetic unless it is absolutely mandated for a given application.

Binary coded decimal representation does offer one big advantage over binary representation: it is fairly trivial to convert between the string representation of a decimal number and the BCD representation. This feature is particularly beneficial when working with fractional values since fixed and floating point binary representations cannot exactly represent many commonly used values between zero and one (e.g.,  $1/10$ ).

Therefore, BCD operations can be efficient when reading from a BCD device, doing a simple arithmetic operation (e.g., a single addition) and then writing the BCD value to some other device.

---

#### 4.4.1 Literal BCD Constants

HLA does not provide, nor do you need, a special literal BCD constant. Since BCD is just a special form of hexadecimal notation that does not allow the values \$A..\$F, you can easily create BCD constants using HLA's hexadecimal notation. Of course, you must take care not to include the symbols 'A'..'F' in a BCD constant since they are illegal BCD values. As an example, consider the following MOV instruction that copies the BCD value '99' into the AL register:

```
mov($99, al);
```

The important thing to keep in mind is that you must not use HLA literal decimal constants for BCD values. That is, "mov( 95, al );" does not load the BCD representation for ninety-five into the AL register. Instead, it loads \$5F into AL and that's an illegal BCD value. Any computations you attempt with illegal BCD values will produce garbage results. Always remember that, even though it seems counter-intuitive, you use hexadecimal literal constants to represent literal BCD values.

---

#### 4.4.2 The 80x86 DAA and DAS Instructions

The integer unit on the 80x86 does not directly support BCD arithmetic. Instead, the 80x86 requires that you perform the computation using binary arithmetic and use some auxiliary instructions to convert the binary result to BCD. To support packed BCD addition and subtraction with two digits per byte, the 80x86 provides two instructions: decimal adjust after addition (DAA) and decimal adjust after subtraction (DAS). You would execute these two instructions immediately after an ADD/ADC or SUB/SBB instruction to correct the binary result in the AL register.

To add a pair of two-digit (i.e., single-byte) BCD values together, you would use the following sequence:

```
mov(bcd_1, al); // Assume that bcd1 and bcd2 both contain
add(bcd_2, al); // value BCD values.
daa();
```

The first two instructions above add the two byte values together using standard binary arithmetic. This may not produce a correct BCD result. For example, if *bcd\_1* contains \$9 and *bcd\_2* contains \$1, then the first two instructions above will produce the binary sum \$A instead of the correct BCD result \$10. The DAA instruction corrects this invalid result. It checks to see if there was a carry out of the low order BCD digit and adjusts the value (by adding six to it) if there was an overflow. After adjusting for overflow out of the L.O. digit, the DAA instruction repeats this process for the H.O. digit. DAA sets the carry flag if there was a (decimal) carry out of the H.O. digit of the operation.

The DAA instruction only operates on the AL register. It will not adjust (properly) for a decimal addition if you attempt to add a value to AX, EAX, or any other register. Specifically note that DAA limits you to adding two decimal digits (a single byte) at a time. This means that for the purposes of computing decimal sums, you have to treat the 80x86 as though it were an eight-bit processor, capable of adding only eight bits at a time. If you wish to add more than two digits together, you must treat this as a multiprecision operation. For example, to add four decimal digits together (using DAA), you must execute a sequence like the following:

```
// Assume "bcd_1:byte[2];", "bcd_2:byte[2];", and "bcd_3:byte[2];"
mov(bcd_1[0], al);
add(bcd_2[0], al);
daa();
mov(al, bcd_3[0]);
mov(bcd_1[1], al);
```

```

 adc(bcd_2[1], al);
 daa();
 mov(al, bcd_3[1], al);

// Carry is set at this point if there was unsigned overflow.

```

Since a binary addition of a word requires only three instructions, you can see why decimal arithmetic is so expensive<sup>6</sup>.

The DAS (decimal adjust after subtraction) adjusts the decimal result after a binary SUB or SBB instruction. You use it the same way you use the DAA instruction. Examples:

```

// Two-digit (one byte) decimal subtraction:

mov(bcd_1, al); // Assume that bcd1 and bcd2 both contain
sub(bcd_2, al); // value BCD values.
das();

// Four-digit (two-byte) decimal subtraction.
// Assume "bcd_1:byte[2];", "bcd_2:byte[2];", and "bcd_3:byte[2];"

mov(bcd_1[0], al);
sub(bcd_2[0], al);
das();
mov(al, bcd_3[0]);
mov(bcd_1[1], al);
sbb(bcd_2[1], al);
das();
mov(al, bcd_3[1], al);

// Carry is set at this point if there was unsigned overflow.

```

Unfortunately, the 80x86 only provides support for addition and subtraction of packed BCD values using the DAA and DAS instructions. It does not support multiplication, division, or any other arithmetic operations. Because decimal arithmetic using these instructions is so limited, you'll rarely see any programs use these instructions.

---

### 4.4.3 The 80x86 AAA, AAS, AAM, and AAD Instructions

In addition to the *packed decimal* instructions (DAA and DAS), the 80x86 CPUs support four *unpacked decimal* adjustment instructions. Unpacked decimal numbers store only one digit per eight-bit byte. As you can imagine, this data representation scheme wastes a considerable amount of memory. However, the unpacked decimal adjustment instructions support the multiplication and division operations, so they are marginally more useful.

The instruction mnemonics AAA, AAS, AAM, and AAD stand for "ASCII adjust for Addition, Subtraction, Multiplication, and Division" (respectively). Despite their name, these instructions do not process ASCII characters. Instead, they support an unpacked decimal value in AL whose L.O. four bits contain the decimal digit and the H.O. four bits contain zero. Note, though, that you can easily convert an ASCII decimal digit character to an unpacked decimal number by simply ANDing AL with the value \$0F.

The AAA instruction adjusts the result of a binary addition of two unpacked decimal numbers. If the addition of those two values exceeds 10, then AAA will subtract 10 from AL and increment AH by one (as well as set the carry flag). AAA assumes that the two values you add together were legal unpacked decimal values. Other than the fact that AAA works with only one decimal digit at a time (rather than two), you use it the same way you use the DAA instruction. Of course, if you need to add together a string of decimal dig-

---

6. You'll also soon see that it's rare to find decimal arithmetic done this way. So it hardly matters.

its, using unpacked decimal arithmetic will require twice as many operations and, therefore, twice the execution time.

You use the AAS instruction the same way you use the DAS instruction except, of course, it operates on unpacked decimal values rather than packed decimal values. As for AAA, AAS will require twice the number of operations to add the same number of decimal digits as the DAS instruction. If you're wondering why anyone would want to use the AAA or AAS instructions, keep in mind that the unpacked format supports multiplication and division, while the packed format does not. Since packing and unpacking the data is usually more expensive than working on the data a digit at a time, the AAA and AAS instruction are more efficient if you have to work with unpacked data (because of the need for multiplication and division).

The AAM instruction modifies the result in the AX register to produce a correct unpacked decimal result after multiplying two unpacked decimal digits using the MUL instruction. Because the largest product you may obtain is 81 ( $9*9$  produces the largest possible product of two single digit values), the result will fit in the AL register. AAM unpacks the binary result by dividing it by 10, leaving the quotient (H.O. digit) in AH and the remainder (L.O. digit) in AL. Note that AAM leaves the quotient and remainder in different registers than a standard eight-bit DIV operation.

Technically, you do not have to use the AAM instruction immediately after a multiply. AAM simply divides AL by ten and leaves the quotient and remainder in AH and AL (respectively). If you have need of this particular operation, you may use the AAM instruction for this purpose (indeed, that's about the only use for AAM in most programs these days).

If you need to multiply more than two unpacked decimal digits together using MUL and AAM, you will need to devise a multiprecision multiplication that uses the manual algorithm from earlier in this chapter. Since that is a lot of work, this section will not present that algorithm. If you need a multiprecision decimal multiplication, see the next section; it presents a better solution.

The AAD instruction, as you might expect, adjusts a value for unpacked decimal division. The unusual thing about this instruction is that you must execute it *before* a DIV operation. It assumes that AL contains the least significant digit of a two-digit value and AH contains the most significant digit of a two-digit unpacked decimal value. It converts these two numbers to binary so that a standard DIV instruction will produce the correct unpacked decimal result. Like AAM, this instruction is nearly useless for its intended purpose as extended precision operations (e.g., division of more than one or two digits) are extremely inefficient. However, this instruction is actually quite useful in its own right. It computes  $AX = AH*10 + AL$  (assuming that AH and AL contain single digit decimal values). You can use this instruction to easily convert a two-character string containing the ASCII representation of a value in the range 0..99 to a binary value. E.g.,

```
mov('9', al);
mov('9', ah); // "99" is in AH:AL.
and($0F0F, ax); // Convert from ASCII to unpacked decimal.
aad(); // After this, AX contains 99.
```

The decimal and ASCII adjust instructions provide an extremely poor implementation of decimal arithmetic. To better support decimal arithmetic on 80x86 systems, Intel incorporated decimal operations into the FPU. The next section discusses how to use the FPU for this purpose. However, even with FPU support, decimal arithmetic is inefficient and less precise than binary arithmetic. Therefore, you should carefully consider whether you really need to use decimal arithmetic before incorporating it into your programs.

#### 4.4.4 Packed Decimal Arithmetic Using the FPU

To improve the performance of applications that rely on decimal arithmetic, Intel incorporated support for decimal arithmetic directly into the FPU. Unlike the packed and unpacked decimal formats of the previous sections, the FPU easily supports values with up to 18 decimal digits of precision, all at FPU speeds. Furthermore, all the arithmetic capabilities of the FPU (e.g., transcendental operations) are available in addition to addition, subtraction, multiplication, and division. Assuming you can live with *only* 18 digits of precision and a few other restrictions, decimal arithmetic on the FPU is the right way to go if you must use decimal arithmetic in your programs.

The first fact you must note when using the FPU is that it doesn't really support decimal arithmetic. Instead, the FPU provides two instructions, `FBLD` and `FBSTP`, that convert between packed decimal and binary floating point formats when moving data to and from the FPU. The `FBLD` (float/BCD load) instruction loads an 80-bit packed BCD value onto the top of the FPU stack after converting that BCD value to the IEEE binary floating point format. Likewise, the `FBSTP` (float/BCD store and pop) instruction pops the floating point value off the top of stack, converts it to a packed BCD value, and stores the BCD value into the destination memory location.

Once you load a packed BCD value into the FPU, it is no longer BCD. It's just a floating point value. This presents the first restriction on the use of the FPU as a decimal integer processor: calculations are done using binary arithmetic. If you have an algorithm that absolutely positively depends upon the use of decimal arithmetic, it may fail if you use the FPU to implement it<sup>7</sup>.

The second limitation is that the FPU supports only one BCD data type: a ten-byte 18-digit packed decimal value. It will not support smaller values nor will it support larger values. Since 18 digits is usually sufficient and memory is cheap, this isn't a big restriction.

A third consideration is that the conversion between packed BCD and the floating point format is not a cheap operation. The `FBLD` and `FBSTP` instructions can be quite slow (more than two orders of magnitude slower than `FLD` and `FSTP`, for example). Therefore, these instructions can be costly if you're doing simple additions or subtractions; the cost of conversion far outweighs the time spent adding the values a byte at a time using the `DAA` and `DAS` instructions (multiplication and division, however, are going to be faster on the FPU).

You may be wondering why the FPU's packed decimal format only supports 18 digits. After all, with ten bytes it should be possible to represent 20 BCD digits. As it turns out, the FPU's packed decimal format uses the first nine bytes to hold the packed BCD value in a standard packed decimal format (the first byte contains the two L.O. digits and the ninth byte holds the H.O. two digits). The H.O. bit of the tenth byte holds the sign bit and the FPU ignores the remaining bits in the tenth byte. If you're wondering why Intel didn't squeeze in one more digit (i.e., use the L.O. four bits of the tenth byte to allow for 19 digits of precision), just keep in mind that doing so would create some possible BCD values that the FPU could not exactly represent in the native floating point format. Hence the limitation to 18 digits.

The FPU uses a one's complement notation for negative BCD values. That is, the sign bit contains a one if the number is negative or zero and it contains a zero if the number is positive or zero (like the binary one's complement format, there are two distinct representations for zero).

HLA's `tbyte` type is the standard data type you would use to define packed BCD variables. The `FBLD` and `FBSTP` instructions require a `tbyte` operand. Unfortunately, the current version of HLA does not let you (directly) provide an initializer for a `tbyte` variable. There are several solutions to this problem, the next chapter will present some of them. One solution is to put any `tbyte` objects you need to initialize in the `DATA` section of your program. For example, consider the following code fragment:

```
data
 tbyteObject: tbyte;
 byte $21, $43, $65, 0, 0, 0, 0, 0, 0, 0;
```

The `tbyteObject` declaration tells HLA that this is a `tbyte` object but does not explicitly set aside any space for the variable (see "The Static Sections" on page 161). The following `BYTE` directive sets aside ten bytes of storage and initializes these ten bytes with the value `$654321` (remember that the 80x86 organizes data from the L.O. byte to the H.O. byte in memory). While this scheme is inelegant, it will get the job done. The next chapter on Macros and the Compile-Time Language will discuss a better way to initialize `tbyte` and `qword` data.

Because the FPU converts packed decimal values to the internal floating point format, you can mix packed decimal, floating point, and (binary) integer formats in the same calculation. The following program demonstrates how you might achieve this:

7. An example of such an algorithm might be a multiplication by ten by shifting the number one digit to the left. However, such operations are not possible within the FPU itself, so algorithms that misbehave inside the FPU are actually quite rare.

```

program MixedArithmetic;
#include("stdlib.hhf")

static
 tb: tbyte; nostorage;
 byte $21,$43,$65,0,0,0,0,0,0,0;

begin MixedArithmetic;

 fbld(tb);
 fmul(2.0);
 fiadd(1);
 fbstp(tb);
 stdout.put("bcd value is ");
 stdout.puttb(tb);
 stdout.newln();

end MixedArithmetic;

```

---

#### Program 4.7 Mixed Mode FPU Arithmetic

---

The FPU treats packed decimal values as integer values. Therefore, if your calculations produce fractional results, the FBSTP instruction will round the result according to the current FPU rounding mode. If you need to work with fractional values, you need to stick with floating point results.

---

## 4.5 Sample Program

The sample program for this chapter demonstrates BCD I/O. The following program provides two procedures, BCDin and BCDout. These two procedures read an 18-digit BCD value from the user (with possible leading minus sign) and write a BCD value to the standard output device.

---

```

program bcdIO;
#include("stdlib.hhf")

// The following is equivalent to TBYTE except it
// lets us easily gain access to the individual
// components of a BCD value.

type
 bcd: record
 LO8: dword;
 MID8: dword;
 HO2: byte;
 Sign: byte;
 endrecord;

// BCDin-
//

```

```

// This function reads a BCD value from the standard input
// device. The number can be up to 18 decimal digits long
// and may contain a leading minus sign.
//
// This procedure stores the BCD value in the variable passed
// by reference as a parameter to this routine.

procedure BCDin(var input:tbyte); nodisplay;
var
 bcdVal: bcd;
 delimiters: cset;

begin BCDin;

 push(eax);
 push(ebx);

 // Get a copy of the input delimiter characters and
 // make sure that #0 is a member of this set.

 conv.getDelimiters(delimiters);
 cs.unionChar(#0, delimiters);

 // Skip over any leading delimiter characters in the text:

 while(stdin.peekc() in delimiters) do

 // If we're at the end of an input line, read a new
 // line of text from the user, otherwise remove the
 // delimiter character from the input stream.

 if(stdin.peekc() = #0) then

 stdin.ReadLn(); // Get a new line of input text.

 else

 stdin.getc(); // Remove the delimiter.

 endif;

 endwhile;

 // Initialize our input accumulator to zero:

 xor(eax, eax);
 mov(eax, bcdVal.LO8);
 mov(eax, bcdVal.MID8);
 mov(al, bcdVal.HO2);
 mov(al, bcdVal.Sign);

 // If the first character is a minus sign, then eat it and
 // set the sign bit to one.

 if(stdin.peekc() = '-') then

 stdin.getc(); // Eat the sign character.
 mov($80, bcdVal.Sign); // Make this number negative.

```

```

endif;

// We must have at least one decimal digit in this number:
if(stdin.peekc() not in '0'..'9') then
 raise(ex.ConversionError);
endif;

// Okay, read in up to 18 decimal digits:
while(stdin.peekc() in '0'..'9') do
 stdin.getc(); // Read this decimal digit.
 shl(4, al); // Move digit to H.O. bits of AL

 mov(4, ebx);
 repeat
 // Cheesy way to SHL bcdVal by four bits and
 // merge in the new character.

 shl(1, al);
 rcl(1, bcdVal.LO8);
 rcl(1, bcdVal.MID8);
 rcl(1, bcdVal.HO2);

 // If the user has entered more than 18
 // decimal digits, the carry will be set
 // after the RCL above. Test that here.

 if(@c) then
 raise(ex.ValueOutOfRange);
 endif;
 dec(ebx);
 until(@z);
endwhile;

// Be sure that the number ends with a proper delimiter:
if(stdin.peekc() not in delimiters) then
 raise(ex.ConversionError);
endif;

// Okay, store the ten-byte input result into
// the location specified by the parameter.

mov(input, ebx);
mov(bcdVal.LO8, eax);
mov(eax, [ebx]);
mov(bcdVal.MID8, eax);
mov(eax, [ebx+4]);

```

```

mov((type word bcdVal.H02), ax); // Grabs "Sign" too.
mov(ax, [ebx+8]);

pop(ebx);
pop(eax);

end BCDin;

// BCDout-
//
// The converse of the above. Prints the string representation
// of the packed BCD value to the standard output device.

procedure BCDout(output:tbyte); nodisplay;
var
 q:qword;

begin BCDout;

 // This code cheats *big time*.
 // It converts the BCD value to a 64-bit integer
 // and then calls the stdout.puti64 routine to
 // actually print the number. In theory, this is
 // a whole lot slower than converting the BCD value
 // to ASCII and printing the ASCII chars, however,
 // I/O is so much slower than the conversion that
 // no one will notice the extra time.

 fbld(output);
 fistp(q);
 stdout.puti64(q);

end BCDout;

static
 tb1: tbyte;
 tb2: tbyte;
 tbRslt: tbyte;

begin bcdIO;

 stdout.put("Enter a BCD value: ");
 BCDin(tb1);
 stdout.put("Enter a second BCD value: ");
 BCDin(tb2);

 fbld(tb1);
 fbld(tb2);
 fadd();
 fbstp(tbRslt);

 stdout.put("The sum of ");
 BCDout(tb1);
 stdout.put(" + ");
 BCDout(tb2);

```

```
 stdout.put(" is ");
 BCDout(tbRslt);
 stdout.newln();

end bcdIO;
```

---

**Program 4.8** BCD I/O Sample Program

---

---

## 4.6 Putting It All Together

Extended precision arithmetic is one of those activities where assembly language truly shines. It's much easier to perform extended precision arithmetic in assembly language than in most high level languages; it's far more efficient to do it in assembly language, as well. Extended precision arithmetic was, perhaps, the most important subject that this chapter teaches.

Although extended precision arithmetic and logical calculations are important, what good are extended precision calculations if you can't get the extend precision values in and out of the machine? Therefore, this chapter devotes a good chunk of its space to describing how to write your own extended precision I/O routines. Between the calculations and the I/O this chapter describes, you're set to perform those really hairy calculations you've always dreamed of!

Although decimal arithmetic is nowhere near as prominent as it once was, the need for decimal arithmetic does arise on occasion. Therefore, this chapter spends some time discussing BCD arithmetic on the 80x86.

---

# Bit Manipulation

# Chapter Five

---

## 5.1 Chapter Overview

Manipulating bits in memory is, perhaps, the thing that assembly language is most famous for. Indeed, one of the reasons people claim that the “C” programming language is a “medium-level” language rather than a high level language is because of the vast array of bit manipulation operators that it provides. Even with this wide array of bit manipulation operations, the C programming language doesn’t provide as complete a set of bit manipulation operations as assembly language.

This chapter will discuss how to manipulate strings of bits in memory and registers using 80x86 assembly language. This chapter begins with a review of the bit manipulation instructions covered thus far in this text and it also introduces a few new instructions. This chapter reviews information on packing and unpacking bit strings in memory since this is the basis for many bit manipulation operations. Finally, this chapter discusses several bit-centric algorithms and their implementation in assembly language.

---

## 5.2 What is Bit Data, Anyway?

Before describing how to manipulate bits, it might not be a bad idea to define exactly what this text means by “bit data.” Most readers probably assume that “bit manipulation programs” twiddle individual bits in memory. While programs that do this are definitely “bit manipulation programs,” we’re not going to limit this title to just those programs. For our purposes, bit manipulation refers to working with data types that consist of strings of bits that are non-contiguous or are not an even multiple of eight bits long. Generally, such bit objects will not represent numeric integers, although we will not place this restriction on our bit strings.

A *bit string* is some contiguous sequence of one or more bits (this term even applies if the bit string’s length is an even multiple of eight bits). Note that a bit string does not have to start or end at any special point. For example, a bit string could start in bit seven of one byte in memory and continue through to bit six of the next byte in memory. Likewise, a bit string could begin in bit 30 of EAX, consume the upper two bits of EAX, and then continue from bit zero through bit 17 of EBX. In memory, the bits must be physically contiguous (i.e., the bit numbers are always increasing except when crossing a byte boundary, and at byte boundaries the byte number increases by one). In registers, if a bit string crosses a register boundary, the application defines the continuation register but the bit string always continues in bit zero of that second register.

A *bit set* is a collection of bits, not necessarily contiguous (though it may be), within some larger data structure. For example, bits 0..3, 7, 12, 24, and 31 from some double word object forms a set of bits. Usually, we will limit bit sets to some reasonably sized *container object* (that is, the data structure that encapsulates the bit set), but the definition doesn’t specifically limit the size. Normally, we will deal with bit sets that are part of an object no more than about 32 or 64 bits in size. Note that bit strings are special cases of bit sets.

A *bit run* is a sequence of bits with all the same value. A *run of zeros* is a bit string containing all zeros, a *run of ones* is a bit string containing all ones. The *first set bit* in a bit string is the bit position of the first set bit in a bit string, i.e., the first set bit following a run of zeros (assuming of course, that such a bit even exists). A similar definition exists for the *first clear bit*. The *last set bit* is the last bit position in a bit string containing a one; afterwards, the remainder of the string forms an uninterrupted run of zeros. A similar definition exists for the *last clear bit*.

A *bit offset* is the number of bits from some boundary position (usually a byte boundary) to the specified bit. As noted in Volume One, we’ll number the bits starting from zero at the boundary location. If the offset is less than 32, then the bit offset is the same as the bit number in a byte, word, or double word value.

A *mask* is a sequence of bits that we’ll use to manipulate certain bits in another value. For example, the bit string %0000\_1111\_0000, when used with the AND instruction, can mask away (clear) all the bits except

bits four through seven. Likewise, if you use this same value with the OR instruction, it can force bits four through seven to ones in the destination operand. The term “mask” comes from the use of these bit strings with the AND instruction; in those situations the one and zero bits behave like masking tape when you’re painting something; they pass through certain bits unchanged while masking out the other bits.

Armed with these definitions, we’re ready to start manipulating some bits!

### 5.3 Instructions That Manipulate Bits

Bit manipulation generally consists of six activities: setting bits, clearing bits, inverting bits, testing and comparing bits, extracting bits from a bit string, and inserting bits into a bit string. By now you should be familiar with most of the instructions we’ll use to perform these operations; their introduction started way back in the earliest chapters of Volume One. Nevertheless, it’s worthwhile to review the old instructions here as well as present the few bit manipulation instructions we’ve yet to consider.

The most basic bit manipulation instructions are the AND, OR, XOR, NOT, TEST, and shift and rotate instructions. Indeed, on the earliest 80x86 processors, these were the only instructions available for bit manipulation. The following paragraphs review these instructions, concentrating on how you could use them to manipulate bits in memory or registers.

The AND instruction provides the ability to strip away unwanted bits from some bit sequence, replacing the unwanted bits with zeros. This instruction is especially useful for isolating a bit string or a bit set that is merged with other, unrelated data (or, at least, data that is not part of the bit string or bit set). For example, suppose that a bit string consumes bit positions 12 through 24 of the EAX register, we can isolate this bit string by setting all other bits in EAX to zero by using the following instruction:

```
and(%1_1111_1111_1111_0000_0000_0000, eax);
```

Most programs use the AND instruction to clear bits that are not part of the desired bit string. In theory, you could use the OR instruction to mask all unwanted bits to ones rather than zeros, but later comparisons and operations are often easier if the unneeded bit positions contain zero.

**Figure 5.1** Isolating a Bit String Using the AND Instruction

Once you’ve cleared the unneeded bits in a set of bits, you can often operate on the bit set in place. For example, to see if the string of bits in positions 12 through 24 of EAX contain \$12F3 you could use the following code:

```
and(%1_1111_1111_1111_0000_0000_0000, eax);
cmp(eax, %1_0010_1111_0011_0000_0000_0000);
```

Notice the use of the compile-time not operator (“!”) to invert the bit mask in order to clear the bit positions in EBX where the code inserts the bits from EAX. This saves having to create another constant in the program that has to be changed anytime you modify the *BitMask* constant. Having to maintain two separate symbols whose values are dependent on one another is not a good thing in a program.

Of course, in addition to merging one bit set with another, the OR instruction is also useful for forcing bits to one in a bit string. By setting various bits in a source operand to one you can force the corresponding bits in the destination operand to one by using the OR instruction.

The XOR instruction, as you may recall, gives you the ability to invert selected bits belonging to a bit set. Although the need to invert bits isn’t as common as the need to set or clear them, the XOR instruction still sees considerable use in bit manipulation programs. Of course, if you want to invert all the bits in some destination operand, the NOT instruction is probably more appropriate than the XOR instruction; however, to invert selected bits while not affecting others, the XOR is the way to go.

One interesting fact about XOR’s operation is that it lets you manipulate known data in just about any way imaginable. For example, if you know that a field contains %1010 you can force that field to zero by XORing it with %1010. Similarly, you can force it to %1111 by XORing it with %0101. Although this might seem like a waste, since you can easily force this four-bit string to zero or all ones using AND or OR, the XOR instruction has two advantages: (1) you are not limited to forcing the field to all zeros or all ones; you can actually set these bits to any of the 16 valid combination via XOR; (2) if you need to manipulate other bits in the destination operand at the same time, AND/OR may not be able to accommodate you. For example, suppose that you know that one field contains %1010 that you want to force to zero and another field contains %1000 and you wish to increment that field by one (i.e., set the field to %1001). You cannot accomplish both operations with a single AND or OR instruction, but you can do this with a single XOR instruction; just XOR the first field with %1010 and the second field with %0001. Remember, however, that this trick only works if you know the current value of a bit set within the destination operand. Of course, while you’re adjusting the values of bit fields containing known values, you can invert bits in other fields simultaneously.

In addition to setting, clearing, and inverting bits in some destination operand, the AND, OR, and XOR instructions also affect various condition codes in the FLAGS register. These instructions affect the flags as follows:

- These instructions always clear the carry and overflow flags.
- These instructions set the sign flag if the result has a one in the H.O. bit; they clear it otherwise. I.e., these instructions copy the H.O. bit of the result into the sign flag.
- These instructions set/clear the zero flag depending on whether the result is zero.
- These instructions set the parity flag if there are an even number of set bits in the L.O. byte of the destination operand, they clear the parity flag if there are an odd number of one bits in the L.O. byte of the destination operand.

The first thing to note is that these instructions always clear the carry and overflow flags. This means that you cannot expect the system to preserve the state of these two flags across the execution of these instructions. A very common mistake in many assembly language programs is the assumption that these instructions do not affect the carry flag. Many people will execute an instruction that sets/clears the carry flag, execute an AND/OR/XOR instruction, and then attempt to test the state of the carry from the previous instruction. This simply will not work.

One of the more interesting aspects to these instructions is that they copy the H.O. bit of their result into the sign flag. This means that you can easily test the setting of the H.O. bit of the result by testing the sign flag (using SETS/SETNS, JS/JNS, or by using the @S/@NS flags in a boolean expression). For this reason, many assembly language programmers will often place an important boolean variable in the H.O. bit of some operand so they can easily test the state of that bit using the sign flag after a logical operation.

We haven’t talked much about the parity flag in this text. Indeed, earlier volumes have done little more than acknowledge its existence. We’re not going to get into a big discussion of this flag and what you use it for since the primary purpose for this flag has been taken over by hardware<sup>1</sup>. However, since this is a chap-

---

1. Serial communications chips and other communication hardware that uses parity for error checking normally computes the parity in hardware, you don’t have to use software for this purpose.

ter on bit manipulation and parity computation is a bit manipulation operation, it seems only fitting to provide a brief discussion of the parity flag at this time.

Parity is a very simple error detection scheme originally employed by telegraphs and other serial communication schemes. The idea was to count the number of set bits in a character and include an extra bit in the transmission to indicate whether that character contained an even or odd number of set bits. The receiving end of the transmission would also count the bits and verify that the extra “parity” bit indicated a successful transmission. We’re not going to explore the information theory aspects of this error checking scheme at this point other than to point out that the purpose of the parity flag is to help compute the value of this extra bit.

The 80x86 AND, OR, and XOR instructions set the parity bit if the L.O. byte of their operand contains an even number of set bits. An important fact bears repeating here: the parity flag only reflects the number of set bits in the L.O. byte of the destination operand; it does not include the H.O. bytes in a word, double word, or other sized operand. The instruction set only uses the L.O. byte to compute the parity because communication programs that use parity are typically character-oriented transmission systems (there are better error checking schemes if you transmit more than eight bits at a time).

Although the need to know whether the L.O. (or only) byte of some computation has an even or odd number of set bits isn’t common in modern programs, it does come in useful once in a great while. Since this is, intrinsically, a bit operation, it’s worthwhile to mention the use of this flag and how the AND/OR/XOR instructions affect this flag.

The zero flag setting is one of the more important results the AND/OR/XOR instructions produce. Indeed, programs reference this flag so often after the AND instruction that Intel added a separate instruction, TEST, whose main purpose was to logically AND two results and set the flags without otherwise affecting either instruction operand.

There are three main uses of the zero flag after the execution of an AND or TEST instruction: (1) checking to see if a particular bit in an operand is set; (2) checking to see if at least one of several bits in a bit set is one; and (3) checking to see if an operand is zero. Use (1) is actually a special case of (2) where the bit set contains only a single bit. We’ll explore each of these uses in the following paragraphs.

A common use for the AND instruction, and also the original reason for the inclusion of the TEST instruction in the 80x86 instruction set, is to test to see if a particular bit is set in a given operand. To perform this type of test, you would normally AND/TEST a constant value containing a single set bit with the operand you wish to test. These clears all the other bits in the second operand leaving a zero in the bit position under test (the bit position with the single set bit in the constant operand) if the operand contains a zero in that position and leaving a one if the operand contains a one in that position. Since all of the other bits in the result are zero, the entire result will be zero if that particular bit is zero, the entire result will be non-zero if that bit position contains a one. The 80x86 reflects this status in the zero flag (Z=1 indicates a zero bit, Z=0 indicates a one bit). The following instruction sequence demonstrates how to test to see if bit four is set in EAX:

```
test(%1_000, eax); // Check bit #4 to see if it is 0/1
if(@nz) then

 << Do this if the bit is set >>

else

 << Do this if the bit is clear >>

endif;
```

You can also use the AND/TEST instructions to see if any one of several bits is set. Simply supply a constant that has one bits in all the positions you want to test (and zeros everywhere else). AND such a value with an unknown quantity will produce a non-zero value if one or more of the bits in the operand under test contain a one. The following example tests to see if the value in EAX contains a one in bit positions one, two, four, and seven:

```
test(%1001_0010, eax);
if(@nz) then // at least one of the bits is set.
```

```

 << do whatever needs to be done if one of the bits is set >>

endif;

```

Note that you cannot use a single AND or TEST instruction to see if all the corresponding bits in the bit set are equal to one. To accomplish this, you must first mask out the bits that are not in the set and then compare the result against the mask itself. If the result is equal to the mask, then all the bits in the bit set contain ones. You must use the AND instruction for this operation as the TEST instruction does not mask out any bits. The following example checks to see if all the bits corresponding to a value this code calls *bitMask* are equal to one:

```

and(bitMask, eax);
cmp(eax, bitMask);
if(@e) then

 << All the bit positions in EAX corresponding to the set >>
 << bits in bitMask are equal to one if we get here. >>

endif;

```

Of course, once we stick the CMP instruction in there, we don't really have to check to see if all the bits in the bit set contain ones. We can check for any combination of values by specifying the appropriate value as the operand to the CMP instruction.

Note that the TEST/AND instructions will only set the zero flag in the above code sequences if all the bits in EAX (or other destination operand) have zeros in the positions where ones appear in the constant operand. This suggests another way to check for all ones in the bit set: invert the value in EAX prior to using the AND or TEST instruction. Then if the zero flag is set, you know that there were all ones in the (original) bit set, e.g.,

```

not(eax);
test(bitMask, eax);
if(@z) then

 << At this point, EAX contained all ones in the bit positions >>
 << occupied by ones in the bitMask constant. >>

endif;

```

The paragraphs above all suggest that the *bitMask* (i.e., source operand) is a constant. This was for purposes of example only. In fact, you can use a variable or other register here, if you prefer. Simply load that variable or register with the appropriate bit mask before you execute the TEST, AND, or CMP instructions in the examples above.

Another set of instructions we've already seen that we can use to manipulate bits are the bit test instructions. These instructions include BT (bit test), BTS (bit test and set), BTC (bit test and complement), and BTR (bit test and reset). We've used these instructions to manipulate bits in HLA character set variables, we can also use them to manipulate bits in general. The BTx instructions allow the following syntactical forms:

```

btx(BitNumber, BitsToTest);

btx(reg16, reg16);
btx(reg32, reg32);
btx(constant, reg16);
btx(constant, reg32);

btx(reg16, mem16);
btx(reg32, mem32);
btx(constant, mem16);
btx(constant, mem32);

```

The BT instruction's first operand is a bit number that specifies which bit to check in the second operand. If the second operand is a register, then the first operand must contain a value between zero and the size of the register (in bits) minus one; since the 80x86's largest registers are 32 bits, this value have the maximum value 31 (for 32-bit registers). If the second operand is a memory location, then the bit count is not limited to values in the range 0..31. If the first operand is a constant, it can be any eight-bit value in the range 0..255. If the first operand is a register, it has no limitation.

The BT instruction copies the specified bit from the second operand into the carry flag. For example, the "bt( 8, eax );" instruction copies bit number eight of the EAX register into the carry flag. You can test the carry flag after this instruction to determine whether bit eight was set or clear in EAX.

In general, the BT instruction is, perhaps, not the best instruction for testing individual bits in a register. The TEST (or AND) instruction is a bit more efficient. These latter two instructions are Intel "RISC Core" instructions while the BT instruction is a "Complex" instruction. Therefore, you will often get better performance using TEST or AND rather than BT. If you want to test bits in memory operands (especially in bit arrays), then the BT instruction is probably a reasonable way to go.

The BTS, BTC, and BTR instructions manipulate the bit they test while they are testing it. These instructions are rather slow and you should avoid them if performance is your primary concern. In a later volume when we discuss semaphores you will see the true purpose for these instructions. Until then, if performance (versus convenience) is an issue, you should always try two different algorithms, one that uses these instructions, one that uses AND/OR instructions, and measure the performance difference; then choose the best of the two different approaches.

The shift and rotate instructions are another group of instructions you can use to manipulate and test bits. Of course, all of these instructions move the H.O. (left shift/rotate) or L.O. (right shift/rotate) bits into the carry flag. Therefore, you can test the carry flag after you execute one of these instructions to determine the original setting of the operand's H.O. or L.O. bit (depending on the direction). Of course, the shift and rotate instructions are invaluable for aligning bit strings, packing, and unpacking data. Volume One has several examples of this and, of course, some earlier examples in the section also use the shift instructions for this purpose.

---

## 5.4 The Carry Flag as a Bit Accumulator

The BTx, shift, and rotate instructions all set or clear the carry flag depending on the operation and/or selected bit. Since these instructions place their "bit result" in the carry flag, it is often convenient to think of the carry flag as a one-bit register or accumulator for bit operations. In this section we will explore some of the operations possible with this bit result in the carry flag.

Instructions that will be useful for manipulating bit results in the carry flag are those that use the carry flag as some sort of input value. The following is a sampling of such instructions:

- ADC, SBB
- RCL, RCR
- CMC (we'll throw in CLC and STC even though they don't use the carry as input)
- JC, JNC
- SETC, SETNC

The ADC and SBB instructions add or subtract their operands along with the carry flag. So if you've computed some bit result into the carry flag, you can figure that result into an addition or subtraction using these instructions. This isn't a common operation, but it is available if it's useful to you.

To merge a bit result in the carry flag, you most often use the rotate through carry instructions (RCL and RCR). These instructions, of course, move the carry flag into the L.O. or H.O. bits of their destination operand. These instructions are very useful for packing a set of bit results into a byte, word, or double word value.

The CMC (complement carry) instruction lets you easily invert the result of some bit operation. You can also use the CLC and STC instructions to initialize the carry flag prior to some string of bit operations involving the carry flag.

Of course, instructions that test the carry flag are going to be very popular after a calculation that leaves a bit result in the carry flag. The JC, JNC, SETC, and SETNC instructions are quite useful here. You can also use the HLA @C and @NC operands in a boolean expression to test the result in the carry flag.

If you have a sequence of bit calculations and you would like to test to see if the calculations produce a specific sequence of one-bit results, the easiest way to do this is to clear a register or memory location and use the RCL or RCR instructions to shift each result into that location. Once the bit operations are complete, then you can compare the register or memory location against a constant value to see if you've obtained a particular result. If you want to test a sequence of results involving conjunction and disjunction (i.e., strings of results involving ANDs and ORs) then you could use the SETC and SETNC instruction to set a register to zero or one and then use the AND/OR instructions to merge the results.

## 5.5 Packing and Unpacking Bit Strings

A common bit operation is inserting a bit string into an operand or extracting a bit string from an operand. Previous chapters in this text have provided simple examples of packing and unpacking such data, now it is time to formally describe how to do this.

For the purposes of the current discussion, we will assume that we're dealing with bit strings; that is, a contiguous sequence of bits. A little later in this chapter we'll take a look at how to extract and insert bit sets in an operand. Another simplification we'll make is that the bit string completely fits within a byte, word, or double word operand. Large bit strings that cross object boundaries require additional processing; a discussion of bit strings that cross double word boundaries appears later in this section.

A bit string has two attributes that we must consider when packing and unpacking that bit string in a larger operand: a starting bit position and a length. The starting bit position is the bit number of the L.O. bit of the bit string in the larger operand. The length, of course, is the number of bits in the operand. To insert (pack) data into a destination operand we will assume that we start with a bit string of the appropriate length that is right-justified (i.e., starts in bit position zero) in an operand and is zero extended to eight, sixteen, or thirty-two bits. The task is to insert this data at the appropriate starting position in some other operand that is eight, sixteen, or thirty-bits wide. There is no guarantee that the destination bit positions contain any particular value.

The first two steps (which can occur in any order) is to clear out the corresponding bits in the destination operand and shift (a copy of) the bit string so that the L.O. bit begins at the appropriate bit position. After completing these two steps, the third step is to OR the shifted result with the destination operand. This inserts the bit string into the destination operand.

| 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | Y | Y | Y | Y | 0 | 0 | 0 | 0 | 0 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

Final result appears in the destination operand.

**Figure 5.3** Inserting a Bit String Into a Destination Operand

It only takes three instructions to insert a bit string of known length into a destination operand. The following three instructions demonstrate how to handle the insertion operation in Figure 5.3; These instructions assume that the source operand is in BX and the destination operand is AX:

```
shl(5, bx);
and(%111111000011111, ax);
or(bx, ax);
```

If the length and the starting position aren't known when you're writing the program (that is, you have to calculate them at run time), then bit string insertion is a little more difficult. However, with the use of a lookup table it's still an easy operation to accomplish. Let's assume that we have two eight-bit values: a starting bit position for the field we're inserting and a non-zero eight-bit length value. Also assume that the source operand is in EBX and the destination operand is EAX. The code to insert one operand into another could take the following form:

readonly

```
// The index into the following table specifies the length of the bit string
// at each position:
```

```
MaskByLen: dword[32] :=
```

```

[
 0, $1, $3, $7, $f, $1f, $3f, $7f,
 $ff, $1ff, $3fff, $7fff, $fff, $1fff, $3fff, $7fff, $ffff,
 $1_ffff, $3_ffff, $7_ffff, $f_ffff,
 $1f_ffff, $3f_ffff, $7f_ffff, $ff_ffff,
 $1ff_ffff, $3ff_ffff, $7ff_ffff, $fff_ffff,
 $1fff_ffff, $3fff_ffff, $7fff_ffff, $ffff_ffff
];
.
.
.
movzx(Length, edx);
mov(MaskByLen[edx*4], edx);
mov(StartingPosition, cl);
shl(cl, edx);
not(edx);
shl(cl, ebx);
and(edx, eax);
or(ebx, eax);

```

Each entry in the *MaskByLen* table contains the number of one bits specified by the index into the table. Using the *Length* value as an index into this table fetches a value that has as many one bits as the *Length* value. The code above fetches an appropriate mask, shifts it to the left so that the L.O. bit of this run of ones matches the starting position of the field into which we want to insert the data, then it inverts the mask and uses the inverted value to clear the appropriate bits in the destination operand.

To extract a bit string from a larger operand is just as easy as inserting a bit string into some larger operand. All you've got to do is mask out the unwanted bits and then shift the result until the L.O. bit of the bit string is in bit zero of the destination operand. For example, to extract the four-bit field starting at bit position five in EBX and leave the result in EAX, you could use the following code:

```

mov(ebx, eax); // Copy data to destination.
and(%1_1110_0000, ebx); // Strip unwanted bits.
shr(5, eax); // Right justify to bit position zero.

```

If you do not know the bit string's length and starting position when you're writing the program, you can still extract the desired bit string. The code is very similar to insertion (though a tiny bit simpler). Assuming you have the *Length* and *StartingPosition* values we used when inserting a bit string, you can extract the corresponding bit string using the following code (assuming source=EBX and dest=EAX):

```

movzx(Length, edx);
mov(MaskByLen[edx*4], edx);
mov(StartingPosition, cl);
mov(ebx, eax);
shr(cl, eax);
and(edx, eax);

```

The examples up to this point all assume that the bit string appears completely within a double word (or smaller) object. This will always be the case if the bit string is less than or equal to 24 bits in length. However, if the length of the bit string plus its starting position (mod eight) within an object is greater than 32, then the bit string will cross a double word boundary within the object. To extract such bit strings requires up to three operations: one operation to extract the start of the bit string (up to the first double word boundary), an operation that copies whole double words (assuming the bit string is so long that it consumes several double words), and a final operation that copies left-over bits in the last double word at the end of the bit string. The actual implementation of this operation is left as an exercise at the end of this volume.

## 5.6 Coalescing Bit Sets and Distributing Bit Strings

Inserting and extract bit sets is little different than inserting and extract bit strings if the “shape” of the bit set you’re inserting (or resulting bit set you’re extracting) is the same as the bit set in the main object. The “shape” of a bit set is the distribution of the bits in the set, ignoring the starting bit position of the set. So a bit set that includes bits zero, four, five, six, and seven has the same shape as a bit set that includes bits 12, 16, 17, 18, and 19 since the distribution of the bits is the same. The code to insert or extract this bit set is nearly identical to that of the previous section; the only difference is the mask value you use. For example, to insert this bit set starting at bit number zero in EAX into the corresponding bit set starting at position 12 in EBX, you could use the following code:

```
and(%1111_0001_0000_0000_0000, ebx); // Mask out destination bits.
shl(12, eax); // Move source bits into posn.
or(eax, ebx); // Merge the bit set into EBX.
```

However, suppose you have five bits in bit positions zero through four in EAX and you want to merge them into bits 12, 16, 17, 18, and 19 in EBX. Somehow you’ve got to distribute the bits in EAX prior to logically ORing the values into EBX. Given the fact that this particular bit set has only two runs of one bits, the process is somewhat simplified, the following code achieves this in a somewhat sneaky fashion:

```
and(%1111_0001_0000_0000_0000, ebx);
shl(3, eax); // Spread out the bits: 1-4 goes to 4-7 and 0 to 3.
btr(3, eax); // Bit 3->carry and then clear bit 3
rcl(12, eax); // Shift in carry and put bits into final position
or(eax, ebx); // Merge the bit set into EBX.
```

This trick with the BTR (bit test and reset) instruction worked well because we only had one bit out of place in the original source operand. Alas, had the bits all been in the wrong location relative to one another, this scheme might not have worked quite as well. We’ll see a more general solution in just a moment.

Extracting this bit set and collecting (“coalescing”) the bits into a bit string is not quite as easy. However, there are still some sneaky tricks we can pull. Consider the following code that extracts the bit set from EBX and places the result into bits 0..4 of EAX:

```
mov(ebx, eax);
and(%1111_0001_0000_0000_0000, eax); // Strip unwanted bits.
shr(5, eax); // Put bit 12 into bit 7, etc.
shr(3, ah); // Move bits 11..14 to 8..11.
shr(7, eax); // Move down to bit zero.
```

This code moves (original) bit 12 into bit position seven, the H.O. bit of AL. At the same time it moves bits 16..19 down to bits 11..14 (bits 3..6 of AH). Then the code shifts the bits 3..6 in AH down to bit zero. This positions the H.O. bits of the bit set so that they are adjacent to the bit left in AL. Finally, the code shifts all the bits down to bit zero. Again, this is not a general solution, but it shows a clever way to attack this problem if you think about it carefully.

The problem with the coalescing and distribution algorithms above is that they are not general. They apply only to their specific bit sets. In general, specific solutions are going to provide the most efficient solution. A generalized solution (perhaps that lets you specify a mask and the code distributes or coalesces the bits accordingly) is going to be a bit more difficult. The following code demonstrates how to distribute the bits in a bit string according to the values in a bit mask:

```
// EAX- Originally contains some value into which we insert bits from EBX.
// EBX- L.O. bits contain the values to insert into EAX.
// EDX- bitmap with ones indicating the bit positions in EAX to insert.
// CL- Scratchpad register.

mov(32, cl); // Count # of bits we rotate.
jmp DistLoop;

CopyToEAX: rcr(1, ebx); // Don't use SHR here, must preserve Z-flag.
```

```

 rcr(1, eax);
 jz Done;
DistLoop: dec(cl);
 shr(1, edx);
 jc CopyToEAX;
 ror(1, eax); // Keep current bit in EAX.
 jnz DistLoop;

Done: ror(cl, eax); // Reposition remaining bits.

```

In the code above, if we load EDX with `%1100_1001` then this code will copy bits 0..3 to bits 0, 3, 6, and 7 in EAX. Notice the short circuit test that checks to see if we've exhausted the values in EDX (by checking for a zero in EDX). Note that the rotate instructions do not affect the zero flag while the shift instructions do. Hence the SHR instruction above will set the zero flag when there are no more bits to distribute (i.e., when EDX becomes zero).

The general algorithm for coalescing bits is a tad more efficient than distribution. Here's the code that will extract bits from EBX via the bit mask in EDX and leave the result in EAX:

```

// EAX- Destination register.
// EBX- Source register.
// EDX- Bitmap with ones representing bits to copy to EAX.
// EBX and EDX are not preserved.

 sub(eax, eax); // Clear destination register.
 jmp ShiftLoop;

ShiftInEAX: rcl(1, ebx); // Up here we need to copy a bit from
 rcl(1, eax); // EBX to EAX.
ShiftLoop: shl(1, edx); // Check mask to see if we need to copy a bit.
 jc ShiftInEAX; // If carry set, go copy the bit.
 rcl(1, ebx); // Current bit is uninteresting, skip it.
 jnz ShiftLoop; // Repeat as long as there are bits in EDX.

```

This sequence takes advantage of one sneaky trait of the shift and rotate instructions: the shift instructions affect the zero flag while the rotate instructions do not. Therefore, the `"shl( 1, edx);"` instruction sets the zero flag when EDX becomes zero (after the shift). If the carry flag was also set, the code will make one additional pass through the loop in order to shift a bit into EAX, but the next time the code shifts EDX one bit to the left, EDX is still zero and so the carry will be clear. On this iteration, the code falls out of the loop.

Another way to coalesce bits is via table lookup. By grabbing a byte of data at a time (so your tables don't get too large) you can use that byte's value as an index into a lookup table that coalesces all the bits down to bit zero. Finally, you can merge the bits at the low end of each byte together. This might produce a more efficient coalescing algorithm in certain cases. The implementation is left to the reader...

---

## 5.7 Packed Arrays of Bit Strings

Although it is far more efficient to create arrays whose elements' have an integral number of bytes, it is quite possible to create arrays of elements whose size is not a multiple of eight bits. The drawback is that calculating the "address" of an array element and manipulating that array element involves a lot of extra work. In this section we'll take a look at a few examples of packing and unpacking array elements in an array whose elements are an arbitrary number of bits long.

Before proceeding, it's probably worthwhile to discuss why you would want to bother with arrays of bit objects. The answer is simple: space. If an object only consumes three bits, you can get 2.67 times as many elements into the same space if you pack the data rather than allocating a whole byte for each object. For

very large arrays, this can be a substantial savings. Of course, the cost of this space savings is speed: you've got to execute extra instructions to pack and unpack the data, thus slowing down access to the data.

The calculation for locating the bit offset of an array element in a large block of bits is almost identical to the standard array access; it is

$$\text{Element\_Address\_in\_bits} = \text{Base\_address\_in\_bits} + \text{index} * \text{element\_size\_in\_bits}$$

Once you calculate the element's address in bits, you need to convert it to a byte address (since we have to use byte addresses when accessing memory) and extract the specified element. Because the base address of an array element (almost) always starts on a byte boundary, we can use the following equations to simplify this task:

$$\begin{aligned} \text{Byte\_of\_1st\_bit} &= \text{Base\_Address} + (\text{index} * \text{element\_size\_in\_bits}) / 8 \\ \text{Offset\_to\_1st\_bit} &= (\text{index} * \text{element\_size\_in\_bits}) \% 8 \quad (\text{note } \% = \text{MOD}) \end{aligned}$$

For example, suppose we have an array of 200 three-bit objects that we declare as follows:

```
static
AO3Bobjects: byte[(200*3)/8 + 1]; // "+1" handles truncation.
```

The constant expression in the dimension above reserves space for enough bytes to hold 600 bits (200 elements, each three bits long). As the comment notes, the expression adds an extra byte at the end to ensure we don't lose any odd bits (that won't happen in this example since 600 is evenly divisible by 8, but in general you can't count on this; one extra byte usually won't hurt things).

Now suppose you want to access the  $i^{\text{th}}$  three-bit element of this array. You can extract these bits by using the following code:

```
// Extract the ith group of three bits in AO3Bobjects and leave this value
// in EAX.

 sub(ecx, ecx); // Put of i/8 remainder here.
 mov(i, eax); // Get the index into the array.
 shr(3, eax, ecx); // EAX/8 -> EAX and EAX mod 8 -> ECX (H.O. bits)
 rol(3, ecx); // Put remainder into L.O. three bits of ECX.

 // Okay, fetch the word containing the three bits we want to extract.
 // We have to fetch a word because the last bit or two could wind up
 // crossing the byte boundary (i.e., bit offset six and seven in the
 // byte).

 mov(AO3Bobjects[eax], eax);
 shr(cl, eax); // Move bits down to bit zero.
 and(%111, eax); // Remove the other bits.
```

Inserting an element into the array is a bit more difficult. In addition to computing the base address and bit offset of the array element, you've also got to create a mask to clear out the bits in the destination where you're going to insert the new data. The following code inserts the L.O. three bits of EAX into the  $i^{\text{th}}$  element of the AO3Bobjects array.

```
// Insert the L.O. three bits of AX into the ith element of AO3Bobjects:
```

```
readonly
Masks: word[8] :=
 [
 !%0000_0111, !%0000_1110, !%0001_1100, !%0011_1000,
 !%0111_0000, !%1110_0000, !%1_1100_0000, !%11_1000_0000
];
 .
 .
 .
 sub(ecx, ecx); // Put remainder here.
 mov(i, ebx); // Get the index into the array.
```

```

shrd(3, ebx, ecx); // i/8 -> EBX, i % 8 -> ECX.
rol(3, ecx);

and(%111, ax); // Clear unneeded bits from AX.
mov(Masks[ecx], dx); // Mask to clear out our array element.
and(AO3Bobjects[ebx], dx); // Grab the bits and clear those
// we're inserting.
shl(cl, ax); // Put our three bits in their proper location.
or(ax, dx); // Merge bits into destination.
mov(dx, AO3Bobjects[ebx]); // Store back into memory.

```

Notice the use of a lookup table to generate the masks needed to clear out the appropriate position in the array. Each element of this array contains all ones except for three zeros in the position we need to clear for a given bit offset (note the use of the “!” operator to invert the constants in the table).

## 5.8 Searching for a Bit

A very common bit operation is to locate the end of some run of bits. A very common special case of this operation is to locate the first (or last) set or clear bit in a 16- or 32-bit value. In this section we’ll explore ways to accomplish this.

Before describing how to search for the first or last bit of a given value, perhaps it’s wise to discuss exactly what the terms “first” and “last” mean in this context. The term “first set bit” means the first bit in a value, scanning from bit zero towards the high order bit, that contains a one. A similar definition exists for the “first clear bit.” The “last set bit” is the first bit in a value, scanning from the high order bit towards bit zero, that contains a one. A similar definition exists for the last clear bit.

One obvious way to scan for the first or last bit is to use a shift instruction in a loop and count the number of iterations before you shift out a one (or zero) into the carry flag. The number of iterations specifies the position. Here’s some sample code that checks for the first set bit in EAX and returns that bit position in ECX:

```

mov(-32, ecx); // Count off the bit positions in ECX.
TstLp: shr(1, eax); // Check to see if current bit position contains
jc Done // a one; exit loop if it does.
inc(ecx); // Bump up our bit counter by one.
jnz TstLp; // Exit if we execute this loop 32 times.

Done: add(32, cl); // Adjust loop counter so it holds the bit posn.

// At this point, ECX contains the bit position of the first set bit.
// ECX contains 32 if EAX originally contained zero (no set bits).

```

The only thing tricky about this code is the fact that it runs the loop counter from -32 to zero rather than 32 down to zero. This makes it slightly easier to calculate the bit position once the loop terminates.

The drawback to this particular loop is that it’s expensive. This loop repeats as many as 32 times depending on the original value in EAX. If the values you’re checking often have lots of zeros in the L.O. bits of EAX, this code runs rather slow.

Searching for the first (or last) set bit is such a common operation that Intel added a couple of instructions on the 80386 specifically to accelerate this process. These instructions are BSF (bit scan forward) and BSR (bit scan reverse). Their syntax is as follows:

```

bsr(source, destReg);
bsf(source, destReg);

```

The source and destinations operands must be the same size and they must both be 16- or 32-bit objects. The destination operand has to be a register, the source operand can be a register or a memory location.

The BSF instruction scans for the first set bit (starting from bit position zero) in the source operand. The BSR instruction scans for the last set bit in the source operand by scanning from the H.O. bit towards the

L.O. bit. If these instructions find a bit that is set in the source operand then they clear the zero flag and put the bit position into the destination register. If the source register contains zero (i.e., there are no set bits) then these instructions set the zero flag and leave an indeterminate value in the destination register. Note that you should test the zero flag immediately after the execution of these instructions to validate the destination register's value. Examples:

```

mov(SomeValue, ebx); // Value whose bits we want to check.
bsf(ebx, eax); // Put position of first set bit in EAX.
jz NoBitsSet; // Branch if SomeValue contains zero.
mov(eax, FirstBit); // Save location of first set bit.
.
.
.

```

You use the BSR instruction in an identical fashion except that it computes the bit position of the last set bit in an operand (that is, the first set bit it finds when scanning from the H.O. bit towards the L.O. bit).

The 80x86 CPUs do not provide instructions to locate the first bit containing a zero. However, you can easily scan for a zero bit by first inverting the source operand (or a copy of the source operand if you must preserve the source operand's value). If you invert the source operand, then the first "1" bit you find corresponds to the first zero bit in the original operand value.

The BSF and BSR instructions are complex instructions (i.e., they are not a part of the 80x86 "RISC core" instruction set). Therefore, these instructions are necessarily as fast as other instructions. Indeed, in some circumstances it may be faster to locate the first set bit using discrete instructions. However, since the execution time of these instructions varies widely from CPU to CPU, you should first test the performance of these instructions prior to using them in time critical code.

Note that the BSF and BSR instructions do not affect the source operand. A common operation is to extract the first (or last) set bit you find in some operand. That is, you might want to clear the bit once you find it. If the source operand is a register (or you can easily move it into a register) then you can use the BTR (or BTC) instruction to clear the bit once you've found it. Here's some code that achieves this result:

```

bsf(eax, ecx); // Locate first set bit in EAX.
if(@nz) then // If we found a bit, clear it.

 btr(ecx, eax); // Clear the bit we just found.

endif;

```

At the end of this sequence, the zero flag indicates whether we found a bit (note that BTR does not affect the zero flag). Alternately, you could add an ELSE section to the IF statement above that handles the case when the source operand (EAX) contains zero at the beginning of this instruction sequence.

Since the BSF and BSR instructions only support 16- and 32-bit operands, you will have to compute the first bit position of an eight-bit operand a little differently. There are a couple of reasonable approaches. First, of course, you can usually zero extend an eight-bit operand to 16 or 32 bits and then use the BSF or BSR instructions on this operand. Another alternative is to create a lookup table where each entry in the table contains the number of bits in the value you use as an index into the table; then you can use the XLAT instruction to "compute" the first bit position in the value (note that you will have to handle the value zero as a special case). Another solution is to use the shift algorithm appearing at the beginning of this section; for an eight-bit operand, this is not an entirely inefficient solution.

One interesting use of the BSF and BSR instructions is to "fill in" a character set with all the values from the lowest-valued character in the set through the highest-valued character. For example, suppose a character set contains the values {'A', 'M', 'a'..'n', 'z'}; if we filled in the gaps in this character set we would have the values {'A'..'z'}. To compute this new set we can use BSF to determine the ASCII code of the first character in the set and BSR to determine the ASCII code of the last character in the set. After doing this, we can feed those two ASCII codes to the *cs.rangeChar* function to compute the new set.

You can also use the BSF and BSR instructions to determine the size of a run of bits, assuming that you have a single run of bits in your operand. Simply locate the first and last bits in the run (as above) and the

compute the difference (plus one) of the two values. Of course, this scheme is only valid if there are no intervening zeros between the first and last set bits in the value.

## 5.9 Counting Bits

The last example in the previous section demonstrates a specific case of a very general problem: counting bits. Unfortunately, that example has a severe limitation: it only counts a single run of one bits appearing in the source operand. This section discusses a more general solution to this problem.

Hardly a week goes by that someone doesn't ask how to count the number of bits in a register operand on one of the Internet news groups. This is a common request, undoubtedly, because many assembly language course instructors assign this task a project to their students as a way to teach them about the shift and rotate instructions. Undoubtedly, the solution these instructor expect is something like the following:

```
// BitCount1:
//
// Counts the bits in the EAX register, returning the count in EBX.

 mov(32, cl); // Count the 32 bits in EAX.
 sub(ebx, ebx); // Accumulate the count here.
CntLoop: shr(1, eax); // Shift next bit out of EAX and into Carry.
 adc(0, bl); // Add the carry into the EBX register.
 dec(cl); // Repeat 32 times.
 jnz CntLoop
```

The “trick” worth noting here is that this code uses the ADC instruction to add the value of the carry flag into the BL register. Since the count is going to be less than 32, the result will fit comfortably into BL. This code uses “adc( 0, bl );” rather than “adc( 0, ebx );” because the former instruction is smaller.

Tricky code or not, this instruction sequence is not particularly fast. As you can tell with just a small amount of analysis, the loop above always executes 32 times, so this code sequence executes 130 instructions (four instructions per iteration plus two extra instructions). One might ask if there is a more efficient solution, the answer is yes. The following code, taken from the AMD Athlon optimization guide, provides a faster solution (see the comments for a description of the algorithm):

```
// bitCount-
//
// Counts the number of "1" bits in a dword value.
// This function returns the dword count value in EAX.

procedure bits.cnt(BitsToCnt:dword); nodisplay;

const
 EveryOtherBit := $5555_5555;
 EveryAlternatePair := $3333_3333;
 EvenNibbles := $0f0f_0f0f;

begin cnt;

 push(edx);
 mov(BitsToCnt, eax);
 mov(eax, edx);

 // Compute sum of each pair of bits
 // in EAX. The algorithm treats
 // each pair of bits in EAX as a two
 // bit number and calculates the
 // number of bits as follows (description
 // is for bits zero and one, it generalizes
 // to each pair):
```

```

//
// EDX = BIT1 BIT0
// EAX = 0 BIT1
//
// EDX-EAX = 00 if both bits were zero.
// 01 if Bit0=1 and Bit1=0.
// 01 if Bit0=0 and Bit1=1.
// 10 if Bit0=1 and Bit1=1.
//
// Note that the result is left in EDX.

shr(1, eax);
and(EveryOtherBit, eax);
sub(eax, edx);

// Now sum up the groups of two bits to
// produces sums of four bits. This works
// as follows:
//
// EDX = bits 2,3, 6,7, 10,11, 14,15, ..., 30,31
// in bit positions 0,1, 4,5, ..., 28,29 with
// zeros in the other positions.
//
// EAX = bits 0,1, 4,5, 8,9, ... 28,29 with zeros
// in the other positions.
//
// EDX+EAX produces the sums of these pairs of bits.
// The sums consume bits 0,1,2, 4,5,6, 8,9,10, ... 28,29,30
// in EAX with the remaining bits all containing zero.

mov(edx, eax);
shr(2, edx);
and(EveryAlternatePair, eax);
and(EveryAlternatePair, edx);
add(edx, eax);

// Now compute the sums of the even and odd nibbles in the
// number. Since bits 3, 7, 11, etc. in EAX all contain
// zero from the above calculation, we don't need to AND
// anything first, just shift and add the two values.
// This computes the sum of the bits in the four bytes
// as four separate value in EAX (AL contains number of
// bits in original AL, AH contains number of bits in
// original AH, etc.)

mov(eax, edx);
shr(4, eax);
add(edx, eax);
and(EvenNibbles, eax);

// Now for the tricky part.
// We want to compute the sum of the four bytes
// and return the result in EAX. The following
// multiplication achieves this. It works
// as follows:
// (1) the $01 component leaves bits 24..31
// in bits 24..31.
//
// (2) the $100 component adds bits 17..23
// into bits 24..31.
//

```

```

// (3) the $1_0000 component adds bits 8..15
// into bits 24..31.
//
// (4) the $1000_0000 component adds bits 0..7
// into bits 24..31.
//
// Bits 0..23 are filled with garbage, but bits
// 24..31 contain the actual sum of the bits
// in EAX's original value. The SHR instruction
// moves this value into bits 0..7 and zeroes
// out the H.O. bits of EAX.

intmul($0101_0101, eax);
shr(24, eax);

pop(edx);

end cnt;

```

---

## 5.10 Reversing a Bit String

Another common programming project instructions assign, and a useful function in its own right, is a program that reverses the bits in an operand. That is, it swaps the L.O. bit with the H.O. bit, bit #1 with the next-to-H.O. bit, etc. The typical solution an instructor probably expects for this assignment is the following:

```

// Reverse the 32-bits in EAX, leaving the result in EBX:

 mov(32, cl);
RvsLoop: shr(1, eax); // Move current bit in EAX to the carry flag.
 rcl(1, ebx); // Shift the bit back into EBX, backwards.
 dec(cl);
 jnz RvsLoop

```

As with the previous examples, this code suffers from the fact that it repeats the loop 32 times for a grand total of 129 instructions. By unrolling the loop you can get it down to 64 instructions, but this is still somewhat expensive.

As usual, the best solution to an optimization problem is often a better algorithm rather than attempting to tweak your code by trying to choose faster instructions to speed up some code. However, a little intelligence goes a long way when manipulating bits. In the last section, for example, we were able to speed up counting the bits in a string by substituting a more complex algorithm for the simplistic “shift and count” algorithm. In the example above, we are once again faced with a very simple algorithm with a loop that repeats for one bit in each number. The question is: “Can we discover an algorithm that doesn’t execute 129 instructions to reverse the bits in a 32-bit register?” The answer is “yes” and the trick is to do as much work as possible in parallel.

Suppose that all we wanted to do was swap the even and odd bits in a 32-bit value. We can easily swap the even and odd bits in EAX using the following code:

```

mov(eax, edx); // Make a copy of the odd bits in the data.
shr(1, eax); // Move the even bits to the odd positions.
and($5555_5555, edx); // Isolate the odd bits by clearing even bits.
and($5555_5555, eax); // Isolate the even bits (in odd posn now).
shl(1, edx); // Move the odd bits to the even positions.
or(edx, eax); // Merge the bits and complete the swap.

```

Of course, swapping the even and odd bits, while somewhat interesting, does not solve our larger problem of reversing all the bits in the number. But it does take us part of the way there. For example, if after executing the code sequence above, we swap adjacent pairs of bits, then we've managed to swap the bits in all the nibbles in the 32-bit value. Swapping adjacent pairs of bits is done in a manner very similar to the above, the code is

```
mov(eax, edx); // Make a copy of the odd numbered bit pairs.
shr(2, eax); // Move the even bit pairs to the odd posn.
and($3333_3333, edx); // Isolate the odd pairs by clearing even pairs.
and($3333_3333, eax); // Isolate the even pairs (in odd posn now).
shl(2, edx); // Move the odd pairs to the even positions.
or(edx, eax); // Merge the bits and complete the swap.
```

After completing the sequence above we swap the adjacent nibbles in the 32-bit register. Again, the only difference is the bit mask and the length of the shifts. Here's the code:

```
mov(eax, edx); // Make a copy of the odd numbered nibbles.
shr(4, eax); // Move the even nibbles to the odd position.
and($0f0f_0f0f, edx); // Isolate the odd nibbles.
and($0f0f_0f0f, eax); // Isolate the even nibbles (in odd posn now).
shl(4, edx); // Move the odd pairs to the even positions.
or(edx, eax); // Merge the bits and complete the swap.
```

You can probably see the pattern developing and can figure out that in the next two steps we've got to swap the bytes and then the words in this object. You can use code like the above, but there is a better way – use the BSWAP instruction. The BSWAP (byte swap) instruction uses the following syntax:

```
bswap(reg32);
```

This instruction swaps bytes zero and three and it swaps bytes one and two in the specified 32-bit register. The principle use of this instruction is to convert data between the so-called “little endian” and “big-endian” data formats<sup>2</sup>. Although we don't specifically need this instruction for this purpose here, the BSWAP instruction does swap the bytes and words in a 32-bit object exactly the way we want them when reversing bits, so rather than sticking in another 12 instructions to swap the bytes and then the words, we can simply use a “bswap( eax );” instruction to complete the job after the instructions above. The final code sequence is

```
mov(eax, edx); // Make a copy of the odd bits in the data.
shr(1, eax); // Move the even bits to the odd positions.
and($5555_5555, edx); // Isolate the odd bits by clearing even bits.
and($5555_5555, eax); // Isolate the even bits (in odd posn now).
shl(1, edx); // Move the odd bits to the even positions.
or(edx, eax); // Merge the bits and complete the swap.

mov(eax, edx); // Make a copy of the odd numbered bit pairs.
shr(2, eax); // Move the even bit pairs to the odd posn.
and($3333_3333, edx); // Isolate the odd pairs by clearing even pairs.
and($3333_3333, eax); // Isolate the even pairs (in odd posn now).
shl(2, edx); // Move the odd pairs to the even positions.
or(edx, eax); // Merge the bits and complete the swap.

mov(eax, edx); // Make a copy of the odd numbered nibbles.
shr(4, eax); // Move the even nibbles to the odd position.
and($0f0f_0f0f, edx); // Isolate the odd nibbles.
and($0f0f_0f0f, eax); // Isolate the even nibbles (in odd posn now).
shl(4, edx); // Move the odd pairs to the even positions.
or(edx, eax); // Merge the bits and complete the swap.
```

---

2. In the little endian system, which the native 80x86 format, the L.O. byte of an object appears at the lowest address in memory. In the big endian system, which various RISC processors use, the H.O. byte of an object appears at the lowest address in memory. The BSWAP instruction converts between these two data formats.

```
bswap(eax); // Swap the bytes and words.
```

This algorithm only requires 13 instructions and it executes much faster than the bit shifting loop appearing earlier. Of course, this sequence does consume a bit more memory, so if you're trying to save memory rather than clock cycles, the loop is probably a better solution.

## 5.11 Merging Bit Strings

Another common bit string operation is producing a single bit string by merging, or interleaving, bits from two different sources. The following example code sequence creates a 32-bit string by merging alternate bits from two 16-bit strings:

```
// Merge two 16-bit strings into a single 32-bit string.
// AX - Source for even numbered bits.
// BX - Source for odd numbered bits.
// CL - Scratch register.
// EDX- Destination register.

mov(16, cl);
MergeLp: shrd(1, eax, edx); // Shift a bit from EAX into EDX.
 shrd(1, ebx, edx); // Shift a bit from EBX into EDX.
 dec(cl);
 jne MergeLp;
```

This particular example merged two 16-bit values together, alternating their bits in the result value. For a faster implementation of this code, unrolling the loop is probably your best bet since this eliminates half the instructions that execute on each iteration of the loop above.

With a few slight modifications, we could also have merged four eight-bit values together, or we could have generated the result using other bit sequences; for example, the following code copies bits 0..5 from EAX, then bits 0..4 from EBX, then bits 6..11 from EAX, then bits 5..15 from EBX, and finally bits 12..15 from EAX:

```
shrd(6, eax, edx);
shrd(5, ebx, edx);
shrd(6, eax, edx);
shrd(11, ebx, edx);
shrd(4, eax, edx);
```

## 5.12 Extracting Bit Strings

Of course, we can easily accomplish the converse of merging two bit streams; i.e., we can extract and distribute bits in a bit string among multiple destinations. The following code takes the 32-bit value in EAX and distributes alternate bits among the BX and DX registers:

```
mov(16, cl); // Count off the number of loop iterations.
ExtractLp: shrd(1, eax, ebx); // Extract even bits to (E)BX.
 shrd(1, eax, edx); // Extract odd bits to (E)DX.
 dec(cl); // Repeat 16 times.
 jnz ExtractLp;
 shr(16, ebx); // Need to move the results from the H.O.
 shr(16, edx); // bytes of EBX/EDX to the L.O. bytes.
```

This sequence executes 51 instructions. This isn't terrible, but we can probably do a little better by using a better algorithm that extracts bits in parallel. Employing the technique we used to reverse bits in a register, we can come up with the following algorithm that relocates all the even bits to the L.O. word of EAX and all the odd bits to the H.O. word of EAX.

Matched:

```
<< If we get to this point, we matched the bit string. We can >>
<< compute the position in the original source as 28-cl. >>
```

Done:

Bit string scanning is a special case of string matching. String matching is a well studied problem in Computer Science and many of the algorithms you can use for string matching are applicable to bit string matching as well. Such algorithms are a bit beyond the scope of this chapter, but to give you a preview of how this works, you compute some function (like XOR or SUB) between the pattern and the current source bits and use the result as an index into a lookup table to determine how many bits you can skip. Such algorithms let you skip several bits rather than only shifting once per each iteration of the scanning loop (as is done by the algorithm above). For more details on string scanning and their possible application to bit string matching, see the appropriate chapter in the volume on Advanced String Handling.

---

## 5.14 The HLA Standard Library Bits Module

The HLA Standard Library provides a “bits” module that provides several bit related functions, including built-in functions for many of the algorithms we’ve studied in this chapter. This section will describe these functions available in the HLA Standard Library.

```
procedure bits.cnt(b:dword); returns("EAX");
```

This procedure returns the number of one bits present in the “b” parameter. It returns the count in the EAX register. To count the number of zero bits in the parameter value, invert the value of the parameter before passing it to *bits.cnt*. If you want to count the number of bits in a 16-bit operand, simply zero extend it to 32 bits prior to calling this function. Here are a couple of examples:

```
// Compute the number of bits in a 16-bit register:
```

```
 pushw(0);
 push(ax);
 call bits.cnt;
```

```
// If you prefer to use a higher-level syntax, try the following:
```

```
 bits.cnt(#{ pushw(0); push(ax); }#);
```

```
// Compute the number of bits in a 16-bit memory location:
```

```
 pushw(0);
 push(mem16);
 bits.cnt;
```

If you want to compute the number of bits in an eight-bit operand it’s probably faster to write a simple loop that rotates all the bits in the source operand and adds the carry into the accumulating sum. Of course, if performance isn’t an issue, you can zero extend the byte to 32 bits and call the *bits.cnt* procedure.

```
procedure bits.distribute(source:dword; mask:dword; dest:dword);
 returns("EAX");
```

This function takes the L.O. *n* bits of *source*, where *n* is the number of “1” bits in *mask*, and inserts these bits into *dest* at the bit positions specified by the “1” bits in *mask* (i.e., the same as the distribute algorithm appearing earlier in this chapter). This function does not change the bits in *dest* that correspond to the zeros in the *mask* value. This function does not affect the value of the actual *dest* parameter, instead, it returns the new value in the EAX register.

```
procedure bits.coalesce(source:dword; mask:dword);
 returns("EAX");
```

This function is the converse of *bits.distribute*. It extracts all the bits in source whose corresponding positions in mask contain a one. This function coalesces (right justifies) these bits in the L.O. bit positions of the result and returns the result in EAX.

```
procedure bits.extract(var d:dword); returns("EAX"); // Really a macro.
```

This function extracts the first set bit in *d* searching from bit #0 and returns the index of this bit in the EAX register; the function will also return the zero flag clear in this case. This function also clears that bit in the operand. If *d* contains zero, then this function returns the zero flag set and EAX will contain -1.

Note that HLA actually implements this function as a macro, not a procedure (see the chapter on Macros for details). This means that you can pass any double word operand as a parameter (i.e., a memory or a register operand). However, the results are undefined if you pass EAX as the parameter (since this function returns the bit number in EAX).

```
procedure bits.reverse32(d:dword); returns("EAX");
procedure bits.reverse16(w:word); returns("AX");
procedure bits.reverse8(b:byte); returns("AL");
```

These three routines return their parameter value with the its bits reversed in the accumulator register (AL/AX/EAX). Call the routine appropriate for your data size.

```
procedure bits.merge32(even:dword; odd:dword); returns("EDX:EAX");
procedure bits.merge16(even:word; odd:word); returns("EAX");
procedure bits.merge8(even:byte; odd:byte); returns("AX");
```

These routines merge two streams of bits to produce a value whose size is the combination of the two parameters. The bits from the “even” parameter occupy the even bits in the result, the bits from the “odd” parameter occupy the odd bits in the result. Notice that these functions return 16, 32, or 64 bits based on byte, word, and double word parameter values.

```
procedure bits.nibbles32(d:dword); returns("EDX:EAX");
procedure bits.nibbles16(w:word); returns("EAX");
procedure bits.nibbles8(b:byte); returns("AX");
```

These routines extract each nibble from the parameter and place those nibbles into individual bytes. The *bits.nibbles8* function extracts the two nibbles from the *b* parameter and places the L.O. nibble in AL and the H.O. nibble in AH. The *bits.nibbles16* function extracts the four nibbles in *w* and places them in each of the four bytes of EAX. You can use the BSWAP or ROx instructions to gain access to the nibbles in the H.O. word of EAX. The *bits.nibbles32* function extracts the eight nibbles in EAX and distributes them through the eight bytes in EDX:EAX. Nibble zero winds up in AL and nibble seven winds up in the H.O. byte of EDX. Again, you can use BSWAP or the rotate instructions to access the upper bytes of EAX and EDX.

---

## 5.15 Putting It All Together

Bit manipulation is one area where assembly language really shines. Not only is bit manipulation far more efficient in assembly language than in high level languages, but it’s often easier as well. Although the need to manipulate bits is not an everyday requirement, bit manipulation is still a very important problem area. In this chapter we’ve explored several ways to manipulate data as bits. Although this chapter only

begins to cover the possibilities, it should give you some ideas for developing your own bit manipulation algorithms for use in your applications.

# The String Instructions

# Chapter Six

## 6.1 Chapter Overview

A string is a collection of objects stored in contiguous memory locations. Strings are usually arrays of bytes, words, or (on 80386 and later processors) double words. The 80x86 microprocessor family supports several instructions specifically designed to cope with strings. This chapter explores some of the uses of these string instructions.

The 80x86 CPUs can process three types of strings: byte strings, word strings, and double word strings. They can move strings, compare strings, search for a specific value within a string, initialize a string to a fixed value, and do other primitive operations on strings. The 80x86's string instructions are also useful for manipulating arrays, tables, and records. You can easily assign or compare such data structures using the string instructions. Using string instructions may speed up your array manipulation code considerably.

## 6.2 The 80x86 String Instructions

All members of the 80x86 family support five different string instructions: `MOVSw`, `CMPSw`, `SCASw`, `LODSw`, and `STOSw`<sup>1</sup>. ( $x = B, W, \text{ or } D$  for byte, word, or double word, respectively. This text will generally drop the  $x$  suffix when talking about these string instructions in a general sense.) They are the string primitives since you can build most other string operations from these five instructions. How you use these five instructions is the topic of the next several sections.

For `MOVSw`:

```
movsb();
movsw();
movsd();
```

For `CMPSw`:

```
cmpsb(); // Note: repz is a synonym for repe
cmpsw();
cmpsd();

cmpsb(); // Note: repnz is a synonym for repne.
cmpsw();
cmpsd();
```

For `SCASw`:

```
scasb(); // Note: repz is a synonym for repe
scasw();
scasd();

scasb(); // Note: repnz is a synonym for repne.
scasw();
scasd();
```

For `STOSw`:

```
stosb();
stosw();
stosd();
```

---

1. The 80x86 processor support two additional string instructions, `INS` and `OUTS` which input strings of data from an input port or output strings of data to an output port. We will not consider these instructions since they are privileged instructions and you cannot execute them in a standard Win32 application.

```

For LODS:
 lodsb();
 lodsw();
 lodsd();

```

---

## 6.2.1 How the String Instructions Operate

The string instructions operate on blocks (contiguous linear arrays) of memory. For example, the MOVS instruction moves a sequence of bytes from one memory location to another. The CMPS instruction compares two blocks of memory. The SCAS instruction scans a block of memory for a particular value. These string instructions often require three operands, a destination block address, a source block address, and (optionally) an element count. For example, when using the MOVS instruction to copy a string, you need a source address, a destination address, and a count (the number of string elements to move).

Unlike other instructions which operate on memory, the string instructions don't have any explicit operands. The operands for the string instructions include

- the ESI (source index) register,
- the EDI (destination index) register,
- the ECX (count) register,
- the AL/AX/EAX register, and
- the direction flag in the FLAGS register.

For example, one variant of the MOVS (move string) instruction copies a string from the source address specified by ESI to the destination address specified by EDI, of length ECX. Likewise, the CMPS instruction compares the string pointed at by ESI, of length ECX, to the string pointed at by EDI.

Not all instructions have source and destination operands (only MOVS and CMPS support them). For example, the SCAS instruction (scan a string) compares the value in the accumulator (AL, AX, or EAX) to values in memory.

---

## 6.2.2 The REP/REPE/REPZ and REPNZ/REPNE Prefixes

The string instructions, by themselves, do not operate on strings of data. The MOVS instruction, for example, will move a single byte, word, or double word. When executed by itself, the MOVS instruction ignores the value in the ECX register. The repeat prefixes tell the 80x86 to do a multi-byte string operation. The syntax for the repeat prefix is:

```

For MOVS:
 rep.movsb();
 rep.movsw();
 rep.movsd();

For CMPS:
 repe.cmpsb(); // Note: repz is a synonym for repe.
 repe.cmpsw();
 repe.cmpsd();

 repne.cmpsb(); // Note: repnz is a synonym for repne.
 repne.cmpsw();
 repne.cmpsd();

For SCAS:
 repe.scasb(); // Note: repz is a synonym for repe.
 repe.scasw();
 repe.scasd();

```

```
repne.scasb(); // Note: repnz is a synonym for repne.
repne.scasw();
repne.scasd();
```

```
For STOS:
rep.stosb();
rep.stosw();
rep.stosd();
```

You don't normally use the repeat prefixes with the LODS instruction.

When specifying the repeat prefix before a string instruction, the string instruction repeats ECX times<sup>2</sup>. Without the repeat prefix, the instruction operates only on a single byte, word, or double word.

You can use repeat prefixes to process entire strings with a single instruction. You can use the string instructions, without the repeat prefix, as string primitive operations to synthesize more powerful string operations.

### 6.2.3 The Direction Flag

Besides the ESI, EDI, ECX, and AL/AX/EAX registers, one other register controls the 80x86's string instructions – the flags register. Specifically, the *direction flag* in the flags register controls how the CPU processes strings.

If the direction flag is clear, the CPU increments ESI and EDI after operating upon each string element. For example, if the direction flag is clear, then executing MOVSB will move the byte, word, or double word at ESI to EDI and will increment ESI and EDI by one, two, or four. When specifying the REP prefix before this instruction, the CPU increments ESI and EDI for each element in the string. At completion, the ESI and EDI registers will be pointing at the first item beyond the string.

If the direction flag is set, then the 80x86 decrements ESI and EDI after processing each string element. After a repeated string operation, the ESI and EDI registers will be pointing at the first byte or word before the strings if the direction flag was set.

The direction flag may be set or cleared using the CLD (clear direction flag) and STD (set direction flag) instructions. When using these instructions inside a procedure, keep in mind that they modify the machine state. Therefore, you may need to save the direction flag during the execution of that procedure. The following example exhibits the kinds of problems you might encounter:

```
procedure Str2; nodisplay;
begin Str2;

 std();
 <Do some string operations>
 .
 .
 .
end Str2;
 .
 .
 .
 cld();
 <do some operations>
 Str2();
 <do some string operations requiring D=0>
```

2. Except for the cmps instruction which repeats *at most* the number of times specified in the cx register.

This code will not work properly. The calling code assumes that the direction flag is clear after *Str2* returns. However, this isn't true. Therefore, the string operations executed after the call to *Str2* will not function properly.

There are a couple of ways to handle this problem. The first, and probably the most obvious, is always to insert the CLD or STD instructions immediately before executing a sequence of one or more string instructions. The other alternative is to save and restore the direction flag using the PUSHFD and POPFD instructions. Using these two techniques, the code above would look like this:

Always issuing CLD or STD before a string instruction:

```
procedure Str2; nodisplay;
begin Str2;

 std();
 <Do some string operations>
 .
 .
 .
end Str2;
 .
 .
 .
 cld();
 <do some operations>
 Str2();
 cld();
 <do some string operations requiring D=0>
```

Saving and restoring the flags register:

```
procedure Str2; nodisplay;
begin Str2;

 pushfd();
 std();
 <Do some string operations>
 .
 .
 .
 popfd();
end Str2;
 .
 .
 .
 cld();
 <do some operations>
 Str2();
 <do some string operations requiring D=0>
```

If you use the PUSHFD and POPFD instructions to save and restore the flags register, keep in mind that you're saving and restoring all the flags. Therefore, such subroutines cannot return any information in the flags. For example, you will not be able to return an error condition in the carry flag if you use PUSHFD and POPFD.

## 6.2.4 The MOVS Instruction

The MOVS instruction uses the following syntax:

```
movsb()
```

```

movsw()
movsd()
rep.movsb()
rep.movsw()
rep.movsd()

```

The **MOVSB** (move string, bytes) instruction fetches the byte at address **ESI**, stores it at address **EDI** and then increments or decrements the **ESI** and **EDI** registers by one. If the **REP** prefix is present, the CPU checks **ECX** to see if it contains zero. If not, then it moves the byte from **ESI** to **EDI** and decrements the **ECX** register. This process repeats until **ECX** becomes zero.

The **MOVSW** (move string, words) instruction fetches the word at address **ESI**, stores it at address **EDI** and then increments or decrements **ESI** and **EDI** by two. If there is a **REP** prefix, then the CPU repeats this procedure as many times as specified in **ECX**.

The **MOVSD** instruction operates in a similar fashion on double words. Incrementing or decrementing **ESI** and **EDI** by four for each data movement.

When you use the *rep* prefix, the **MOVSB** instruction moves the number of bytes you specify in the **ECX** register. The following code segment copies 384 bytes from *CharArray1* to *CharArray2*:

```

CharArray1: byte[384];
CharArray2: byte[384];
.
.
.
cld();
lea(esi, CharArray1);
lea(edi, CharArray2);
mov(384, ecx);
rep.movsb();

```

If you substitute **MOVSW** for **MOVSB**, then the code above will move 384 words (768 bytes) rather than 384 bytes:

```

WordArray1: word[384];
WordArray2: word[384];
.
.
.
cld();
lea(esi, WordArray1);
lea(edi, WordArray2);
mov(384, ecx);
rep.movsw();

```

Remember, the **ECX** register contains the element count, not the byte count. When using the **MOVSW** instruction, the CPU moves the number of words specified in the **ECX** register. Similarly, **MOVSD** moves the number of double words you specify in the **ECX** register, not the number of bytes.

If you've set the direction flag before executing a **MOVSB/MOVSW/MOVSD** instruction, the CPU decrements the **ESI** and **EDI** registers after moving each string element. This means that the **ESI** and **EDI** registers must point at the end of their respective strings before issuing a **MOVSB**, **MOVSW**, or **MOVSD** instruction. For example,

```

CharArray1: byte[384];
CharArray2: byte[384];
.
.
.
cld();
lea(esi, CharArray1[383]);
lea(edi, CharArray2[383]);
mov(384, ecx);

```

```
rep.movsb();
```

Although there are times when processing a string from tail to head is useful (see the CMPS description in the next section), generally you'll process strings in the forward direction since it's more straightforward to do so. There is one class of string operations where being able to process strings in both directions is absolutely mandatory: processing strings when the source and destination blocks overlap. Consider what happens in the following code:

```
CharArray1: byte;
CharArray2: byte[384];
.
.
.
cld();
lea(esi, CharArray1);
lea(edi, CharArray2);
mov(384, ecx);
rep.movsb();
```

This sequence of instructions treats *CharArray1* and *CharArray2* as a pair of 384 byte strings. However, the last 383 bytes in the *CharArray1* array overlap the first 383 bytes in the *CharArray2* array. Let's trace the operation of this code byte by byte.

When the CPU executes the MOVSB instruction, it copies the byte at ESI (*CharArray1*) to the byte pointed at by EDI (*CharArray2*). Then it increments ESI and EDI, decrements ECX by one, and repeats this process. Now the ESI register points at *CharArray1+1* (which is the address of *CharArray2*) and the EDI register points at *CharArray2+1*. The MOVSB instruction copies the byte pointed at by ESI to the byte pointed at by EDI. However, this is the byte originally copied from location *CharArray1*. So the MOVSB instruction copies the value originally in location *CharArray1* to both locations *CharArray2* and *CharArray2+1*. Again, the CPU increments ESI and EDI, decrements ECX, and repeats this operation. Now the movsb instruction copies the byte from location *CharArray1+2* (*CharArray2+1*) to location *CharArray2+2*. But once again, this is the value that originally appeared in location *CharArray1*. Each repetition of the loop copies the next element in *CharArray1[0]* to the next available location in the *CharArray2* array. Pictorially, it looks something like that shown in Figure 6.1.

**Figure 6.1 Copying Data Between Two Overlapping Arrays (forward direction)**

The end result is that the MOVSB instruction replicates X throughout the string. The MOVSB instruction copies the source operand into the memory location which will become the source operand for the very next move operation, which causes the replication.

If you really want to move one array into another when they overlap, you should move each element of the source string to the destination string starting at the end of the two strings as shown in Figure 6.2.

**Figure 6.2 Using a Backwards Copy to Copy Data in Overlapping Arrays**

Setting the direction flag and pointing ESI and EDI at the end of the strings will allow you to (correctly) move one string to another when the two strings overlap and the source string begins at a lower address than the destination string. If the two strings overlap and the source string begins at a higher address than the destination string, then clear the direction flag and point ESI and EDI at the beginning of the two strings.

If the two strings do not overlap, then you can use either technique to move the strings around in memory. Generally, operating with the direction flag clear is the easiest, so that makes the most sense in this case.

You shouldn't use the `MOVSB` instruction to fill an array with a single byte, word, or double word value. Another string instruction, `STOS`, is much better for this purpose. However, for arrays whose elements are larger than four bytes, you can use the `MOVSD` instruction to initialize the entire array to the content of the first element. See the questions for additional information.

The `MOVSD` instruction is far more efficient when copying double words than it is copying bytes or words. In fact, it typically takes the same amount of time to copy a byte using `MOVSB` as it does to copy a double word using `MOVSD`<sup>3</sup>. Therefore, if you are moving a large number of bytes from one array to another, the copy operation will be faster if you can use the `MOVSD` instruction rather than the `MOVSB`

3. This is true for `MOVSW`, as well.

instruction. Of course, if the number of bytes you wish to move is an even multiple of four, this is a trivial change; just divide the number of bytes to copy by four, load this value into ECX, and then use the MOVSB instruction. If the number of bytes is not evenly divisible by four, then you can use the MOVSD instruction to copy all but the last one, two, or three bytes of the array (that is, the remainder after you divide the byte count by four). For example, if you want to efficiently move 4099 bytes, you can do so with the following instruction sequence:

```

lea(esi, Source);
lea(edi, Destination);
mov(1024, ecx); // Copy 1024 dwords = 4096 bytes
rep.movsd();
movsw(); // Copy bytes 4097 and 4098.
movsb(); // Copy the last byte.

```

Using this technique to copy data never requires more than three MOVSB instructions since you can copy one, two, or three bytes with no more than two MOVSB and MOVSW instructions. The scheme above is most efficient if the two arrays are aligned on double word boundaries. If not, you might want to move the MOVSB or MOVSW instruction (or both) before the MOVSD so that the MOVSD instruction works with dword-aligned data (see Chapter Three for an explanation of the performance benefits of double word aligned data).

If you do not know the size of the block you are copying until the program executes, you can still use code like the following to improve the performance of a block move of bytes:

```

lea(esi, Source);
lea(edi, Dest);
mov(Length, ecx);
shr(2, ecx); // divide by four.
if(@nz) then // Only execute MOVSD if four or more bytes.

 rep.movsd(); // Copy the dwords.

endif;
mov(Length, ecx);
and(%11, ecx); // Compute (Length mod 4).
if(@nz) then // Only execute MOVSB if #bytes/4 <> 0.

 rep.movsb(); // Copy the remaining one, two, or three bytes.

endif;

```

On most computer systems, the MOVSD instruction provides about the fastest way to copy bulk data from one location to another. While there are, arguably, faster ways to copy the data on certain CPUs, ultimately the memory bus performance is the limiting factor and the CPUs are generally much faster than the memory bus. Therefore, unless you have a special system, writing fancy code to improve memory to memory transfers is probably a waste of time.

---

## 6.2.5 The CMPS Instruction

The CMPS instruction compares two strings. The CPU compares the string referenced by EDI to the string pointed at by ESI. CX contains the length of the two strings (when using the REPE or REPNE prefix). Like the MOVS instruction, HLA allows several different forms of this instruction:

```

cmpsb();
cmpsw();
cmpsd();

repe.cmpsb();
repe.cmpsw();
repe.cmpsd();

```

```
repne.cmpsb();
repne.cmpsw();
repne.cmpsd();
```

Like the `MOVS` instruction you specify the actual operand addresses in the `ESI` and `EDI` registers.

Without a repeat prefix, the `CMPS` instruction subtracts the value at location `EDI` from the value at `ESI` and updates the flags. Other than updating the flags, the CPU doesn't use the difference produced by this subtraction. After comparing the two locations, `CMPS` increments or decrements the `ESI` and `EDI` registers by one, two, or four (for `CMPSB/CMPSW/CMPSD`, respectively). `CMPS` increments the `ESI` and `EDI` registers if the direction flag is clear and decrements them otherwise.

Of course, you will not tap the real power of the `CMPS` instruction using it to compare single bytes, words, or double words in memory. This instruction shines when you use it to compare whole strings. With `CMPS`, you can compare consecutive elements in a string until you find a match or until consecutive elements do not match.

To compare two strings to see if they are equal or not equal, you must compare corresponding elements in a string until they don't match. Consider the following strings:

“String1”

“String1”

The only way to determine that these two strings are equal is to compare each character in the first string to the corresponding character in the second. After all, the second string could have been “String2” which definitely is not equal to “String1”. Of course, once you encounter a character in the destination string which doesn't equal the corresponding character in the source string, the comparison can stop. You needn't compare any other characters in the two strings.

The `REPE` prefix accomplishes this operation. It will compare successive elements in a string as long as they are equal and `ECX` is greater than zero. We could compare the two strings above using the following 80x86 assembly language code:

```
cld();
mov(AdrsString1, esi);
mov(AdrsString2, edi);
mov(7, ecx);
repe.cmpsb();
```

After the execution of the `CMPSB` instruction, you can test the flags using the standard conditional jump instructions. This lets you check for equality, inequality, less than, greater than, etc.

Character strings are usually compared using *lexicographical ordering*. In lexicographical ordering, the least significant element of a string carries the most weight. This is in direct contrast to standard integer comparisons where the most significant portion of the number carries the most weight. Furthermore, the length of a string affects the comparison only if the two strings are identical up to the length of the shorter string. For example, “Zebra” is less than “Zebras”, because it is the shorter of the two strings, however, “Zebra” is greater than “AAAAAAAAAAH!” even though it is shorter. Lexicographical comparisons compare corresponding elements until encountering a character which doesn't match, or until encountering the end of the shorter string. If a pair of corresponding characters do not match, then this algorithm compares the two strings based on that single character. If the two strings match up to the length of the shorter string, we must compare their length. The two strings are equal if and only if their lengths are equal and each corresponding pair of characters in the two strings is identical. Lexicographical ordering is the standard alphabetical ordering you've grown up with.

For character strings, use the `CMPS` instruction in the following manner:

- The direction flag must be cleared before comparing the strings.
- Use the `CMPSB` instruction to compare the strings on a byte by byte basis. Even if the strings contain an even number of characters, you cannot use the `CMPSW` or `CMPSD` instructions. They do not compare strings in lexicographical order.
- You must load the `ECX` register with the length of the smaller string.

- Use the REPE prefix.
- The ESI and EDI registers must point at the very first character in the two strings you want to compare.

After the execution of the CMPS instruction, if the two strings were equal, their lengths must be compared in order to finish the comparison. The following code compares a couple of character strings:

```

mov(AdrsStr1, esi);
mov(AdrsStr2, edi);
mov(LengthSrc, ecx);
if(ecx > LengthDest) then // Put the length of the shorter string in ECX.

 mov(LengthDest, ecx);

endif;
repe.cmpsb();
if(@z) then // If equal to the length of the shorter string, cmp lengths.

 mov(LengthSrc, ecx);
 cmp(ecx, LengthDest);

endif;

```

If you're using bytes to hold the string lengths, you should adjust this code appropriately (i.e., use a MOVZX instruction to load the lengths into ECX). Of course, HLA strings use a double word to hold the current length value, so this isn't an issue when using HLA strings.

You can also use the CMPS instruction to compare multi-word integer values (that is, extended precision integer values). Because of the amount of setup required for a string comparison, this isn't practical for integer values less than six or eight double words in length, but for large integer values, it's an excellent way to compare such values. Unlike character strings, we cannot compare integer strings using a lexicographical ordering. When comparing strings, we compare the characters from the least significant byte to the most significant byte. When comparing integers, we must compare the values from the most significant byte (or word/double word) down to the least significant byte, word or double word. So, to compare two 32-byte (256-bit) integer values, use the following code on the 80x86:

```

std();
lea(esi, SourceInteger[28]);
lea(edi, DestInteger[28]);
mov(8, ecx);
rep.cmpsd();

```

This code compares the integers from their most significant word down to the least significant word. The CMPSD instruction finishes when the two values are unequal or upon decrementing ECX to zero (implying that the two values are equal). Once again, the flags provide the result of the comparison.

The REPNE prefix will instruct the CMPS instruction to compare successive string elements as long as they do not match. The 80x86 flags are of little use after the execution of this instruction. Either the ECX register is zero (in which case the two strings are totally different), or it contains the number of elements compared in the two strings until a match. While this form of the CMPS instruction isn't particularly useful for comparing strings, it is useful for locating the first pair of matching items in a couple of byte, word, or double word arrays. In general, though, you'll rarely use the REPNE prefix with CMPS.

One last thing to keep in mind with using the CMPS instruction – the value in the ECX register determines the number of elements to process, not the number of bytes. Therefore, when using CMPSW, ECX specifies the number of words to compare. This, of course, is twice the number of bytes to compare. Likewise, for CMPSD, ECX contains the number of double words to process.

## 6.2.6 The SCAS Instruction

The CMPS instruction compares two strings against one another. You do not use it to search for a particular element within a string. For example, you could not use the CMPS instruction to quickly scan for a zero throughout some other string. You can use the SCAS (scan string) instruction for this task.

Unlike the MOVS and CMPS instructions, the SCAS instruction only requires a destination string (pointed at by EDI) rather than both a source and destination string. The source operand is the value in the AL (SCASB), AX (SCASW), or EAX (SCASD) register. The SCAS instruction compares the value in the accumulator (AL, AX, or EAX) against the value pointed at by EDI and then increments (or decrements) EDI by one, two, or four. The CPU sets the flags according to the result of the comparison. While this might be useful on occasion, SCAS is a lot more useful when using the REPE and REPNE prefixes.

With the REPE prefix (repeat while equal), SCAS scans the string searching for an element which does not match the value in the accumulator. When using the REPNE prefix (repeat while not equal), SCAS scans the string searching for the first string element which is equal to the value in the accumulator.

You're probably wondering "why do these prefixes do exactly the opposite of what they ought to do?" The paragraphs above haven't quite phrased the operation of the SCAS instruction properly. When using the REPE prefix with SCAS, the 80x86 scans through the string while the value in the accumulator is equal to the string operand. This is equivalent to searching through the string for the first element which does not match the value in the accumulator. The SCAS instruction with REPNE scans through the string while the accumulator is not equal to the string operand. Of course, this form searches for the first value in the string which matches the value in the accumulator register. The SCAS instructions take the following forms:

```
scasb()
scasw()
scasd()

repe.scasb()
repe.scasw()
repe.scasd()

repne.scasb()
repne.scasw()
repne.scasd()
```

Like the CMPS and MOVS instructions, the value in the ECX register specifies the number of elements to process, not bytes, when using a repeat prefix.

## 6.2.7 The STOS Instruction

The STOS instruction stores the value in the accumulator at the location specified by EDI. After storing the value, the CPU increments or decrements EDI depending upon the state of the direction flag. Although the STOS instruction has many uses, its primary use is to initialize arrays and strings to a constant value. For example, if you have a 256-byte array you want to clear out with zeros, use the following code:

```
cld();
lea(edi, DestArray);
mov(64, ecx); // 64 double words = 256 bytes.
xor(eax, eax); // Zero out EAX.
rep.stosd();
```

This code writes 64 double words rather than 256 bytes because a single STOSD operation is faster than four STOSB operations.

The STOS instructions take four forms. They are

```
stosb();
stosw();
```

```

stosd();

rep.stosb();
rep.stosw();
rep.stosd();

```

The STOSB instruction stores the value in the AL register into the specified memory location(s), the STOSW instruction stores the AX register into the specified memory location(s) and the STOSD instruction stores EAX into the specified location(s).

Keep in mind that the STOS instruction is useful only for initializing a byte, word, or double word array to a constant value. If you need to initialize an array to different values, you cannot use the STOS instruction. See the exercises for additional details.

## 6.2.8 The LODS Instruction

The LODS instruction is unique among the string instructions. You will probably never use a repeat prefix with this instruction. The LODS instruction copies the byte, word, or double word pointed at by ESI into the AL, AX, or EAX register, after which it increments or decrements the ESI register by one, two, or four. Repeating this instruction via the repeat prefix would serve no purpose whatsoever since the accumulator register will be overwritten each time the LODS instruction repeats. At the end of the repeat operation, the accumulator will contain the last value read from memory.

Instead, use the LODS instruction to fetch bytes (LODSB), words (LODSW), or double words (LODSD) from memory for further processing. By using the STOS instruction, you can synthesize powerful string operations.

Like the STOS instruction, the LODS instructions take four forms:

```

lodsb();
lodsw();
lodsd();

rep.lodsb();
rep.lodsw();
rep.lodsd();

```

As mentioned earlier, you'll rarely, if ever, use the REP prefixes with these instructions<sup>4</sup>. The 80x86 increments or decrements ESI by one, two, or four depending on the direction flag and whether you're using the LODSB, LODSW, or LODSD instruction.

## 6.2.9 Building Complex String Functions from LODS and STOS

The 80x86 supports only five different string instructions: MOVS, CMPS, SCAS, LODS, and STOS<sup>5</sup>. These certainly aren't the only string operations you'll ever want to use. However, you can use the LODS and STOS instructions to easily generate any particular string operation you like. For example, suppose you wanted a string operation that converts all the upper case characters in a string to lower case. You could use the following code:

```

mov(StringAddress, esi); // Load string address into ESI.
mov(esi, edi); // Also point EDI here.
mov((type str.strrec [esi].length, ecx);

repeat

```

4. They appear here simply because they are allowed. They're not useful, but they are allowed.

5. Not counting INS and OUTS which we're ignoring here.

```
lodsb(); // Get the next character in the string.
if(al in 'A'..'Z') then

 or($20, al); // Convert upper case character to lower case.

endif;
stosb(); // Store converted character back into string.
dec(ecx);

until(ecx == 0);
```

Since the LODS and STOS instructions use the accumulator as an intermediary, you can use any accumulator operation to quickly manipulate string elements.

---

### 6.3 Putting It All Together

In this chapter we took a quick look at the 80x86's string instructions. We studied their implementation and saw how to use them. These instructions are quite useful for synthesizing character set functions (see the source code for the HLA Standard Library string module for examples). We also saw how to use these instructions for non-character string purpose such as moving large blocks of memory (i.e., assigning one array to another) and comparing large integer values. For more information on the use of these instructions, please see the volume on Advanced String Handling.

# The HLA Compile-Time Language

# Chapter Seven

## 6.1 Chapter Overview

Now we come to the fun part. For the past nine chapters this text has been molding and conforming you to deal with the HLA language and assembly language programming in general. In this chapter you get to turn the tables; you'll learn how to force HLA to conform to your desires. This chapter will teach you how to extend the HLA language using HLA's *compile-time language*. By the time you are through with this chapter, you should have a healthy appreciation for the power of the HLA compile-time language. You will be able to write short compile-time programs. You will also be able to add new statements, of your own choosing, to the HLA language.

## 6.2 Introduction to the Compile-Time Language (CTL)

HLA is actually two languages rolled into a single program. The *run-time language* is the standard 80x86/HLA assembly language you've been reading about for the past nine chapters. This is called the run-time language because the programs you write execute when you run the executable file. HLA contains an interpreter for a second language, the HLA Compile-Time Language (or CTL) that executes programs while HLA is compiling a program. The source code for the CTL program is embedded in an HLA assembly language source file; that is, HLA source files contain instructions for both the HLA CTL and the run-time program. HLA executes the CTL program during compilation. Once HLA completes compilation, the CTL program terminates; the CTL application is not a part of the run-time executable that HLA emits, although the CTL application can *write* part of the run-time program for you and, in fact, this is the major purpose of the CTL.

**Figure 6.1** Compile-Time vs. Run-Time Execution

It may seem confusing to have two separate languages built into the same compiler. Perhaps you're even questioning why anyone would need a compile time language. To understand the benefits of a compile time language, consider the following statement that you should be very comfortable with at this point:

```
stdout.put("i32=", i32, " strVar=", strVar, " charVar=", charVar, nl);
```

This statement is neither a statement in the HLA language nor a call to some HLA Standard Library procedure. Instead, *stdout.put* is actually a statement in a CTL application provided by the HLA Standard Library. The *stdout.put* "application" processes a list of objects (the parameter list) and makes calls to various other Standard Library procedures; it chooses the procedure to call based on the type of the object it is currently processing. For example, the *stdout.put* "application" above will emit the following statements to the run-time executable:

```
stdout.puts("i32=");
stdout.puti32(i32);
stdout.puts(" strVar=");
stdout.puts(strVar);
stdout.puts(" charVar=");
stdout.putc(charVar);
stdout.newln();
```

Clearly the *stdout.put* statement is much easier to read and write than the sequence of statements that *stdout.put* emits in response to its parameter list. This is one of the more powerful capabilities of the HLA programming language: the ability to modify the language to simplify common programming tasks. Printing lots of different data objects in a sequential fashion is a common task; the *stdout.put* "application" greatly simplifies this process.

The HLA Standard Library is *loaded* with lots of HLA CTL examples. In addition to standard library usage, the HLA CTL is quite adept at handling "one-off" or "one-use" applications. A classic example is filling in the data for a lookup table. In Chapter Six this text noted that it is possible to construct look-up tables using the HLA CTL (see "Tables" on page 625 and "Generating Tables" on page 629). Not only is this possible, but it is often far less work to use the HLA CTL to construct these look-up tables. This chapter abounds with examples of exactly this application of the CTL.

Although the CTL itself is relatively inefficient, it does maximize the use of that one precious commodity of which there is so little available: your time. By learning how to use the HLA CTL, and applying it properly, you can develop assembly language applications as rapidly as high level language applications (even faster since HLA's CTL lets you create *very* high level language constructs).

### 6.3 The #PRINT and #ERROR Statements

Chapter One of this textbook began with the typical first program most people write when learning a new language; the "Hello World" program. It is only fitting for this chapter to present that same program when discussing the second language of this text. So here it is, the basic "Hello World" program written in the HLA compile time language:

```
program ctlHelloWorld;
begin ctlHelloWorld;

 #print("Hello, World of HLA/CTL")

end ctlHelloWorld;
```

Program 6.1 The CTL "Hello World" Program

The only CTL statement in this program is the "#print" statement. The remaining lines are needed just to keep the compiler happy (we could reduced the overhead to two lines by using a UNIT rather than a PROGRAM declaration).

The #PRINT statement displays the textual representation of its argument list during the compilation of an HLA program. Therefore, if you compile the program above with the command "hla ctlHW.hla" the HLA compiler will immediately print, before returning control to the command line, the text:

```
Hello, World of HLA/CTL
```

Note that there is a big difference between the following two statements in an HLA source file:

```
#print("Hello World")
stdout.puts("Hello World" nl);
```

The first statement prints "Hello World" (and a newline) during the compilation process. This first statement does not have any effect on the executable program. The second line doesn't affect the compilation process (other than the emission of code to the executable file). However, when you run the executable file, the second statement prints the string "Hello World" followed by a new line sequence.

The HLA/CTL #PRINT statement uses the following basic syntax:

```
#print(list_of_comma_separated_constants)
```

Note that a semicolon does not terminate this statement. Semicolons terminate run-time statements, they generally do not terminate compile-time statements (there is one big exception, as you will see a little later).

The #PRINT statement must have at least one operand; if multiple operands appear in the parameter list, you must separate each operand with a comma (just like *stdout.put*). If a particular operand is not a string constant, HLA will translate that constant to its corresponding string representation and print that string. Example:

```
#print("A string Constant ", 45, ' ', 54.9, ' ', true)
```

You may specify named symbolic constants and constant expressions. However, all #PRINT operands must be constants (either literal constants or constants you define in the CONST or VAL sections) and those constants must be defined before you use them in the #PRINT statement. Example:

```
const
 pi := 3.14159;
 charConst := 'c';

#print("PI = ", pi, " CharVal=", CharConst)
```

The HLA #PRINT statement is particularly invaluable for debugging CTL programs (since there is no debugger available for CTL code). This statement is also useful for displaying the progress of the compilation and displaying assumptions and default actions that take place during compilation. Other than displaying the text associated with the #PRINT parameter list, the #PRINT statement does not have any affect on the compilation of the program.

The #ERROR statement allows a single string constant operand. Like #PRINT this statement will display the string to the console during compilation. However, the #ERROR statement treats the string as a error message and displays the string as part of an HLA error diagnostic. Further, the #ERROR statement increments the error count and this will cause HLA to stop the compilation (without assembly or linking) at the conclusion of the source file. You would normally use the #ERROR statement to display an error message during compilation if your CTL code discovers something that prevents it from creating valid code. Example:

```
#error("Statement must have exactly one operand")
```

Like the #PRINT statement, the #ERROR statement does not end with a semicolon. Although #ERROR only allows a string operand, it's very easy to print other values by using the string (constant) concatenation operator and several of the HLA built-in compile-time functions (see "Compile-Time Constants and Variables" on page 924 and "Compile-Time Functions" on page 927) for more details).

## 6.4 Compile-Time Constants and Variables

Just as the run-time language supports constants and variables, so does the compile-time language. You declare compile-time constants in the CONST section, the same as for the run-time language. You declare compile-time variables in the VAL section. Objects you declare in the VAL sections are constants as far as the run-time language is concerned, but remember that you can change the value of an object you declare in the VAL section throughout the source file. Hence the term "compile-time variable." See "HLA Constant and Value Declarations" on page 381 for more details.

The CTL assignment statement ("?:") computes the value of the constant expression to the right of the assignment operator (":=") and stores the result into the VAL object name appearing immediately to the left of the assignment operator<sup>1</sup>. The following example is a rework of the example above; this example, however, may appear anywhere in your HLA source file, not just in the VAL section of the program.

```
?ConstToPrint := 25;
#print("ConstToPrint = ", ConstToPrint)
?ConstToPrint := ConstToPrint + 5;
#print("Now ConstToPrint = ", ConstToPrint)
```

Note that HLA's CTL ignores the distinction between the different sizes of numeric objects. HLA always reserves storage for the largest possible object of a given type, so HLA merges the following types:

```
byte, word, dword -> dword
uns8, uns16, uns32 -> uns32
int8, int16, int32 -> int32
real32, real64, real80 -> real80
```

For most practical applications of the CTL, this shouldn't make a difference in the operation of the program.

## 6.5 Compile-Time Expressions and Operators

As the previous section states, the HLA CTL supports constant expressions in the CTL assignment statement. Unlike the run-time language (where you have to translate algebraic notation into a sequence of machine instructions), the HLA CTL allows a full set of arithmetic operations using familiar expression syntax. This gives the HLA CTL considerable power, especially when combined with the built-in compile-time functions the next section discusses.

HLA's CTL supports the following operators in compile-time expressions:

**Table 1: Compile-Time Operators**

| Operator(s) | Operand Types <sup>a</sup> | Description                                            |
|-------------|----------------------------|--------------------------------------------------------|
| - (unary)   | numeric                    | Negates the specific numeric value (int, uns, real).   |
|             | cset                       | Returns the complement of the specified character set. |
| ! (unary)   | integer                    | Inverts all the bits in the operand (bitwise not).     |
|             | boolean                    | Boolean NOT of the operand.                            |
| *           | numericL * numericR        | Multiplies the two operands.                           |
|             | csetL * csetR              | Computes the intersection of the two sets              |

1. If the identifier to the left of the assignment operator is undefined, HLA will automatically declare this object at the current scope level.

**Table 1: Compile-Time Operators**

| Operator(s) | Operand Types <sup>a</sup>    | Description                                                                                                                                                         |
|-------------|-------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| div         | integerL div integerR         | Computes the quotient of the two integer (int/uns/dword) operands.                                                                                                  |
| mod         | integerL mod integerR         | Computes the remainder of the division of the two integer (int/uns/dword) operands.                                                                                 |
| /           | numericL / numericR           | Computes the real quotient of the two numeric operands. Returns a real result even if both operands are integers.                                                   |
| <<          | integerL << integerR          | Shifts integerL operand to the left the number of bits specified by the integerR operand.                                                                           |
| >>          | integerL >> integerR          | Shifts integerL operand to the right the number of bits specified by the integerR operand.                                                                          |
| +           | numericL + numericR           | Adds the two numeric operands.                                                                                                                                      |
|             | csetL + csetR                 | Computes the union of the two sets.                                                                                                                                 |
|             | strL + strR                   | Concatenates the two strings.                                                                                                                                       |
| -           | numericL - numericR           | Computes the difference between numericL and numericR.                                                                                                              |
|             | csetL - csetR                 | Computes the set difference of csetL-csetR.                                                                                                                         |
| = or ==     | numericL = numericR           | Returns true if the two operands have the same value.                                                                                                               |
|             | csetL = csetR                 | Returns true if the two sets are equal.                                                                                                                             |
|             | strL = strR                   | Returns true if the two strings/chars are equal.                                                                                                                    |
|             | typeL = typeR                 | Returns true if the two values are equal. They must be the same type.                                                                                               |
| <> or !=    | typeL <> typeR<br>(Same as =) | Returns false if the two (compatible) operands are not equal to one another.                                                                                        |
| <           | numericL < numericR           | Returns true if numericL is less than numericR.                                                                                                                     |
|             | csetL < csetR                 | Returns true if csetL is a proper subset of csetR.                                                                                                                  |
|             | strL < strR                   | Returns true if strL is less than strR                                                                                                                              |
|             | booleanL < booleanR           | Returns true if left operand is less than right operand (note: false < true).                                                                                       |
|             | enumL < enumR                 | Returns true if enumL appears in the same enum list as enumR and enumL appears first.                                                                               |
| <=          | Same as <                     | Returns true if the left operand is less than or equal to the right operand. For character sets, this means that the left operand is a subset of the right operand. |
| >           | Same as <                     | Returns true if the left operand is greater than the right operand. For character sets, this means that the left operand is a proper superset of the right operand. |

**Table 1: Compile-Time Operators**

| Operator(s) | Operand Types <sup>a</sup> | Description                                                                                                                                                              |
|-------------|----------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| >=          | Same as <=                 | Returns true if the left operand is greater than or equal to the right operand. For character sets, this means that the left operand is a superset of the right operand. |
| &           | integerL & integerR        | Computes the bitwise AND of the two operands.                                                                                                                            |
|             | booleanL & booleanR        | Computes the logical AND of the two operands.                                                                                                                            |
|             | integerL   integerR        | Computes the bitwise OR of the two operands.                                                                                                                             |
|             | booleanL   booleanR        | Computes the logical OR of the two operands.                                                                                                                             |
| ^           | integerL ^ integerR        | Computes the bitwise XOR of the two operands.                                                                                                                            |
|             | booleanL ^ booleanR        | Computes the logical XOR of the two operands. Note that this is equivalent to "booleanL <> booleanR".                                                                    |
| in          | charL in csetR             | Returns true if charL is a member of csetR.                                                                                                                              |

a. Numeric is {intXX, unsXX, byte, word, dword, and realXX} values. Cset is a character set operand. Type integer is { intXX, unsXX, byte, word, dword }. Type str is any string or character value. "TYPE" indicates an arbitrary HLA type. Other types specify an explicit HLA data type.

**Table 2: Operator Precedence and Associativity**

| Associativity | Precedence (Highest to Lowest) | Operator |
|---------------|--------------------------------|----------|
| Right-to-left | 6                              | !        |
|               |                                | -        |
| Left to right | 5                              | *        |
|               |                                | div      |
|               |                                | mod      |
|               |                                | /        |
|               |                                | >>       |
|               |                                | <<       |
| Left to right | 4                              | +        |
|               |                                | -        |

**Table 2: Operator Precedence and Associativity**

| Associativity  | Precedence (Highest to Lowest) | Operator |
|----------------|--------------------------------|----------|
| Left to right  | 3                              | = or ==  |
|                |                                | <> or != |
|                |                                | <        |
|                |                                | <=       |
|                |                                | >        |
|                |                                | >=       |
| Left to right  | 2                              | &        |
|                |                                |          |
|                |                                | ^        |
| Nonassociative | 1                              | in       |

Of course, you can always override the default precedence and associativity of an operator by using parentheses in an expression.

---

## 6.6 Compile-Time Functions

HLA provides a wide range of compile-time functions you can use. These functions compute values during compilation the same way a high level language function computes values at run-time. The HLA compile-time language includes a wide variety of numeric, string, and symbol table functions that help you write sophisticated compile-time programs.

Most of the names of the built-in compile-time functions begin with the special symbol "@" and have names like *@sin* or *@length*. The use of these special identifiers prevents conflicts with common names you might want to use in your own programs (like *length*). The remaining compile-time functions (those that do not begin with "@") are typically data conversion functions that use type names like *int8* and *real64*. You can even create your own compile-time functions using macros (see "Macros" on page 941).

HLA organizes the compile-time functions into various classes depending on the type of operation. For example, there are functions that convert constants from one form to another (e.g., string to integer conversion), there are many useful string functions, and HLA provides a full set of compile-time numeric functions.

The complete list of HLA compile-time functions is too lengthy to present here. Instead, a complete description of each of the compile-time objects and functions appears in Appendix H (see "HLA Compile-Time Functions" on page 1447); this section will highlight a few of the functions in order to demonstrate their use. Later sections in this chapter, as well as future chapters, will make extensive use of the various compile-time functions.

Perhaps the most important concept to understand about the compile-time functions is that they are equivalent to constants in your assembly language code (i.e., the run-time program). For example, the compile-time function invocation "*@sin( 3.1415265358979328 )*" is roughly equivalent to specifying "0.0" at that point in your program<sup>2</sup>. A function invocation like "*@sin( x )*" is legal only if *x* is a constant with a previous declaration at the point of the function call in the source file. In particular, *x* cannot be a run-time vari-

---

2. Actually, since *@sin*'s parameter in this example is not exactly  $\pi$ , you will get a small positive number instead of zero as the function result, but in theory you should get zero.

able or other object whose value exists at run-time rather than compile-time. Since HLA replaces compile-time function calls with their constant result, you may ask why you should even bother with compile time functions. After all, it's probably more convenient to type "0.0" than it is to type "@sin( 3.1415265358979328 )" in your program. However, compile-time functions are really handy for generating lookup tables (see "Generating Tables" on page 629) and other mathematical results that may change whenever you change a CONST value in your program. Later sections in this chapter will explore these ideas farther.

---

### 6.6.1 Type Conversion Compile-time Functions

One set of commonly used compile-time functions are the type conversion functions. These functions take a single parameter of one type and convert that information to some specified type. These functions use several of the HLA built-in data type names as the function names. Functions in this category are

- boolean
- int8, int16, and int32
- uns8, uns16, and uns32
- byte, word, dword (these are effectively equivalent to uns8, uns16, and uns32)
- real32, real64, and real80
- char
- string
- cset
- text

These functions accept a single constant expression parameter and, if at all reasonable, convert that expression's value to the type specified by the type name. For example, the following function call returns the value -128 since it converts the string constant to the corresponding integer value:

```
int8("-128")
```

Certain conversions don't make sense or have restrictions associated with them. For example, the *boolean* function will accept a string parameter, but that string must be "true" or "false" or the function will generate a compile-time error. Likewise, the numeric conversion functions (e.g., *int8*) allow a string operand but the string operand must represent a legal numeric value. Some conversions (e.g., *int8* with a character set parameter) simply don't make sense and are always illegal.

One of the most useful functions in this category is the *string* function. This function accepts nearly all constant expression types and it generates a string that represents the parameter's data. For example, the invocation "string( 128 )" produces the string "128" as the return result. This function is real handy when you have a value that you wish to use where HLA requires a string. For example, the #ERROR compile-time statement only allows a single string operand. You can use the string function and the string concatenation operator ("+") to easily get around this limitation, e.g.,

```
#error("Value (" + string(Value) + ") is out of range")
```

---

### 6.6.2 Numeric Compile-Time Functions

The functions in this category perform standard mathematical operations at compile time. These functions are real handy for generating lookup tables and "parameterizing" your source code by recalculating functions on constants defined at the beginning of your program. Functions in this category include the following:

- @abs
- @ceil, @floor
- @sin, @cos, @tan
- @exp, @log, @log10
- @min, @max

- @random, @randomize
- @sqrt

See Appendix H for more details on these functions.

### 6.6.3 Character Classification Compile-Time Functions

The functions in this group all return a boolean result. They test a character (or all the characters in a string) to see if it belongs to a certain class of characters. The functions in this category include

- @isAlpha, @isAlphanum
- @isDigit, @isxDigit
- @isLower, @isUpper
- @isSpace

In addition to these character classification functions, the HLA language provides a set of pattern matching functions that you can also use to classify character and string data. See the appropriate sections a little later for the discussion of these routines.

### 6.6.4 Compile-Time String Functions

The functions in this category operate on string parameters. Most return a string result although a few (e.g., @length and @index) return integer results. These functions do not directly affect the values of their parameters; instead, they return an appropriate result that you can assign back to the parameter if you wish to do so.

- @delete, @insert
- @index, @rindex
- @length
- @lowercase, @uppercase
- @strbrk, @strspan
- @strset
- @substr, @tokenize, @trim

For specific details concerning these functions and their parameters and their types, see Appendix H. Combined with the pattern matching functions, the string handling functions give you the ability to extend the HLA language by processing textual data that appears in your source files. Later sections appearing in this chapter will discuss ways to do this.

The @length function deserves a special discussion because it is probably the most popular function in this category. It returns an *uns32* constant specifying the number of characters found in its string parameter. The syntax is the following:

```
@length(string_expression)
```

Where *string\_expression* represents any compile-time string expression. As noted above, this function returns the length, in characters, of the specified expression.

### 6.6.5 Compile-Time Pattern Matching Functions

HLA provides a very rich set of string/pattern matching functions that let you test a string to see if it begins with certain types of characters or strings. Along with the string processing functions, the pattern matching functions let you extend the HLA language and provide several other benefits as well. There are far too many pattern matching functions to list here (see Appendix H for complete details). However, a few examples will demonstrate the power and convenience of these routines.

The pattern matching functions all return a boolean true/false result. If a function returns true, we say that the function *succeeds* in matching its operand. If the function returns false, then we say it *fails* to match its operand. An important feature of the pattern matching functions is that they do not have to match the entire string you supply as a parameter, these patterns will (usually) succeed as long as they match a prefix of the string parameter. The `@matchStr` function is a good example, the following function invocation always returns true:

```
@matchStr("Hello World", "Hello")
```

The first parameter of all the pattern matching functions ("Hello World" in this example) is the string to match. The matching functions will attempt to match the characters at the beginning of the string with the other parameters supplied for that particular function. In the `@matchStr` example above, the function succeeds if the first parameter begins with the string specified as the second parameter (which it does). The fact that the "Hello World" string contains additional characters beyond "Hello" is irrelevant; it only needs to begin with the string "Hello" is doesn't require equality with "Hello".

Most of the compile-time pattern matching functions support two optional parameters. The functions store additional data into the VAL objects specified by these two parameters if the function is successful (conversely, if the function fails, it does not modify these objects). The first parameter is where the function stores the *remainder*. The remainder after the execution of a pattern matching function is those characters that follow the matched characters in the string. In the example above, the remainder would be " World". If you wanted to capture this remainder data, you would add a third parameter to the `@matchStr` function invocation:

```
@matchStr("Hello World", "Hello", World)
```

This function invocation would leave " World" sitting in the *World* VAL object. Note that *World* must be pre-declared in the VAL section (or via the "?" statement) prior to the invocation of this function.

By using the conjunction operator ("&") you can combine several pattern matching functions into a single expression, e.g.,

```
@matchStr("Hello There World", "Hello ", tw) & @matchStr(tw, "There ", World)
```

This full expression returns true and leaves "World" sitting in the *World* variable. It also leaves "There World" sitting in *tw*, although *tw* is probably a temporary object whose value has no meaning beyond this expression. Of course, the above could be more efficiently implemented as follows:

```
@matchStr("Hello There World", "Hello There", World)
```

However, keep in mind that you can combine different pattern matching functions using conjunction, they needn't all be calls to `@matchStr`.

The second optional parameter to most pattern matching functions holds a copy of the text that the function matched. E.g., the following call to `@matchStr` returns "Hello" in the Hello VAL object<sup>3</sup>

```
@matchStr("Hello World", "Hello", World, Hello)
```

For more information on these pattern matching functions please see Appendix H. The chapter on Domain Specific Languages (see "Domain Specific Embedded Languages" on page 975) and several other sections in this chapter will also make further use of these functions.

### 6.6.6 Compile-Time Symbol Information

During compilation HLA maintains an internal database known as the *symbol table*. The symbol table contains lots of useful information concerning all the identifiers you've defined up to a given point in the program. In order to generate machine code output, HLA needs to query this database to determine how to

3. Strictly speaking, this example is rather contrived since we generally know the string that `@matchStr` matches. However, for other pattern matching functions this is not the case.

treat certain symbols. In your compile-time programs, it is often necessary to query the symbol table to determine how to handle an identifier or expression in your code. The HLA compile-time symbol information functions handle this task.

Many of the compile-time symbol information functions are well beyond the scope of this chapter (and, in some cases, beyond the scope of this text). This chapter will present a few of the functions and later chapters will add to this list. For a complete list of the compile-time symbol table functions, see Appendix H. The functions we will consider in this chapter include the following:

- @size
- @defined
- @typeName
- @elements
- @elementSize

Without question, the @size function is probably the most important function in this group. Indeed, previous chapters have made use of this function already. The @size function accepts a single HLA identifier or constant expression as a parameter. It returns the size, in bytes, of the data type of that object (or expression). If you supply an identifier, it can be a constant, type, or variable identifier. HLA returns the size of the type of the object. As you've seen in previous chapters, this function is invaluable for allocating storage via *malloc* and allocating arrays.

Another very useful function in this group is the @defined function. This function accepts a single HLA identifier as a parameter, e.g.,

```
@defined(MyIdentifier)
```

This function returns true if the identifier is defined at that point in the program, it returns false otherwise.

The @typeName function returns a string specifying the type name of the identifier or expression you supply as a parameter. For example, if *i32* is an *int32* object, then "@typeName( i32 )" returns the string "int32". This function is useful for testing the types of objects you are processing in your compile-time programs.

The @elements function requires an array identifier or expression. It returns the total number of array elements as the function result. Note that for multi-dimensional arrays this function returns the product of all the array dimensions<sup>4</sup>.

The @elementSize function returns the size, in bytes, of an element of an array whose name you pass as a parameter. This function is extremely valuable for computing indices into an array (i.e., this function computes the *element\_size* component of the array index calculation, see "Accessing Elements of a Single Dimension Array" on page 447).

## 6.6.7 Compile-Time Expression Classification Functions

The HLA compile-time language provides functions that will classify some arbitrary text and determine if that text is a constant expression, a register, a memory operand, a type identifier, and more. Some of the more common functions are

- @isConst
- @isReg, @isReg8, @isReg16, @isReg32, @isFReg
- @isMem
- @isType

Except for @isType, which requires an HLA identifier as a parameter, these functions all take some arbitrary text as their parameter. These functions return true or false depending upon whether that parameter satisfies the function requirements (e.g., @isConst returns true if its parameter is a constant identifier or expression). The @isType function returns true if its parameter is a type identifier.

4. There is an @dim function that returns an array specifying the bounds on each dimension of a multidimensional array. See the appendices for more details if you're interested in this function.

The HLA compile-time language includes several other classification functions that are beyond the scope of this chapter. See Appendix H for details on those functions.

---

### 6.6.8 Miscellaneous Compile-Time Functions

The HLA compile-time language contains several additional functions that don't fall into one of the categories above. Some of the more useful miscellaneous functions include

- @odd
- @lineNumber
- @text

The @odd function takes an ordinal value (i.e., non-real numeric or character) as a parameter and returns true if the value is odd, false if it is even. The @lineNumber function requires no parameters, it returns the current line number in the source file. This function is quite useful for debugging compile-time (and run-time!) programs.

The @text function is probably the most useful function in this group. It requires a single string parameter. It expands that string as text in place of the @text function call. This function is quite useful in conjunction with the compile-time string processing functions. You can build an instruction (or a portion of an instruction) using the string manipulation functions and then convert that string to program source code using the @text function. The following is a trivial example of this function in operation:

```
?id1:string := "eax";
?id2:string := "i32";
@text("mov(" + id1 + ", " + id2 + ");")
```

The sequence above compiles to

```
mov(eax, i32);
```

---

### 6.6.9 Predefined Compile-Time Variables

In addition to functions, HLA also includes several predefined compile-time variables. The use of most of HLA's compile time variables is beyond the scope of this text. However, the following you've already seen:

- @bound
- @into

Volume Three (see "Some Additional Instructions: INTMUL, BOUND, INTO" on page 377) discusses the use of these objects to control the emission of the INTO and BOUND instructions. These two boolean pseudo-variables determine whether HLA will compile the BOUND (@bound) and INTO (@into) instructions or treat them as comments. By default, these two variables contain true and HLA will compile these instructions to machine code. However, if you set these values to false, using one or both of the following statements then HLA will not compile the associated statement:

```
?@bound := false;
?@into := false;
```

If you set @bound to false, then HLA treats BOUND instructions as though they were comments. If you set @into to false, then HLA treats INTO instructions as comments. You can control the emission of these statements throughout your program by selectively setting these pseudo-variables to true or false at different points in your code.

## 6.6.10 Compile-Time Type Conversions of TEXT Objects

Once you create a text constant in your program, it's difficult to manipulate that object. The following example demonstrates a programmer's desire to change the definition of a text symbol within a program:

```
val
 t:text := "stdout.put";
 .
 .
 .
 ?t:text := "fileio.put";
```

The basic idea in this example is that *t* expands to "stdout.put" in the first half of the code and it expands to "fileio.put" in the second half of the program. Unfortunately, this simple example will not work. The problem is that HLA will expand a text symbol in place almost anywhere it finds that symbol. This includes occurrences of *t* within the "?" statement above. Therefore, the code above expands to the following (incorrect) text:

```
val
 t:text := "stdout.put";
 .
 .
 .
 ?stdout.put:text := "fileio.put";
```

HLA doesn't know how to deal with the "?" statement above, so it generates a syntax error.

At times you may not want HLA to expand a text object. Your code may want to further process the string data held by the text object. HLA provides a couple of operators that deal with these two problems:

- @string:*identifier*
- @toString:*identifier*

The @string:*identifier* operator consists of @string, immediately followed by a colon and a text identifier (with no interleaving spaces or other characters). HLA returns a string constant corresponding to the text data associated with the text object. In other words, this operator lets you treat a text object as though it were a string constant within an expression.

Unfortunately, the @string operator converts a text object to a string constant, not a string identifier. Therefore, you cannot say something like

```
?@string:t := "Hello"
```

This doesn't work because @string:t replaces itself with the string constant associated with the text object *t*. Given the former assignment to *t*, this statement expands to

```
? "stdout.put" := "Hello";
```

This statement is still illegal.

The @toString:*identifier* operator comes to the rescue in this case. The @toString operator requires a text object as the associated identifier. It converts this text object to a string object (still maintaining the same string data) and then returns the identifier. Since the identifier is now a string object, you can assign a value to it (and change its type to something else, e.g., *text*, if that's what you need). To achieve the original goal, therefore, you'd use code like the following:

```
val
 t:text := "stdout.put";
 .
 .
 .
 ?@tostring:t : text := "fileio.put";
```

## 6.7 Conditional Compilation (Compile-Time Decisions)

HLA's compile-time language provides an IF statement, #IF, that lets you make various decisions at compile-time. The #IF statement has two main purposes: the traditional use of #IF is to support *conditional compilation* (or *conditional assembly*) allowing you to include or exclude code during a compilation depending on the status of various symbols or constant values in your program. The second use of this statement is to support the standard IF statement decision making process in the HLA compile-time language. This section will discuss these two uses for the HLA #IF statement.

The simplest form of the HLA compile-time #IF statement uses the following syntax:

```
#if(constant_boolean_expression)

 << text >>

#endif
```

Note that you do not place semicolons after the #ENDIF clause. If you place a semicolon after the #ENDIF, it becomes part of the source code and this would be identical to inserting that semicolon immediately before the next text item in the program.

At compile-time, HLA evaluates the expression in the parentheses after the #IF. This must be a constant expression and its type must be boolean. If the expression evaluates true, then HLA continues processing the text in the source file as though the #IF statement were not present. However, if the expression evaluates false, then HLA treats all the text between the #IF and the corresponding #ENDIF clause as though it were a comment (i.e., it ignores this text).

```
#if(constant_boolean_expression)
```

HLA compiles this code if the expression is true. Else HLA treats this code like a comment.

```
#endif
```

**Figure 6.1 Operation of HLA Compile-Time #IF Statement**

Keep in mind that HLA's constant expressions support a full expression syntax like you'd find in a high level language like C or Pascal. The #IF expression syntax is not limited as are expressions in the HLA IF statement. Therefore, it is perfectly reasonable to write fancy expressions like the following:

```
#if(@length(someStrConst) < 10 & (MaxItems < 100 | MinItems < 10))

 << text >>

#endif
```

Keep in mind that the items in a compile-time expression must all be CONST or VAL identifiers or an HLA compile-time function call (with appropriate parameters). In particular, remember that HLA evaluates these expressions at compile-time so they cannot contain run-time variables<sup>5</sup>. Also note that HLA's compile time language uses complete boolean evaluation, so any side effects that occur in the expression may produce undesired results.

5. Except, of course, as parameters to certain HLA compile-time functions like @size or @typeName.

The HLA #IF statement supports optional #ELSEIF and #ELSE clauses that behave in the intuitive fashion. The complete syntax for the #IF statement looks like the following:

```
#if(constant_boolean_expression1)

 << text1 >>

#elseif(constant_boolean_expression2)

 << text2 >>

#else

 << text3 >>

#endif
```

If the first boolean expression evaluates true then HLA processes the text up to the #ELSEIF clause. It then skips all text (i.e., treats it like a comment) until it encounters the #ENDIF clause. HLA continues processing the text after the #ENDIF clause in the normal fashion.

If the first boolean expression above evaluates false, then HLA skips all the text until it encounters a #ELSEIF, #ELSE, or #ENDIF clause. If it encounters a #ELSEIF clause (as above), then HLA evaluates the boolean expression associated with that clause. If it evaluates true, then HLA processes the text between the #ELSEIF and the #ELSE clauses (or to the #ENDIF clause if the #ELSE clause is not present). If, during the processing of this text, HLA encounters another #ELSEIF or, as above, a #ELSE clause, then HLA ignores all further text until it finds the corresponding #ENDIF.

If both the first and second boolean expressions in the example above evaluate false, then HLA skips their associated text and begins processing the text in the #ELSE clause. As you can see, the #IF statement behaves in a relatively intuitive fashion once you understand how HLA "executes" the body of these statements (that is, it processes the text or treats it as a comment depending on the state of the boolean expression). Of course, you can create a nearly infinite variety of different #IF statement sequences by including zero or more #ELSEIF clauses and optionally supplying the #ELSE clause. Since the construction is identical to the HLA IF..THEN..ELSEIF..ELSE..ENDIF statement, there is no need to elaborate further here.

A very traditional use of conditional compilation is to develop software that you can easily configure for several different environments. For example, the FCOMIP instruction makes floating point comparisons very easy but this instruction is available only on Pentium Pro and later processors. If you want to use this instruction on the processors that support it, and fall back to the standard floating point comparison on the older processors you would normally have to write two versions of the program - one with the FCOMIP instruction and one with the traditional floating point comparison sequence. Unfortunately, maintaining two different source files (one for newer processors and one for older processors) is very difficult. Most engineers prefer to use conditional compilation to embed the separate sequences in the same source file. The following example demonstrates how to do this.

```
const
 PentProOrLater: boolean := false; // Set true to use FCOMIxx instrs.
 .
 .
 .
#if(PentProOrLater)

 fcomip(); // Compare st1 to st0 and set flags.

#else

 fcomp(); // Compare st1 to st0.
 fstsw(ax); // Move the FPU condition code bits
 sahf(); // into the FLAGS register.
```

```
#endif
```

As currently written, this code fragment will compile the three instruction sequence in the `#ELSE` clause and ignore the code between the `#IF` and `#ELSE` clauses (because the constant `PentProOrLater` is false). By changing the value of `PentProOrLater` to true, you can tell HLA to compile the single `FCOMIP` instruction rather than the three-instruction sequence. Of course, you can use the `PentProOrLater` constant in other `#IF` statements throughout your program to control how HLA compiles your code.

Note that conditional compilation does not let you create a single *executable* that runs efficiently on all processors. When using this technique you will still have to create two executable programs (one for Pentium Pro and later processors, one for the earlier processors) by compiling your source file twice; during the first compilation you must set the `PentProOrLater` constant to false, during the second compilation you must set this constant to true. Although you must create two separate executables, you need only maintain a single source file.

If you are familiar with conditional compilation in other languages, such as the C/C++ language, you may be wondering if HLA supports a statement like C's `"#ifdef"` statement. The answer is no, it does not. However, you can use the HLA compile-time function `@DEFINED` to easily test to see if a symbol has been defined earlier in the source file. Consider the following modification to the above code that uses this technique:

```
const
// Note: uncomment the following line if you are compiling this
// code for a Pentium Pro or later CPU.

// PentProOrLater :=0; // Value and type are irrelevant
.
.
.
#if(@defined(PentProOrLater))

 fcomip(); // Compare st1 to st0 and set flags.

#else

 fcomp(); // Compare st1 to st0.
 fstsw(ax); // Move the FPU condition code bits
 sahf(); // into the FLAGS register.

#endif
```

Another common use of conditional compilation is to introduce debugging and testing code into your programs. A typical debugging technique that many HLA programmers use is to insert "print" statements at strategic points throughout their code in order to trace through their code and display important values at various checkpoints. A big problem with this technique is that they must remove the debugging code prior to completing the project. The software's customer (or a student's instructor) probably doesn't want to see debugging output in the middle of a report the program produces. Therefore, programmers who use this technique tend to insert code temporarily and then remove the code once they run the program and determine what is wrong. There are at least two problems with this technique:

- Programmers often forget to remove some debugging statements and this creates defects in the final program, and
- After removing a debugging statement, these programmers often discover that they need that same statement to debug some different problem at a later time. Hence they are constantly inserting, removing, and inserting the same statements over and over again.

Conditional compilation can provide a solution to this problem. By defining a symbol (say, *debug*) to control debug output in your program, you can easily activate or deactivate *all* debugging output by simply modifying a single line of source code. The following code fragment demonstrates this:

```
const
```

```

debug: boolean := false; // Set to true to activate debug output.
.
.
.
#if(debug)

 stdout.put("At line ", @lineNumber, " i=", i, nl);

#endif

```

As long as you surround all debugging output statements with a #IF statement like the one above, you don't have to worry about debug output accidentally appearing in your final application. By setting the *debug* symbol to false you can automatically disable all such output. Likewise, you don't have to remove all your debugging statements from your programs once they've served their immediate purpose. By using conditional compilation, you can leave these statements in your code because they are so easy to deactivate. Later, if you decide you need to view this same debugging information during a program run, you won't have to reenter the debugging statement - you simply reactivate it by setting the *debug* symbol to true.

We will return to this issue of inserting debugging code into your programs in the chapter on macros.

Although program configuration and debugging control are two of the more common, traditional, uses for conditional compilation, don't forget that the #IF statement provides the basic conditional statement in the HLA compile-time language. You will use the #IF statement in your compile-time programs the same way you would use an IF statement in HLA or some other language. Later sections in this text will present lots of examples of using the #IF statement in this capacity.

## 6.8 Repetitive Compilation (Compile-Time Loops)

HLA's #WHILE..#ENDWHILE statement provides a compile-time loop construct. The #WHILE statement tells HLA to repetitively process the same sequence of statements during compilation. This is very handy for constructing data tables (see "Constructing Data Tables at Compile Time" on page 968) as well as providing a traditional looping structure for compile-time programs. Although you will not employ the #WHILE statement anywhere near as often as the #IF statement, this compile-time control structure is very important when writing advanced HLA programs.

The #WHILE statement uses the following syntax:

```

#while(constant_boolean_expression)

 << text >>

#endwhile

```

When HLA encounters the #WHILE statement during compilation, it will evaluate the constant boolean expression. If the expression evaluates false, then HLA will skip over the text between the #WHILE and the #ENDWHILE clause (the behavior is similar to the #IF statement if the expression evaluates false). If the expression evaluates true, then HLA will process the statements between the #WHILE and #ENDWHILE clauses and then "jump back" to the start of the #WHILE statement in the source file and repeat this process.

```
#while(constant_boolean_expression)
```

HLA repetitively compiles this code as long as the expression is true. It effectively inserts multiple copies of this statement sequence into your source file (the exact number of copies depends on the value of the loop control expression).

```
#endwhile
```

---

**Figure 6.1 HLA Compile-Time #WHILE Statement Operation**

---

To understand how this process works, consider the following program:

---

```
program ctWhile;
#include("stdlib.hhf")

static
 ary: uns32[5] := [2, 3, 5, 8, 13];

begin ctWhile;

 ?i := 0;
 #while(i < 5)

 stdout.put("array[", i, "] = ", ary[i*4], nl);
 ?i := i + 1;

 #endwhile

end ctWhile;
```

---

**Program 6.2 #WHILE..#ENDWHILE Demonstration**

---

As you can probably surmise, the output from this program is the following:

```
array[0] = 2
array[1] = 3
array[2] = 4
array[3] = 5
array[4] = 13
```

What is not quite obvious is how this program generates this output. Remember, the #WHILE..#ENDWHILE construct is a compile-time language feature, not a run-time control construct. Therefore, the #WHILE loop above repeats five times during *compilation*. On each repetition of the loop, the HLA compiler processes the statements between the #WHILE and #ENDWHILE clauses. Therefore, the program above is really equivalent to the following:

---

```
program ctWhile;
#include("stdlib.hhf")

static
 ary: uns32[5] := [2, 3, 5, 8, 13];

begin ctWhile;

 stdout.put("array[", 0, "] = ", ary[0*4], nl);
 stdout.put("array[", 1, "] = ", ary[1*4], nl);
 stdout.put("array[", 2, "] = ", ary[2*4], nl);
 stdout.put("array[", 3, "] = ", ary[3*4], nl);
 stdout.put("array[", 4, "] = ", ary[4*4], nl);

end ctWhile;
```

---

---

**Program 6.3** Program Equivalent to the Code in Program 6.2

---

---

As you can see, the #WHILE statement is very convenient for constructing repetitive code sequences. This is especially invaluable for unrolling loops. Additional uses of the #WHILE loop appear in later sections of this text.

---

## 6.9 Putting It All Together

The HLA compile-time language provides considerable power. With the compile-time language you can automate the generation of tables, selectively compile code for different environments, easily unroll loops to improve performance, and check the validity of code you're writing. Combined with macros and other features that HLA provides, the compile-time language is probably the premier feature of the HLA language – no other assembler provides comparable features. For more information about the HLA compile time language, be sure to read the next chapter on macros.

---

# Macros

# Chapter Eight

---

## 7.1 Chapter Overview

This chapter continues where the previous chapter left off – continuing to discuss the HLA compile time language. This chapter discusses what is, perhaps, the most important component of the HLA compile-time language, macros. Many people judge the power of an assembler by the power of its macro processing capabilities. If you happen to be one of these people, you'll probably agree that HLA is one of the more powerful assemblers on the planet after reading this chapter; because HLA has one of the most powerful macro processing facilities of any computer language processing system.

---

## 7.2 Macros (Compile-Time Procedures)

Macros are symbols that a language processor replaces with other text during compilation. Macros are great devices for replacing long repetitive sequences of text with much shorter sequences of text. In addition to the traditional role that macros play (e.g., "#define" in C/C++), HLA's macros also serve as the equivalent of a compile-time language procedure or function. Therefore, macros are very important in HLA's compile-time language; just as important as functions and procedures are in other high level languages.

Although macros are nothing new, HLA's implementation of macros far exceeds the macro processing capabilities of other programming languages. The following sections explore HLA's macro processing facilities and the relationship between macros and other HLA CTL control constructs.

---

### 7.2.1 Standard Macros

HLA supports a straight-forward macro facility that lets you define macros in a manner that is similar to declaring a procedure. A typical, simple, macro declaration takes the following form:

```
macro macroname;

 << macro body >>

endmacro;
```

Although macro and procedure declarations are similar, there are several immediate differences between the two that are obvious from this example. First, of course, macro declarations use the reserved word `MACRO` rather than `PROCEDURE`. Second, you do not begin the body of the macro with a "`BEGIN macroname;`" clause. This is because macros don't have a declaration section like procedures so there is no need for a keyword that separates the macro declarations from the macro body. Finally, you will note that macros end with the "`ENDMACRO;`" clause rather than "`END macroname;`" The following is a concrete example of a macro declaration:

```
macro neg64;

 neg(edx);
 neg(eax);
 sbb(0, edx);

endmacro;
```

Execution of this macro's code will compute the two's complement of the 64-bit value in EDX:EAX (see "Extended Precision NEG Operations" on page 846).

To execute the code associated with *neg64*, you simply specify the macro's name at the point you want to execute these instructions, e.g.,

```
mov((type dword i64), eax);
mov((type dword i64+4), edx);
neg64;
```

Note that you do *not* follow the macro's name with a pair of empty parentheses as you would a procedure call (the reason for this will become clear a little later).

Other than the lack of parentheses following *neg64*'s invocation<sup>1</sup> this looks just like a procedure call. You could implement this simple macro as a procedure using the following procedure declaration:

```
procedure neg64p;
begin neg64p;

 neg(edx);
 neg(eax);
 sbb(0, edx);

end neg64p;
```

Note that the following two statements will both negate the value in EDX:EAX:

```
neg64; neg64p();
```

The difference between these two (i.e., the macro invocation versus the procedure call) is the fact that macros expand their text in-line whereas a procedure call emits a call to the associate procedure elsewhere in the text. That is, HLA replaces the invocation "neg64;" directly with the following text:

```
neg(edx);
neg(eax);
sbb(0, edx);
```

On the other hand, HLA replaces the procedure call "neg64p();" with the single call instruction:

```
call neg64p;
```

Presumably, you've defined the *neg64p* procedure earlier in the program.

You should make the choice of macro versus procedure call on the basis of efficiency. Macros are slightly faster than procedure calls because you don't execute the CALL and corresponding RET instructions. On the other hand, the use of macros can make your program larger because a macro invocation expands to the text in the body of the macro on each invocation. Procedure calls jump to a single instance of the procedure's body. Therefore, if the macro body is large and you invoke the macro several times throughout your program, it will make your final executable much larger. Also, if the body of your macro executes more than a few simple instructions, the overhead of a CALL/RET sequence has little impact on the overall execution time of the code, so the execution time savings are nearly negligible. On the other hand, if the body of a procedure is very short (like the *neg64* example above), you'll discover that the macro implementation is much faster and doesn't expand the size of your program by much. Therefore, a good rule of thumb is

- ❑ **Use macros for short, time-critical program units. Use procedures for longer blocks of code and when execution time is not as critical.**

Macros have many other disadvantages over procedures. Macros cannot have local (automatic) variables, macro parameters work differently than procedure parameters, macros don't support (run-time) recur-

---

1. To differentiate macros and procedures, this text will use the term *invocation* when describing the use of a macro and *call* when describing the use of a procedure.

sion, and macros are a little more difficult to debug than procedures (just to name a few disadvantages). Therefore, you shouldn't really use macros as a substitute for procedures except in some rare situations.

---

## 7.2.2 Macro Parameters

Like procedures, macros let you define parameters that let you supply different data on each macro invocation. This lets you write generic macros whose behavior can vary depending on the parameters you supply. By processing these macro parameters at compile-time, you can write very sophisticated macros.

Macro parameter declaration syntax is very straight-forward. You simply supply a list of parameter names within parentheses in a macro declaration:

```
macro neg64 (reg32HO, reg32LO);

 neg (reg32HO);
 neg (reg32LO);
 sbb (0, reg32HO);

endmacro;
```

Note that you do not associate a data type with a macro parameter like you do procedural parameters. This is because HLA macros are always *text* objects. The next section will explain the exact mechanism HLA uses to substitute an actual parameter for a formal parameter.

When you invoke a macro, you simply supply the actual parameters the same way you would for a procedure call:

```
neg64 (edx, eax);
```

Note that a macro invocation that requires parameters expects you to enclose the parameter list within parentheses.

---

### 7.2.2.1 Standard Macro Parameter Expansion

As the previous section explains, HLA automatically associates the type *text* with macro parameters. This means that during a macro expansion, HLA substitutes the text you supply as the actual parameter everywhere the formal parameter name appears. The semantics of "pass by textual substitution" are a little different than "pass by value" or "pass by reference" so it is worthwhile exploring those differences here.

Consider the following macro invocations, using the *neg64* macro from the previous section:

```
neg64 (edx, eax);
neg64 (ebx, ecx);
```

These two invocations expand into the following code:

```
// neg64 (edx, eax);

 neg (edx);
 neg (eax);
 sbb (0, edx);

// neg64 (ebx, ecx);

 neg (ebx);
 neg (ecx);
 sbb (0, ebx);
```

Note that macro invocations do not make a local copy of the parameters (as pass by value does) nor do they pass the address of the actual parameter to the macro. Instead, a macro invocation of the form "neg64( edx, eax );" is equivalent to the following:

```
?reg32HO: text := "edx";
?reg32LO: text := "eax";

neg(reg32HO);
neg(reg32LO);
sbb(0, reg32HO);
```

Of course, the text objects immediately expand their string values in-line, producing the former expansion for "neg64( edx, eax );".

Note that macro parameters are not limited to memory, register, or constant operands as are instruction or procedure operands. Any text is fine as long as its expansion is legal wherever you use the formal parameter. Similarly, formal parameters may appear anywhere in the macro body, not just where memory, register, or constant operands are legal. Consider the following macro declaration and sample invocations:

```
macro chkError(instr, jump, target);

 instr;
 jump target;

endmacro;

chkError(cmp(eax, 0), jnl, RangeError); // Example 1
...
chkError(test(1, bl), jnz, ParityError); // Example 2

// Example 1 expands to

 cmp(eax, 0);
 jnl RangeError;

// Example 2 expands to

 test(1, bl);
 jnz ParityError;
```

In general, HLA assumes that all text between commas constitutes a single macro parameter. If HLA encounters any opening "bracketing" symbols (left parentheses, left braces, or left brackets) then it will include all text up to the appropriate closing symbol, ignoring any commas that may appear within the bracketing symbols. This is why the *chkError* invocations above treat "cmp( eax, 0 )" and "test( 1, bl )" as single parameters rather than as a pair of parameters. Of course, HLA does not consider commas (and bracketing symbols) within a string constant as the end of an actual parameter. So the following macro and invocation is perfectly legal:

```
macro print(strToPrint);

 stdout.out(strToPrint);

endmacro;

.
.
.
print("Hello, world!");
```

HLA treats the string "Hello, world!" as a single parameter since the comma appears inside a literal string constant, just as your intuition suggests.

If you are unfamiliar with textual macro parameter expansion in other languages, you should be aware that there are some problems you can run into when HLA expands your actual macro parameters. Consider the following macro declaration and invocation:

```
macro Echo2nTimes(n, theStr);

 ?echoCnt: uns32 := 0;
 #while(echoCnt < n*2)

 #print(theStr)
 ?echoCnt := echoCnt + 1;

 #endwhile

endmacro;

.
.
.
Echo2nTimes(3+1, "Hello");
```

This example displays "Hello" five times during compilation rather than the eight times you might intuitively expect. This is because the #WHILE statement above expands to

```
#while(echoCnt < 3+1*2)
```

The actual parameter for *n* is "3+1", since HLA expands this text directly in place of *n*, you get the text above. Of course, at compile time HLA computes "3+1\*2" as the value five rather than as the value eight (which you would get had HLA passed this parameter by value rather than by textual substitution).

The common solution to this problem, when passing numeric parameters that may contain compile-time expressions, is to surround the formal parameter in the macro with parentheses. E.g., you would rewrite the macro above as follows:

```
macro Echo2nTimes(n, theStr);

 ?echoCnt: uns32 := 0;
 #while(echoCnt < (n)*2)

 #print(theStr)
 ?echoCnt := echoCnt + 1;

 #endwhile

endmacro;
```

The previous invocation would expand to the following code:

```
?echoCnt: uns32 := 0;
#while(echoCnt < (3+1)*2)

 #print(theStr)
 ?echoCnt := echoCnt + 1;

#endwhile
```

This version of the macro produces the intuitive result.

If the number of actual parameters does not match the number of formal parameters, HLA will generate a diagnostic message during compilation. Like procedures, the number of actual parameters must agree with the number of formal parameters. If you would like to have optional macro parameters, then keep reading...

### 7.2.2.2 Macros with a Variable Number of Parameters

You may have noticed by now that some HLA macros don't require a fixed number of parameters. For example, the *stdout.put* macro in the HLA Standard Library allows one or more actual parameters. HLA uses a special array syntax to tell the compiler that you wish to allow a variable number of parameters in a macro parameter list. If you follow the last macro parameter in the formal parameter list with "[ ]" then HLA will allow a variable number of actual parameters (zero or more) in place of that formal parameter. E.g.,

```
macro varParms(varying[]);

 << macro body >>

endmacro;

.
.
.
varParms(1);
varParms(1, 2);
varParms(1, 2, 3);
varParms();
```

Note, especially, the last example above. If a macro has any formal parameters, you must supply parentheses with the macro list after the macro invocation. This is true even if you supply zero actual parameters to a macro with a varying parameter list. Keep in mind this important difference between a macro with no parameters and a macro with a varying parameter list but no actual parameters.

When HLA encounters a formal macro parameter with the "[ ]" suffix (which must be the last parameter in the formal parameter list), HLA creates a constant string array and initializes that array with the text associated with the remaining actual parameters in the macro invocation. You can determine the number of actual parameters assigned to this array using the `@ELEMENTS` compile-time function. For example, "`@elements( varying )`" will return some value, zero or greater, that specifies the total number of parameters associated with that parameter. The following declaration for *varParms* demonstrates how you might use this:

```
macro varParms(varying[]);

 ?vpCnt := 0;
 #while(vpCnt < @elements(varying)

 #print(varying[vpCnt])
 ?vpCnt := vpCnt + 1;

 #endwhile

endmacro;

.
.
.
varParms(1); // Prints "1" during compilation.
varParms(1, 2); // Prints "1" and "2" on separate lines.
varParms(1, 2, 3); // Prints "1", "2", and "3" on separate lines.
varParms(); // Doesn't print anything.
```

Since HLA doesn't allow arrays of *text* objects, the varying parameter must be an array of strings. This, unfortunately, means you must treat the varying parameters differently than you handle standard macro parameters. If you want some element of the varying string array to expand as text within the macro body, you can always use the `@TEXT` function to achieve this. Conversely, if you want to use a non-varying for-

mal parameter as a string object, you can always use the @STRING:name operator. The following example demonstrates this:

```
macro ReqAndOpt(Required, optional[]);

 ?@text(optional[0]) := @string:ReqAndOpt;
 #print(@text(optional[0]))

endmacro;

.
.
.
ReqAndOpt(i, j);

// The macro invocation above expands to

?@text("j") := @string:i;
#print("j")

// The above further expands to

j := "i";
#print(j)

// The above simply prints "i" during compilation.
```

Of course, it would be a good idea, in a macro like the above, to verify that there are at least two parameters before attempting to reference element zero of the *optional* parameter. You can easily do this as follows:

```
macro ReqAndOpt(Required, optional[]);

 #if(@elements(optional) > 0)

 ?@text(optional[0]) := @string:ReqAndOpt;
 #print(@text(optional[0]))

 #else

 #error("ReqAndOpt must have at least two parameters")

 #endif

endmacro;
```

---

### 7.2.2.3 Required Versus Optional Macro Parameters

As noted in the previous section, HLA requires exactly one actual parameter for each non-varying formal macro parameter. If there is no varying macro parameter (and there can be at most one) then the number of actual parameters must exactly match the number of formal parameters. If a varying formal parameter is present, then there must be at least as many actual macro parameters as there are non-varying (or required) formal macro parameters. If there is a single, varying, actual parameter, then a macro invocation may have zero or more actual parameters.

There is one big difference between a macro invocation of a macro with no parameters and a macro invocation of a macro with a single, varying, parameter that has no actual parameters: the macro with the

varying parameter list must have an empty set of parentheses after it while the macro invocation of the macro without any parameters does not allow this. You can use this fact to your advantage if you wish to write a macro that doesn't have any parameters but you want to follow the macro invocation with "(") so that it matches the syntax of a procedure call with no parameters. Consider the following macro:

```
macro neg64(JustForTheParens[]);

 #if(@elements(JustForTheParens) = 0)

 neg(edx);
 neg(eax);
 sbb(0, edx);

 #else

 #error("Unexpected operand(s)")

 #endif

endmacro;
```

The macro above allows invocations of the form "neg64();" using the same syntax you would use for a procedure call. This feature is useful if you want the syntax of your parameterless macro invocations to match the syntax of a parameterless procedure call. It's not a bad idea to do this, just in the off chance you need to convert the macro to a procedure at some point (or vice versa, for that matter).

If, for some reason, it is more convenient to operate on your macro parameters as *string* objects rather than *text* objects, you can specify a single varying parameter for the macro and then use #IF and @ELEMENTS to enforce the number of required actual parameters.

### 7.2.2.4 The "#(" and ")#" Macro Parameter Brackets

Once in a (really) great while, you may want to include arbitrary commas (i.e., outside a bracketing pair) within a macro parameter. Or, perhaps, you might want to include other text as part of a macro expansion that HLA would normally process before storing away the text as the value for the formal parameter<sup>2</sup>. The "#(" and ")#" bracketing symbols tell HLA to collect all text, except for surrounding whitespace, between these two symbols and treat that text as a single parameter. Consider the following macro:

```
macro PrintName(theParm);

 ?theName := @string:theParm;
 #print(theName)

endmacro;
```

Normally, this macro will simply print the text of the actual parameter you pass to it. So were you to invoke the macro with "PrintName( j );" HLA would simply print "j" during compilation. This occurs because HLA associates the parameter data ("j") with the string value for the text object *theParm*. The macro converts this text data to a string, puts the string data in *theName*, and then prints this string.

Now consider the following statements:

```
?tt:text := "j";
PrintName(tt);
```

This macro invocation will also print "j". The reason is that HLA expands text constants immediately upon encountering them. So after this expansion, the invocation above is equivalent to

2. For example, HLA will normally expand all *text* objects prior to the creation of the data for the formal parameter. You might not want this expansion to occur.

```
PrintName(j);
```

So this macro invocation prints "j" for the same reason the last example did.

What if you want the macro to print "tt" rather than "j"? Unfortunately, HLA's *eager* evaluation of the text constant gets in the way here. However, if you bracket "tt" with the "#(" and ")"# brackets, you can instruct HLA to *defer* the expansion of this text constant until it actually expands the macro. I.e., the following macro invocation prints "tt" during compilation:

```
PrintName(#(tt)#);
```

Note that HLA allows any amount of arbitrary text within the "#(" and ")"# brackets. This can include commas and other arbitrary text. The following macro invocation prints "Hello, World!" during compilation:

```
PrintName(#(Hello, World!)#);
```

Normally, HLA would complain about the mismatched number of parameters since the comma would suggest that there are two parameters here. However, the deferred evaluation brackets tell HLA to consider all the text between the "#(" and ")"#" symbols as a single parameter.

### 7.2.2.5 Eager vs. Deferred Macro Parameter Evaluation

HLA uses two schemes to process macro parameters. As you saw in the previous section, HLA uses *eager* evaluation when processing text constants appearing in a macro parameter list. You can force *deferred* evaluation of the text constant by surrounding the text with the "#(" and ")"# brackets. For other types of operands, HLA uses deferred macro parameter evaluation. This section discusses the difference between these two forms and describes how to force eager evaluation if necessary.

Eager evaluation occurs while HLA is collecting the text associated with each macro parameter. For example, if "T" is a text constant containing the string "U" and "M" is a macro, then when HLA encounters "M(T)" it will first expand "T" to "U". Then HLA processes the macro invocation "M(U)" as though you had supplied the text "U" as the parameter to begin with.

Deferred evaluation of macro parameters means that HLA does not process the parameter(s), but rather passes the text unchanged to the macro. Any expansion of the text associated with macro parameters occurs within the macro itself. For example, if M and N are both macros accepting a single parameter, then the invocation "M( N( 0 ) )" defers the evaluation of "N(0)" until HLA processes the macro body. It does not evaluate "N(0)" first and pass this expansion on to the macro. The following program demonstrates eager and deferred evaluation:

```
// This program demonstrates the difference
// between deferred and eager macro parameter
// processing.

program EagerVsDeferredEvaluation;

macro ToDefer(tdParm);

 #print("ToDefer: ", @string:tdParm)
 @string:tdParm

endmacro;

macro testEVD(theParm);

 #print("testEVD:'", @string:theParm, "' ")
```

```

endmacro;

const

 txt:text := "Hello";
 str:string := "there";

begin EagerVsDeferredEvaluation;

 testEVD(str); // Deferred evaluation.
 testEVD(txt); // Eager evaluation.
 testEVD(ToDefer(World)); //Deferred evaluation.

end EagerVsDeferredEvaluation;

```

---

---

### Program 7.1 Eager vs. Deferred Macro Parameter Evaluation

---

---

Note that the macro *testEVD* outputs the text associated with the formal parameter as a string during compilation. When you compile Program 7.1 it produces the following output:

```

testEVD:'Hello'
testEVD:'Hello'
testEVD:'ToDefer(World)'

```

The first line prints 'Hello' because this is the text supplied as a parameter for the first call to *testEVD*. Since this is a string constant, not a text constant, HLA uses deferred evaluation. This means that it passes the text appearing between the parentheses unchanged to the *testEVD* macro. That text is "Hello" hence the same output as the parameter text.

The second *testEVD* invocation prints 'Hello'. This is because the macro parameter, *txt*, is a text object. HLA eagerly processes text constants before invoking the macro. Therefore, HLA translates "testEVD(txt)" to "testEVD(Hello)" prior to invoking the macro. Since the macro parameter text is now "Hello", that's what HLA prints during compilation while processing this macro.

The third invocation of *testEVD* above is semantically identical to the first. It is present just to demonstrate that HLA defers processing macros just like it defers the processing of everything else except text constants.

Although the code in Program 7.1 does not actually evaluate the *ToDefer* macro invocation, this is only because the body of *testEVD* does not directly use the parameter. Instead, it converts *theParm* to a string and prints its value. Had this code actually referred to *theParm* in an expression (or as a statement), then HLA would have invoked *ToDefer* and let it do its job. Consider the following modification to the above program:

---

---

```

// This program demonstrates the difference
// between deferred and eager macro parameter
// processing.

program DeferredEvaluation;

macro ToDefer(tdParm);

 @string:tdParm

endmacro;

```

```

macro testEVD(theParm);

 #print("Hello ", theParm)

endmacro;

begin DeferredEvaluation;

 testEVD(ToDefer(World));

end DeferredEvaluation;

```

---

## Program 7.2 Deferred Macro Parameter Expansion

---

The macro invocation "testEVD( ToDefer( World ));" defers the evaluation of its parameter. Therefore, the actual parameter *theParm* is a text object containing the string "ToDefer( World )". Inside the testEVD macro, HLA encounters theParm and expands it to this string, i.e.,

```
#print("Hello ", theParm)
```

expands to

```
#print("Hello ", ToDefer(World))
```

When HLA processes the #PRINT statement, it eagerly processes all parameters. Therefore, HLA expands the statement above to

```
#print("Hello ", "World")
```

since "ToDefer( World )" expands to *@string:tdParm* and that expands to "World".

Most of the time, the choice between deferred and eager evaluation produces the same result. In Program 7.2, for example, it doesn't matter whether the *ToDefer* macro expansion is eager (thus passing the string "World" as the parameter to *testEVD*) or deferred. Either mechanism produces the same output.

There are situations where deferred evaluation is not interchangeable with eager evaluation. The following program demonstrates a problem that can occur when you use deferred evaluation rather than eager evaluation. In this example the program attempts to pass the current line number in the source file as a parameter to a macro. This does not work because HLA expands (and evaluates) the @LINENUMBER function call inside the macro on every invocation. Therefore, this program always prints the same line number (eight) regardless of the invocation line number:

---

```

// This program a situation where deferred
// evaluation fails to work properly.

program DeferredFails;

macro printAt(where);

 #print("at line ", where)

endmacro;

begin DeferredFails;

 printAt(@linenumber);
 printAt(@lineNumber);

```

```
end DeferredFails;
```

---

---

### Program 7.3 An Example Where Deferred Evaluation Fails to Work Properly

---

---

Intuitively, this program should print:

```
at line 14
at line 15
```

Unfortunately, because of deferred evaluation, the two *printAt* invocations simply pass the text "@linenumber" as the actual parameter value rather than the string representing the line numbers of these two statements in the program. Since the formal parameter always expands to @LINENUMBER on the same line (line eight), this program always prints the same line number regardless of the line number of the macro invocation.

If you need an eager evaluation of a macro parameter there are three ways to achieve this. First of all, of course, you can specify a *text* object as a macro parameter and HLA will immediately expand that object prior to passing it as the macro parameter. The second option is to use the @TEXT function (with a string parameter). HLA will also immediately process this object, expanding it to the appropriate text, prior to processing that text as a macro parameter. The third option is to use the @EVAL pseudo-function. Within a macro invocation's parameter list, the @EVAL function instructs HLA to evaluate the @EVAL parameter prior to passing the text to the macro. Therefore, you can correct the problem in Program 7.3 by using the following code (which properly prints at "at line 14" and "at line 15"):

---

---

```
// This program a situation where deferred
// evaluation fails to work properly.

program EvalSucceeds;

macro printAt(where);

 #print("at line ", where)

endmacro;

begin EvalSucceeds;

 printAt(@eval(@linenumber));
 printAt(@eval(@lineNumber));

end EvalSucceeds;
```

---

---

### Program 7.4 Demonstration of @EVAL Compile-time Function

---

---

In addition to immediately processing built-in compiler functions like @LINENUMBER, the @EVAL pseudo-function will also invoke any macros appearing in the @EVAL parameter. @EVAL usually leaves other values unchanged.

---

## 7.2.3 Local Symbols in a Macro

Consider the following macro declaration:

```
macro JZC(target);
```

```

 jnz NotTarget;
 jc target;
NotTarget:

endmacro;

```

The purpose of this macro is to simulate an instruction that jumps to the specified target location if the zero flag is set *and* the carry flag is set. Conversely, if either the zero flag is clear or the carry flag is clear this macro transfers control to the instruction immediately following the macro invocation.

There is a serious problem with this macro. Consider what happens if you use this macro more than once in your program:

```

 JZC(Dest1);
 .
 .
 .
 JZC(Dest2);
 .
 .
 .

```

The macro invocations above expand to the following code:

```

 jnz NotTarget;
 jc Dest1;
NotTarget:
 .
 .
 .
 jnz NotTarget;
 jc Dest2;
NotTarget:
 .
 .
 .

```

The problem with the expansion of these two macro invocations is that they both emit the same label, *NotTarget*, during macro expansion. When HLA processes this code it will complain about a duplicate symbol definition. Therefore, you must take care when defining symbols inside a macro because multiple invocations of that macro may lead to multiple definitions of that symbol.

HLA's solution to this problem is to allow the use of *local symbols* within a macro. Local macro symbols are unique to a specific invocation of a macro. For example, had *NotTarget* been a local symbol in the *JZC* macro invocations above, the program would have compiled properly since HLA treats each occurrence of *NotTarget* as a unique symbol.

HLA does not automatically make internal macro symbol definitions local to that macro<sup>3</sup>. Instead, you must explicitly tell HLA which symbols must be local. You do this in a macro declaration using the following generic syntax:

```

macro macroname (optional_parameters) : optional_list_of_local_names ;
 << macro body >>
endmacro;

```

The list of local names is a sequence of one or more HLA identifiers separated by commas. Whenever HLA encounters this name in a particular macro invocation it automatically substitutes some unique name for that identifier. For each macro invocation, HLA substitutes a different name for the local symbol.

You can correct the problem with the *JZC* macro by using the following macro code:

---

3. Sometimes you actually want the symbols to be global.

```
macro JZC(target):NotTarget;

 jnz NotTarget;
 jc target;
 NotTarget:

endmacro;
```

Now whenever HLA processes this macro it will automatically associate a unique symbol with each occurrence of *NotTarget*. This will prevent the duplicate symbol error that occurs if you do not declare *NotTarget* as a local symbol.

HLA implements local symbols by substituting a symbol of the form "*\_nnnn\_*" (where *nnnn* is a four-digit hexadecimal number) wherever the local symbol appears in a macro invocation. For example, a macro invocation of the form "JZC( SomeLabel );" might expand to

```
 jnz _010A_;
 jc SomeLabel;
010A:
```

For each local symbol appearing within a macro expansion HLA will generate a unique temporary identifier by simply incrementing this numeric value for each new local symbol it needs. As long as you do not explicitly create labels of the form "*\_nnnn\_*" (where *nnnn* is a hexadecimal value) there will never be a conflict in your program. HLA explicitly reserves all symbols that begin and end with a single underscore for its own private use (and for use by the HLA Standard Library). As long as you honor this restriction, there should be no conflicts between HLA local symbol generation and labels in your own programs since all HLA-generated symbols begin and end with a single underscore.

HLA implements local symbols by effectively converting that local symbol to a text constant that expands to the unique symbol HLA generates for the local label. That is, HLA effectively treats local symbol declarations as indicated by the following example:

```
macro JZC(target);
 ?NotTarget:text := "_010A_";

 jnz NotTarget;
 jc target;
 NotTarget:

endmacro;
```

Whenever HLA expands this macro it will substitute "*\_010A\_*" for each occurrence of *NotTarget* it encounters in the expansion. This analogy isn't perfect because the text symbol *NotTarget* in this example is still accessible after the macro expansion whereas this is not the case when defining local symbols within a macro. But this does give you an idea of how HLA implements local symbols.

One important consequence of HLA's implementation of local symbols within a macro is that HLA will produce some puzzling error messages if an error occurs on a line that uses a local symbol. Consider the following (incorrect) macro declaration:

```
macro LoopZC(TopOfLoop): ExitLocation;

 jnz ExitLocation;
 jc TopOfLoop;

endmacro;
```

Note that in this example the macro does not define the *ExitLocation* symbol even though there is a jump (JNZ) to this label. If you attempt to compile this program, HLA will complain about an undefined statement label and it will state that the symbol is something like "*\_010A\_*" rather than *ExitLocation*.

Locating the exact source of this problem can be challenging since HLA cannot report this error until the end of the procedure or program in which *LoopZC* appears (long after you've invoked the macro). If you

have lots of macros with lots of local symbols, locating the exact problem is going to be a lot of work; your only option is to carefully analyze the macros you do call (perhaps by commenting them out of your program one by one until the error goes away) to discover the source of the problem. Once you determine the offending macro, the next step is to determine which local symbol is the culprit (if the macro contains more than one local symbol). Because tracking down bugs associated with local symbols can be tough, you should be especially careful when using local symbols within a macro.

Because local symbols are effectively text constants, don't forget that HLA eagerly processes any local symbols you pass as parameters to other macros. To see this effect, consider the following sample program:

---

---

```
// LocalDemo.HLA
//
// This program demonstrates the effect
// of passing a local macro symbol as a
// parameter to another macro. Remember,
// local macro symbols are text constants
// so HLA eager evaluates them when they
// appear as macro parameters.

program LocalExpansionDemo;

macro printIt(what);

 #print(@string:what)
 #print(what)

endmacro;

macro LocalDemo:local;

 ?local:string := "localStr";

 printIt(local); // Eager evaluation, passes "_nnnn_".
 printIt(#(local)#) // Force deferred evaluation, passes "local".

endmacro;

begin LocalExpansionDemo;

 LocalDemo;

end LocalExpansionDemo;
```

---

---

### Program 7.5 Local Macro Symbols as Macro Parameters

---

---

Inside *LocalDemo* HLA associates the unique symbol "\_0001\_" (or something similar) with the local symbol *local*. Next, HLA defines "\_0001\_" to be a string constant and associates the text "localStr" with this constant.

The first *printIt* macro invocation expands to "printIt( \_0001\_ )" because HLA eagerly processes text constants in macro parameter lists (remember, local symbols are, effectively, text constants). Therefore, *printIt's* *what* parameter contains the text "\_0001\_" for this first invocation. Therefore, the first #PRINT statement prints this textual data ("\_0001\_") and the second print statement prints the value associated with "\_0001\_" which is "localStr".

The second *printIt* macro invocation inside the *LocalDemo* macro explicitly forces HLA to use deferred evaluation since it surrounds *local* with the "#(" and ")"# bracketing symbols. Therefore, HLA associates the text "local" with *printIt's* formal parameter rather than the expansion "\_0001\_". Inside *printIt*, the first

#PRINT statement displays the text associated with the *what* parameter (which is "local" at this point). The second #PRINT statement expands *what* to produce "local". Since *local* is a currently defined text constant (defined within *LocalDemo* that invokes *printIt*), HLA expands this text constant to produce "\_0001\_". Since "\_0001\_" is a string constant, HLA prints the specified string ("localStr") during compilation. The complete output during compilation is

```
0001
localStr
local
localStr
```

Discussing the expansion of local symbols may seem like a lot of unnecessary detail. However, as your macros become more complex you may run into difficulties with your code based on the way HLA expands local symbols. Hence it is necessary to have a good grasp on how HLA processes these symbols.

Quick tip: if you ever need to generate a unique label in your program, you can use HLA local symbol facility to achieve this. Normally, you can only reference HLA's local symbols within the macro that defines the symbol. However, you can convert that local symbol to a string and process that string in your program as the following simple program demonstrates:

---

```
// UniqueSymbols.HLA
//
// This program demonstrates how to generate
// unique symbols in a program.

program UniqueSymsDemo;

macro unique:theSym;

 @string:theSym

endmacro;

begin UniqueSymsDemo;

 ?label:text := unique;

 jmp label;

label:

 ?@tostring:label :text := unique;
 jmp label;

label:

end UniqueSymsDemo;
```

---

### Program 7.6 A Macro That Generates Unique Symbols for a Program

---

The first instance of *label:* in this program expands to "\_0001\_:" while the second instance of *label:* in this program expands to "\_0003\_:". Of course, reusing symbols in this manner is horrible programming style (it's very confusing), but there are some cases you'll encounter when writing advanced macros where you will want to generate a unique symbol for use in your program. The *unique* macro in this program demonstrates exactly how to do this.

## 7.2.4 Macros as Compile-Time Procedures

Although programmers typically use macros to expand to some sequence of machine instructions, there is absolutely no requirement that a macro body contain any executable instructions. Indeed, many macros contain only compile-time language statements (e.g., #IF, #WHILE, "?" assignments, etc.). By placing only compile-time language statements in the body of a macro, you can effectively write compile-time procedures and functions using macros.

The *unique* macro from the previous section is a good example of a compile-time function that returns a string result. Consider, again, the definition of this macro:

```
macro unique:theSym;

 @string:theSym

endmacro;
```

Whenever your code references this macro, HLA replaces the macro invocation with the text "@string:theSym" which, of course, expands to some string like "\_021F\_". Therefore, you can think of this macro as a compile-time function that returns a string result.

Be careful that you don't take the function analogy too far. Remember, macros always expand to their body text at the point of invocation. Some expansions may not be legal at any arbitrary point in your programs. Fortunately, most compile-time statements are legal anywhere whitespace is legal in your programs. Therefore, macros generally behave as you would expect functions or procedures to behave during the execution of your compile-time programs.

Of course, the only difference between a procedure and a function is that a function returns some explicit value while procedures simply do some activity. There is no special syntax for specifying a compile-time function return value. As the example above indicates, simply specifying the value you wish to return as a statement in the macro body suffices. A compile-time procedure, on the other hand, would not contain any non-compile-time language statements that expand into some sort of data during macro invocation.

## 7.2.5 Multi-part (Context-Free) Macros

HLA's macro facilities, as described up to this point, are not particularly amazing. Indeed, most assemblers provide macro facilities very similar to those this chapter presents up to this point. Earlier, this chapter made the claim that HLA's macro facilities are quite a bit more powerful than those found in other assembly languages (or any programming language for that matter). Part of this power comes from the synergy that exists between the HLA compile-time language and HLA's macros. However, the one feature that sets HLA's macro facilities apart from all others is HLA's ability to handle multi-part, or context-free<sup>4</sup>, macros. This section describes this powerful feature.

The best way to introduce HLA's context-free macro facilities is via an example. Suppose you wanted to create a macro to define a new high level language statement in HLA (a very common use for macros). Let's say you wanted to create a statement like the following:

```
nLoop(10)

 << body >>

endloop;
```

---

4. The term "context-free" is an automata theory term used to describe constructs, like programming language control structures, that allow nesting.

The basic idea is that this code would execute the body of the loop ten times (or however many times the *nLoop* parameter specifies). A typical low-level implementation of this control structure might take the following form:

```

 mov(10, ecx);
UniqueLabel:

 << body >>

 dec(ecx);
 jne UniqueLabel;

```

Clearly it will require two macros (*nLoop* and *endloop*) to implement this control structure. The first attempt a beginner might try is doomed to failure:

```

macro nLoop(cnt);
 mov(cnt, ecx);
UniqueLabel:

endmacro;

macro endloop;
 dec(ecx);
 jne UniqueLabel;
endmacro;

```

You've already seen the problem with this pair of macros: they use a global target label. Any attempt to use the *nLoop* macro more than once will result in a duplicate symbol error. Previously, we utilized HLA's local symbol facilities to overcome this problem. However, that approach will not work here because local symbols are local to a specific macro invocation; unfortunately, the *endloop* macro needs to reference *UniqueLabel* inside the *nLoop* invocation, so *UniqueLabel* cannot be a local symbol in this example.

A quick and dirty solution might be to take advantage of the trick employed by the *unique* macro appearing in previous sections. By utilizing a global text constant, you can share the label information across two macros using an implementation like the following:

```

macro nLoop(cnt):UniqueLabel;

 ?nLoop_target:string := @string:UniqueLabel;
 mov(cnt, ecx);
 UniqueLabel:

endmacro;

macro endloop;

 dec(ecx);
 jnz @text(nLoop_target);

endmacro;

```

Using this definition, you can have multiple calls to the *nLoop* and *endloop* macros and HLA will not generate a duplicate symbol error:

```

nLoop(10)

 stdout.put("Loop counter = ", ecx, nl);

endloop;

nLoop(5)

 stdout.put("Second Loop Counter = ", ecx, nl);

```

```
endloop;
```

The macro invocations above produce something like the following (reasonably correct) expansion:

```
mov(10, ecx);
023A: //UniqueLabel, first invocation

 stdout.put("Loop counter = ", ecx, nl);

 dec(ecx);
 jne _023A_; // Expansion of nLoop_target becomes _023A_.

 mov(5, ecx);
023B: // UniqueLabel, second invocation.

 stdout.put("Second Loop Counter = ", ecx, nl);

 dec(ecx);
 jnz _023B_; // Expansion of nLoop_target becomes _023B_.
```

This scheme looks like it's working properly. However, this implementation suffers from a big drawback- it fails if you attempt to nest the *nLoop..endloop* control structure:

```
nLoop(10)

 push(ecx); // Must preserve outer loop counter.
 nLoop(5)

 stdout.put("ecx=", ecx, " [esp]=", (type dword [esp]), nl);

 endloop;
 pop(ecx); // Restore outer loop counter.

endloop;
```

You would expect to see this code print its message 50 times. However, the macro invocations above produce code like the following:

```
mov(10, ecx);
0321: //UniqueLabel, first invocation

 push(ecx);
 mov(5, ecx);
0322:

 stdout.put("ecx=", ecx, " [esp]=", (type dword [esp]), nl);

 dec(ecx);
 jne _0322_; // Expansion of nLoop_target becomes _0322_.
 pop(ecx);
 dec(ecx);
 jne _0322_; // Expansion of nLoop_target incorrectly becomes _0322_.
```

Note that the last JNE should jump to label "\_0321\_" rather than "\_0322\_". Unfortunately, the nested invocation of the *nLoop* macro overwrites the value of the global string constant *nLoop\_target* thus the last JNE transfers control to the wrong label.

It is possible to correct this problem using an array of strings and another compile-time constant to create a *stack* of labels. By pushing and popping these labels as you encounter *nLoop* and *endloop* you can emit the correct code. However, this is a lot of work, is very inelegant, and you must repeat this process for every

nestable control structure you dream up. In other words, it's a total kludge. Fortunately, HLA provides a better solution: multi-part macros.

Multi-part macros let you define a set of macros that work together. The *nLoop* and the *endloop* macros in this section are a good example of a pair of macros that work intimately together. By defining *nLoop* and *endloop* within a multi-part macro definition, the problems with communicating the target label between the two macros goes away because multi-part macros share parameters and local symbols. This provides a much more elegant solution to this problem than using global constants to hold target label information.

As its name suggests, a multi-part macro consists of a sequence of statements containing two matched macro names (e.g., *nLoop* and *endloop*). Multi-part macro invocations always consist of at least two macro invocations: a *beginning* invocation (e.g., *nLoop*) and a *terminating* invocation (e.g., *endloop*). Some number of unrelated (to the macro bodies) instructions may appear between the two invocations. To declare a multi-part macro, you use the following syntax:

```
macro beginningMacro (optional_parameters) : optional_local_symbols;

 << beginningMacro body >>

terminator terminatingMacro (optional_parameters) : optional_local_symbols;

 << terminatingMacro body >>

endmacro;
```

The presence of the TERMINATOR section in the macro declaration tells HLA that this is a multi-part macro declaration. It also ends the macro declaration of the beginning macro and begins the declaration of the terminating macro (i.e., the invocation of *beginningMacro* does not emit the code associated with the TERMINATOR macro). As you would expect, parameters and local symbols are optional in both declarations and the associated glue characters (parentheses and colons) are not present if the parameters and local symbol lists are not present.

Now let's look at the multi-part macro declaration for the *nLoop..endloop* macro pair:

```
macro nLoop(cnt):TopOfLoop;

 mov(cnt, ecx);
 TopOfLoop:

terminator endloop;

 dec(ecx);
 jne TopOfLoop;

endmacro;
```

As you can see in this example, the definition of the *nLoop..endloop* control structure is much simpler when using multi-part macros; better still, multi-part macro declarations work even if you nest the invocations.

The most notable thing in this particular macro declaration is that the *endloop* macro has access to *nLoop*'s parameters and local symbols (in this example the *endloop* macro does not reference *cnt*, but it could if this was necessary). This makes communication between the two macros trivial.

Multi-part macro invocations must always occur in pairs. If the beginning macro appears in the text, the terminating macro must follow at some point. A terminating macro may never appear in the source file without a previous, matching, instance of the beginning macro. These semantics are identical to many of the HLA high level control structures; i.e., you cannot have an ENDIF without having a corresponding IF clause earlier in the source file.

When you nest multi-part macro invocations, HLA "magically" keeps track of local symbols and always emits the appropriate local label value. The nested macros appearing earlier are no problem for multi-part macros:

```
nLoop(10)
```

```

push(ecx); // Must preserve outer loop counter.
nLoop(5)

 stdout.put("ecx=", ecx, " [esp]=", (type dword [esp]), nl);

endloop;
pop(ecx); // Restore outer loop counter.

endloop;

```

The above code properly compiles to something like:

```

 mov(10, ecx);
01FE:

 push(ecx);
 mov(5, ecx);
01FF:

 stdout.put("ecx=", ecx, " [esp]=", (type dword [esp]), nl);

 dec(ecx);
 jne _01FF_;

 pop(ecx);

dec(ecx);
jne _01FE_; // Note the correct label here.

```

In addition to terminating macros, HLA's multi-part macro facilities also provide an option for introducing additional macro declarations associated with the beginning/terminating macro pair: **KEYWORD** macros. **KEYWORD** macros are macros that are active only between a specific beginning and terminating macro pair. The classic use for **KEYWORD** macros is to allow the introduction of context-sensitive keywords into the macro (context-sensitive, in this case, meaning that the terms are only active within the context of the body of statements between the beginning and terminating macros). Classic examples of statements that could employ these types of macros include the **BREAK** and **CONTINUE** statements within a loop body and the **CASE** clause within a **SWITCH..ENDSWITCH** statement.

The syntax for a multi-part macro declaration that includes one or more **KEYWORD** macros is the following:

```

macro beginningMacro(optional_parameters): optional_local_labels;

 << beginningMacro Body >>

keyword keywordMacro(optional_parameters): optional_local_labels;

 << keywordMacro Body >>

terminator terminatingMacro(optional_parameters): optional_local_labels;

 << terminatingMacro Body >>

endmacro;

```

If a **KEYWORD** macro is present in a macro declaration there must also be a terminating macro declaration. You cannot have a **KEYWORD** macro without a corresponding **TERMINATOR** macro. The **TERMINATOR** macro declaration is always last in a multi-part macro declaration.

The syntax example above specifies only a single KEYWORD macro. HLA, however, allows zero or more KEYWORD macro declarations in a multi-part macro. The HLA SWITCH statement, for example, defines two KEYWORD macros, *case* and *default*.

KEYWORD and TERMINATOR macros may refer to the parameters and local symbols defined in the beginning macro, but they may not refer to locals and parameters in other KEYWORD macros. Parameters and local symbols in KEYWORD macro declarations are local to that specific macro. If you really need to communicate information between KEYWORD and TERMINATOR macros, define some local symbols in the beginning macro and assign these local symbols the parameter (or local symbol) values in the affected KEYWORD macro. Then refer to this beginning macro local symbol in other parts of the macro. The following is a trivial example of this:

```
macro ShareParameter:parmValue;

 << beginning macro body >>

keyword ParmToShare(p);

 ?parmValue:text := @string:p;

 << keyword macro body >>

terminator UsesSharedParm;

 mov(parmValue, ecx);

 << terminator macro body >>

endmacro;
```

By assigning *ParmToShare*'s parameter value to the beginning macro's *parmValue* local symbol, this code makes the value of *p* accessible by the *UsesSharedParm* terminating macro.

This section only touches on the capabilities of HLA's multi-part macro facilities. Additional examples appear later in this chapter in the section on Domain Specific Embedded Languages (see "Domain Specific Embedded Languages" on page 975). This text will make use of HLA's multi-part macros in later chapters as well. For more information on multi-part macros, see these sections in this text or check out the HLA documentation.

## 7.2.6 Simulating Function Overloading with Macros

The C++ language supports a nifty feature known as *function overloading*. Function overloading lets you write several different functions or procedures that all have the same name. The difference between these functions is the types of their parameters or the number of parameters. A procedure declaration is said to be unique if it has a different number of parameters than other functions with the same name or if the types of its parameters differs from another function with the same name. HLA does not directly support procedure overloading but you can use macros to achieve the same result. This section explains how to use HLA's macros and the compile-time language to achieve function/procedure overloading.

One good use for procedure overloading is to reduce the number of standard library routines you must remember how to use. For example, the HLA Standard Library provides four different "puti" routines that output an integer value: *stdout.puti64*, *stdout.puti32*, *stdout.puti16*, and *stdout.puti8*. The different routines, as their name suggests, output integer values according to the size of their integer parameter. In the C++ language (or another other language supporting procedure/function overloading) the engineer designing the input routines would probably have chosen to name them all *stdout.puti* and leave it up to the compiler to

select the appropriate one based on the operand size<sup>5</sup>. The following macro demonstrates how to do this in HLA using the compile-time language to figure out the size of the parameter operand:

---

```

// Puti.hla
//
// This program demonstrates procedure overloading via macros.
//
// It defines a "puti" macro that calls stdout.puti8, stdout.puti16,
// stdout.puti32, or stdout.puti64 depending on the size of the operand.

program putiDemo;
#include("stdlib.hhf")

// puti-
//
// Automatically decides whether we have a 64, 32, 16, or 8-bit
// operand and calls the appropriate stdout.putiX routine to
// output this value.

macro puti(operand);

 // If we have an eight-byte operand, call puti64:

 #if(@size(operand) = 8)

 stdout.puti64(operand);

 // If we have a four-byte operand, call puti32:

 #elseif(@size(operand) = 4)

 stdout.puti32(operand);

 // If we have a two-byte operand, call puti16:

 #elseif(@size(operand) = 2)

 stdout.puti16(operand);

 // If we have a one-byte operand, call puti8:

 #elseif(@size(operand) = 1)

 stdout.puti8(operand);

 // If it's not an eight, four, two, or one-byte operand,
 // then print an error message:

 #else

```

---

5. By the way, the HLA Standard Library does this as well. Although it doesn't provide *stdout.puti*, it does provide *stdout.put* that will choose an appropriate output routine based upon the parameter's type. This is a bit more flexible than a *puti* routine.

```

 #error("Expected a 64, 32, 16, or 8-bit operand")

 #endif

endmacro;

// Some sample variable declarations so we can test the macro above.

static
 i8: int8 := -8;
 i16: int16 := -16;
 i32: int32 := -32;
 i64: qword;

begin putiDemo;

 // Initialize i64 since we can't do this in the static section.

 mov(-64, (type dword i64));
 mov($FFFF_FFFF, (type dword i64[4]));

 // Demo the puti macro:

 puti(i8); stdout.newln();
 puti(i16); stdout.newln();
 puti(i32); stdout.newln();
 puti(i64); stdout.newln();

end putiDemo;

```

---

### Program 7.7 Simple Procedure Overloading Based on Operand Size

---

The example above simply tests the size of the operand to determine which output routine to use. You can use other HLA compile-time functions, like @TYPENAME, to do more sophisticated processing. Consider the following program that demonstrates a macro that overloads stdout.puti32, stdout.putu32, and stdout.putd depending on the type of the operand:

---

```

// put32.hla
//
// This program demonstrates procedure overloading via macros.
//
// It defines a "put32" macro that calls stdout.puti32, stdout.putu32,
// or stdout.putdw depending on the type of the operand.

program put32Demo;
#include("stdlib.hhf")

// put32-
//
// Automatically decides whether we have an int32, uns32, or dword
// operand and calls the appropriate stdout.putX routine to
// output this value.

```

```

macro put32(operand);

 // If we have an int32 operand, call puti32:
 #if(@typename(operand) = "int32")

 stdout.puti32(operand);

 // If we have an uns32 operand, call putu32:
 #elseif(@typename(operand) = "uns32")

 stdout.putu32(operand);

 // If we have a dword operand, call putidw:
 #elseif(@typename(operand) = "dword")

 stdout.putdw(operand);

 // If it's not a 32-bit integer value, report an error:
 #else

 #error("Expected an int32, uns32, or dword operand")

 #endif

endmacro;

// Some sample variable declarations so we can test the macro above.

static
 i32: int32 := -32;
 u32: uns32 := 32;
 d32: dword := $32;

begin put32Demo;

 // Demo the put32 macro:

 put32(d32); stdout.newln();
 put32(u32); stdout.newln();
 put32(i32); stdout.newln();

end put32Demo;

```

---

---

### Program 7.8 Procedure Overloading Based on Operand Type

---

---

You can easily extend the macro above to output eight and sixteen-bit operands as well as 32-bit operands. That is left as an exercise.

The number of actual parameters is another way to resolve which overloaded procedure to call. If you specify a variable number of macro parameters (using the "[ ]" syntax, see "Macros with a Variable Number of Parameters" on page 946) you can use the @ELEMENTS compile-time function to determine exactly how many parameters are present and call the appropriate routine. The following sample program uses this trick to determine whether it should call *stdout.puti32* or *stdout.puti32Size*:

```
// puti32.hla
//
// This program demonstrates procedure overloading via macros.
//
// It defines a "puti32" macro that calls stdout.puti32 or stdout.puti32size
// depending on the number of parameters present.

program puti32Demo;
#include("stdlib.hhf")

// puti32-
//
// Automatically decides whether we have an int32, uns32, or dword
// operand and calls the appropriate stdout.putX routine to
// output this value.

macro puti32(operand[]);

 // If we have a single operand, call stdout.puti32:

 #if(@elements(operand) = 1)

 stdout.puti32(@text(operand[0]));

 // If we have two operands, call stdout.puti32size and
 // supply a default value of ' ' for the padding character:

 #elseif(@elements(operand) = 2)

 stdout.puti32Size(@text(operand[0]), @text(operand[1]), ' ');

 // If we have three parameters, then pass all three of them
 // along to puti32size:

 #elseif(@elements(operand) = 3)

 stdout.puti32Size
 (
 @text(operand[0]),
 @text(operand[1]),
 @text(operand[2])
);

 // If we don't have one, two, or three operands, report an error:

 #else

 #error("Expected one, two, or three operands")

 #endif
endmacro

```

```

#endif

endmacro;

// A sample variable declaration so we can test the macro above.

static
 i32: int32 := -32;

begin puti32Demo;

 // Demo the put32 macro:

 puti32(i32); stdout.newln();
 puti32(i32, 5); stdout.newln();
 puti32(i32, 5, '*'); stdout.newln();

end puti32Demo;

```

---

### Program 7.9 Using the Number of Parameters to Resolve Overloaded Procedures

---

All the examples up to this point provide procedure overloading for Standard Library routines (specifically, the integer output routines). Of course, you are not limited to overloading procedures in the HLA Standard Library. You can create your own overloaded procedures as well. All you've got to do is write a set of procedures, all with unique names, and then use a single macro to decide which routine to actually call based on the macro's parameters. Rather than call the individual routines, invoke the common macro and let it decide which procedure to actually call.

Although not strictly an example of procedure overloading, a related use for macros is to rearrange parameters in a procedure call. For example, some languages (most notably C/C++) expect you to pass their parameters on the stack in the reverse order of how you declare them in the parameter list. Since HLA expects the caller to push the parameters in the order they appear in the parameter list, HLA's order is the opposite of C/C++'s. Were you to write a procedure in HLA that you call from C/C++, you would have to reverse the order of the parameters. Similarly, if you call a C/C++ function from HLA, your HLA external declaration must specify the parameters in the reverse order that they appear in the C/C++ declaration. This is often very confusing. You can avoid this problem by simply specifying a macro that declares the (macro) parameters in the correct order and whose body calls the C/C++ function swapping the order of the parameters in the actual call. This allows you to use the same calling sequence (from the programmer's perspective) for both C/C++ and HLA calls to the same function. (Note, of course, that HLA's STDCALL and CDECL calling conventions also serve this purpose, but there are other calling conventions possible for which these macro facilities would be useful.)

---

## 7.3 Writing Compile-Time "Programs"

The HLA compile-time language provides a powerful facility with which to write "programs" that execute while HLA is compiling your assembly language programs. Although it is possible to write some general purpose programs using the HLA compile-time language, the real purpose of the HLA compile-time language is to allow you to write short programs *that write other programs*. In particular, the primary purpose of the HLA compile-time language is to automate the creation of large or complex assembly language sequences. The following subsections provide some simple examples of such compile-time programs.

### 7.3.1 Constructing Data Tables at Compile Time

Earlier, this text suggested that you could write programs to generate large, complex, lookup tables for your assembly language programs (see “Generating Tables” on page 629). That chapter provided examples in HLA but suggested that writing a separate program was unnecessary. This is true, you can generate most look-up tables you’ll need using nothing more than the HLA compile-time language facilities. Indeed, filling in table entries is one of the principle uses of the HLA compile-time language. In this section we will take a look at using the HLA compile-time language to construct data tables during compilation.

In the section on generating tables, this text gave an example of an HLA program that writes a text file containing a lookup table for the trigonometric *sine* function. The table contains 360 entries with the index into the table specifying an angle in degrees. Each *int32* entry in the table contained the value  $\sin(\text{angle}) * 1000$  where *angle* is equal to the index into the table. The section on generating tables suggested running this program and then including the text output from that program into the actual program that used the resulting table. You can avoid much of this work by using the compile-time language. The following HLA program includes a short compile-time code fragment that constructs this table of sines directly.

---

```
// demoSines.hla
//
// This program demonstrates how to create a lookup table
// of sine values using the HLA compile-time language.

program demoSines;
#include("stdlib.hhf")

const
 pi :real80 := 3.1415926535897;

readonly
 sines: int32[360] :=
 [
 // The following compile-time program generates
 // 359 entries (out of 360). For each entry
 // it computes the sine of the index into the
 // table and multiplies this result by 1000
 // in order to get a reasonable integer value.

 ?angle := 0;
 #while(angle < 359)

 // Note: HLA's @sin function expects angles
 // in radians. radians = degrees*pi/180.
 // the "int32" function truncates its result,
 // so this function adds 1/2 as a weak attempt
 // to round the value up.

 int32(@sin(angle * pi / 180.0) * 1000 + 0.5),
 ?angle := angle + 1;

 #endwhile

 // Here's the 360th entry in the table. This code
 // handles the last entry specially because a comma
 // does not follow this entry in the table.

 int32(@sin(359 * pi / 180.0) * 1000 + 0.5)
];
```

```

begin demoSines;

 // Simple demo program that displays all the values in the table.

 for(mov(0, ebx); ebx<360; inc(ebx)) do

 mov(sines[ebx*4], eax);
 stdout.put
 (
 "sin(",
 (type uns32 ebx),
 ")*1000 = ",
 (type int32 eax),
 nl
);

 endfor;

end demoSines;

```

---

### Program 7.10 Generating a SINE Lookup Table with the Compile-time Language

---

Another common use for the compile-time language is to build ASCII character lookup tables for use by the XLAT instruction at run-time. Common examples include lookup tables for alphabetic case manipulation. The following program demonstrates how to construct an upper case conversion table and a lower case conversion table<sup>6</sup>. Note the use of a macro as a compile-time procedure to reduce the complexity of the table generating code:

---

```

// demoCase.hla
//
// This program demonstrates how to create a lookup table
// of alphabetic case conversion values using the HLA
// compile-time language.

program demoCase;
#include("stdlib.hhf")

const
 pi :real80 := 3.1415926535897;

// emitCharRange-
//
// This macro emits a set of character entries
// for an array of characters. It emits a list
// of values (with a comma suffix on each value)
// from the starting value up to, but not including,
// the ending value.

macro emitCharRange(start, last): index;

```

---

6. Note that on modern processors, using a lookup table is probably not the most efficient way to convert between alphabetic cases. However, this is just an example of filling in the table using the compile-time language. The principles are correct even if the code is not exactly the best it could be.

```

?index:uns8 := start;
#while(index < last)

 char(index),
 ?index := index + 1;

#endwhile

endmacro;

readonly

// toUC:
// The entries in this table contain the value of the index
// into the table except for indicies #$61..#$7A (those entries
// whose indicies are the ASCII codes for the lower case
// characters). Those particular table entries contain the
// codes for the corresponding upper case alphabetic characters.
// If you use an ASCII character as an index into this table and
// fetch the specified byte at that location, you will effectively
// translate lower case characters to upper case characters and
// leave all other characters unaffected.

toUC: char[256] :=
 [
 // The following compile-time program generates
 // 255 entries (out of 256). For each entry
 // it computes toupper(index) where index is
 // the character whose ASCII code is an index
 // into the table.

 emitCharRange(0, uns8('a'))

 // Okay, we've generated all the entries up to
 // the start of the lower case characters. Output
 // Upper Case characters in place of the lower
 // case characters here.

 emitCharRange(uns8('A'), uns8('Z') + 1)

 // Okay, emit the non-alphabetic characters
 // through to byte code #$FE:

 emitCharRange(uns8('z') + 1, $FF)

 // Here's the last entry in the table. This code
 // handles the last entry specially because a comma
 // does not follow this entry in the table.

 #$FF
];

// The following table is very similar to the one above.
// You would use this one, however, to translate upper case
// characters to lower case while leaving everything else alone.
// See the comments in the previous table for more details.

Tolc: char[256] :=

```

```

 [
 emitCharRange(0, uns8('A'))
 emitCharRange(uns8('a'), uns8('z') + 1)
 emitCharRange(uns8('Z') + 1, $FF)

 #$$$FF
];

begin demoCase;

 for(mov(uns32(' '), eax); eax <= $$$FF; inc(eax)) do

 mov(toUC[eax], bl);
 mov(TOlc[eax], bh);
 stdout.put
 (
 "toupper('",
 (type char al),
 "') = '",
 (type char bl),
 " tolower('",
 (type char al),
 "') = '",
 (type char bh),
 "'",
 nl
);

 endfor;

end demoCase;

```

---

---

### Program 7.11 Generating Case Conversion Tables with the Compile-Time Language

---

---

One important thing to note about this sample is the fact that a semicolon does not follow the *emitCharRange* macro invocations. Macro invocations do not require a closing semicolon. Often, it is legal to go ahead and add one to the end of the macro invocation because HLA is normally very forgiving about having extra semicolons inserted into the code. In this case, however, the extra semicolons are illegal because they would appear between adjacent entries in the *TOlc* and *toUC* tables. Keep in mind that macro invocations don't require a semicolon, especially when using macro invocations as compile-time procedures.

---

## 7.3.2 Unrolling Loops

In the chapter on Low-Level Control Structures (see “Unraveling Loops” on page 776) this text points out that you can unravel loops to improve the performance of certain assembly language programs. One problem with unravelling, or unrolling, loops is that you may need to do a lot of extra typing, especially if many iterations are necessary. Fortunately, HLA's compile-time language facilities, especially the #WHILE loop, comes to the rescue. With a small amount of extra typing plus one copy of the loop body, you can unroll a loop as many times as you please.

If you simply want to repeat the same exact code sequence some number of times, unrolling the code is especially trivial. All you've got to do is wrap an HLA #WHILE..#ENDWHILE loop around the sequence and count down a VAL object the specified number of times. For example, if you wanted to print "Hello World" ten times, you could encode this as follows:

```
?count := 0;
#while(count < 10)

 stdout.put("Hello World", nl);
 ?count := count + 1;

#endwhile
```

Although the code above looks very similar to a WHILE (or FOR) loop you could write in your program, remember the fundamental difference: the code above simply consists of ten straight *stdout.put* calls in the program. Were you to encode this using a FOR loop, there would be only one call to *stdout.put* and lots of additional logic to loop back and execute that single call ten times.

Unrolling loops becomes slightly more complicated if any instructions in that loop refer to the value of a loop control variable or other value that changes with each iteration of the loop. A typical example is a loop that zeros the elements of an integer array:

```
mov(0, eax);
for(mov(0, ebx); ebx < 20; inc(ebx)) do

 mov(eax, array[ebx*4]);

endfor;
```

In this code fragment the loop uses the value of the loop control variable (in EBX) to index into *array*. Simply copying "mov( eax, array[ ebx\*4 ]);" twenty times is not the proper way to unroll this loop. You must substitute an appropriate constant index in the range 0..76 (the corresponding loop indices, times four) in place of "EBX\*4" in this example. Correctly unrolling this loop should produce the following code sequence:

```
mov(eax, array[0*4]);
mov(eax, array[1*4]);
mov(eax, array[2*4]);
mov(eax, array[3*4]);
mov(eax, array[4*4]);
mov(eax, array[5*4]);
mov(eax, array[6*4]);
mov(eax, array[7*4]);
mov(eax, array[8*4]);
mov(eax, array[9*4]);
mov(eax, array[10*4]);
mov(eax, array[11*4]);
mov(eax, array[12*4]);
mov(eax, array[13*4]);
mov(eax, array[14*4]);
mov(eax, array[15*4]);
mov(eax, array[16*4]);
mov(eax, array[17*4]);
mov(eax, array[18*4]);
mov(eax, array[19*4]);
```

You can do this more efficiently using the following compile-time code sequence:

```
?iteration := 0;
#while(iteration < 20)

 mov(eax, array[iteration*4]);
 ?iteration := iteration+1;

#endwhile
```

If the statements in a loop make use of the loop control variable's value, it is only possible to unroll such loops if those values are known at compile time. You cannot unroll loops when user input (or other run-time information) controls the number of iterations.

---

## 7.4 Using Macros in Different Source Files

Unlike procedures, macros do not have a fixed piece of code at some address in memory. Therefore, you cannot create "external" macros and link them with other modules in your program. However, it is very easy to share macros with different source files – just put the macros you wish to reuse in a header file and include that file using the `#include` directive. You can make the macro will be available to any source file you choose using this simple trick.

---

## 7.5 Putting It All Together

This chapter has barely touched on the capabilities of the HLA macro processor and compile-time language. The HLA language has one of the most powerful macro processors around. None of the other 80x86 assemblers even come close to HLA's capabilities with regard to macros. Indeed, if you could say just one thing about HLA in relation to other assemblers, it would have to be that HLA's macro facilities are, by far, the best.

The combination of the HLA compile-time language and the macro processor give HLA users the ability to extend the HLA language in many ways. In the chapter on Domain Specific Languages, you'll get the opportunity to see how to create your own specialized languages using HLA's macro facilities.

Even if you don't do exotic things like creating your own languages, HLA's macro facilities and compile-time language are really great for automating code generation in your programs. The HLA Standard Library, for example, makes heavy use of HLA's macro facilities; "procedures" like *stdout.put* and *stdin.get* would be very difficult (if not impossible) to create without the power of HLA macro facilities and the compile-time language. For some good examples of the possible complexity one can achieve with HLA's macros, you should scan through the `#include` files in the HLA Standard Library and look at some of the macros appearing therein.

This chapter serves as a basic introduction to HLA's macro facilities. As you use macros in your own programs you will gain even more insight into their power. So by all means, use macros as much as you can – they can help reduce the effort needed to develop programs.

---

# Domain Specific Embedded Languages Chapter Nine

---

## 9.1 Chapter Overview

HLA's compile time language was designed with one purpose in mind: to give the HLA user the ability to change the syntax of the language in a user-defined manner. The compile-time language is actually so powerful that it lets you implement the syntax of other languages (not just an assembly language) within an HLA source file. This chapter discusses how to take this feature to an extreme and implement your own "mini-languages" within the HLA language.

---

## 9.2 Introduction to DSELS in HLA

One of the most interesting features of the HLA language is its ability to support *Domain Specific Embedded Languages* (or DSELS, for short, which you pronounce as D-cells). A domain specific language is a language designed with a specific purpose in mind. Applications written in an appropriate domains specific language (DSL) are often much shorter and much easier to write than that same application written in a general purpose language (like C/C++ or Pascal). Unfortunately, writing a compiler for a DSL is considerable work. Since most DSLs are so specific that few programs are ever written in them, it is generally cost-prohibitive to create a DSL for a given application. This economic fact has led to the popularity of domain specific *embedded* languages. The difference between a DSL and a DSEL is the fact that you don't write a new compiler for DSEL; instead, you provide some tools for use by an existing language translator to let the user extend the language as necessary for the specific application. This allows the language designer to use the features of the existing (i.e., *embedding*) language without having to write the translator for these features in the DSEL. The HLA language incorporates lots of features that let you extend the language to handle your own particular needs. This section discusses how to use these features to extend HLA as you choose.

As you probably suspect by now, the HLA compile-time language is the principle tool at your disposal for creating DSELS. HLA's multi-part macros let you easily create high level language-like control structures. If you need some new control structure that HLA does not directly support, it's generally an easy task to write a macro to implement that control structure. If you need something special, something that HLA's multi-part macros won't directly support, then you can write code in the HLA compile-time language to process portions of your source file as though they were simply string data. By using the compile-time string handling functions you can process the source code in just about any way you can imagine. While many such techniques are well beyond the scope of this text, it's reassuring to know that HLA can handle just about anything you want to do, even once you become an advanced assembly language programmer.

The following sections will demonstrate how to extend the HLA language using the compile-time language facilities. Don't get the idea that these simple examples push the limits of HLA's capabilities, they don't. You can accomplish quite a bit more with the HLA compile-time language; these examples must be fairly simple because of the assumed general knowledge level of the audience for this text.

---

### 9.2.1 Implementing the Standard HLA Control Structures

HLA supports a wide set of high level language-like control structures. These statements are not true assembly language statements, they are high level language statements that HLA compiles into the corresponding low-level machine instructions. They are general control statements, not "domain specific" (which is why HLA includes them) but they are quite typical of the types of statements one can add to HLA in order to extend the language. In this section we will look at how you could implement many of HLA's high-level control structures using the compile-time language. Although there is no real need to implement these statements in this manner, their example should provide a template for implementing other types of control structures in HLA.

The following sections show how to implement the FOREVER..ENDFOR, WHILE..ENDWHILE, and IF..ELSEIF..ELSE..ENDIF statements. The REPEAT..UNTIL and BEGIN..EXIT..EXITIF..END statements appear as exercises at the end of the chapter. The remaining high level language control structures (e.g., TRY..ENDTRY) are a little too complex to present at this point.

Because words like "if" and "while" are reserved by HLA, the following examples will use macro identifiers like "\_if" and "\_while". This will let us create recognizable statements using standard HLA identifiers (i.e., no conflicts with reserved words).

### 9.2.1.1 The FOREVER Loop

The FOREVER loop is probably the easiest control structure to implement. After all, the basic FOREVER loop simply consists of a label and a JMP instruction. So the first pass at implementing `_FOREVER.._ENDFOR` might look like the following:

```
macro _forever: topOfLoop;
 topOfLoop:

terminator _endfor;
 jmp topOfLoop;

endmacro;
```

Unfortunately, there is a big problem with this simple implementation: you'll probably want the ability to exit the loop via `break` and `breakif` statements and you might want the equivalent of a `continue` and `continueif` statement as well. If you attempt to use the standard `BREAK`, `BREAKIF`, `CONTINUE`, and `CONTINUEIF` statements inside this `_forever` loop implementation, you'll quickly discover that they do not work. These statements are valid only inside an HLA loop and the `_forever` macro above is not an HLA loop. Of course, we could easily solve this problem by defining `_FOREVER` thusly:

```
macro _forever;
 forever

terminator _endfor;
 endfor;

endmacro;
```

Now you can use `BREAK`, `BREAKIF`, `CONTINUE`, and `CONTINUEIF` inside the `_forever.._endfor` statement. However, this solution is ridiculous. The purpose of this section is to show you how you could create this statement were it not present in the HLA language. Simply renaming `FOREVER` to `_forever` is not an interesting solution.

Probably the best way to implement these additional statements is via `KEYWORD` macros within the `_forever` macro. Not only is this easy to do, but it has the added benefit of not allowing the use of these statements outside a `_forever` loop.

Implementing a `_continue` statement is very easy. `Continue` must transfer control to the first statement at the top of the loop. Therefore, the `_continue` `KEYWORD` macro will simply expand to a single `JMP` instruction that transfers control to the `topOfLoop` label. The complete implementation is the following:

```
keyword _continue;
 jmp topOfLoop;
```

Implementing `_continueif` is a little bit more difficult because this statement must evaluate a boolean expression and decide whether it must jump to the `topOfLoop` label. Fortunately, the HLA `JT` (jump if true) pseudo-instruction makes this a relatively trivial task. The `JT` pseudo-instruction is passed a boolean expression (the same as allowed by `CONTINUEIF`) and transfers control to the corresponding target label if the result of the expression evaluation is true. The `_continueif` implementation is nearly trivial with `JT`:

```
keyword _continueif(ciExpr);
```

```
JT(ciExpr) topOfLoop;
```

You will implement the `_break` and `_breakif` KEYWORD macros in a similar fashion. The only difference is that you must add a new label just beyond the `JMP` in the `_endfor` macro and the break statements should jump to this local label. The following program provides a complete implementation of the `_forever..endfor` loop as well as a sample test program for the `_forever` loop.

```

/*****
/*
/* foreverMac.hla
/*
/* This program demonstrates how to use HLA's
/* "context-free" macros, along with the JT
/* "medium-level" instruction to create
/* the FOREVER..ENDFOR, BREAK, BREAKIF,
/* CONTINUE, and CONTINUEIF control statements.
/*
/*
/*****

program foreverDemo;
#include("stdlib.hhf")

// Emulate the FOREVER..ENDFOR loop here, plus the
// corresponding CONTINUE, CONTINUEIF, BREAK, and
// BREAKIF statements.

macro _forever:foreverLbl, foreverbrk;

 // Target label for the top of the
 // loop. This is also the destination
 // for the _continue and _continueif
 // macros.

 foreverLbl:

// The _continue and _continueif statements
// transfer control to the label above whenever
// they appear in a _forever..endfor statement.
// (Of course, _continueif only transfers control
// if the corresponding boolean expression evaluates
// true.)

keyword _continue;
 jmp foreverLbl;

keyword _continueif(cifExpr);
 jt(cifExpr) foreverLbl;

// the _break and _breakif macros transfer
// control to the "foreverbrk" label which

```

```

// is at the bottom of the loop.

keyword _break;
 jmp foreverbrk;

keyword _breakif(bifExpr);
 jt(bifExpr) foreverbrk;

// At the bottom of the _forever.._endfor
// loop this code must jump back to the
// label at the top of the loop. The
// _endfor terminating macro must also supply
// the target label for the _break and _breakif
// keyword macros:

terminator _endfor;
 jmp foreverLbl;
 foreverbrk:

endmacro;

begin foreverDemo;

// A simple main program that demonstrates the use of the
// statements above.

mov(0, ebx);
_forever

 stdout.put("Top of loop, ebx = ", (type uns32 ebx), nl);
 inc(ebx);

// On first iteration, skip all further statements.

 _continueif(ebx = 1);

// On fourth iteration, stop.

 _breakif(ebx = 4);

 _continue; // Always jumps to top of loop.
 _break; // Never executes, just demonstrates use.

_endfor;

end foreverDemo;

```

---

**Program 9.1    Macro Implementation of the FOREVER..ENDFOR Loop**

---

---

### 9.2.1.2 The WHILE Loop

Once the FOREVER..ENDFOR loop is behind us, implementing other control structures like the WHILE..ENDWHILE loop is fairly easy. Indeed, the only notable thing about implementing the `_while..endwhile` macros is that the code should implement this control structure as a REPEAT..UNTIL statement for efficiency reasons. The implementation appearing in this section takes a rather lazy approach to implementing the DO reserved word. The following code uses a KEYWORD macro to implement a `_do` clause, but it does not enforce the (proper) use of this keyword. Instead, the code simply ignores the `_do` clause wherever it appears between the `_while` and `_endwhile`. Perhaps it would have been better to check for the presence of this statement (not too difficult to do) and verify that it immediately follows the `_while` clause and associated expression (somewhat difficult to do), but this just seems like a lot of work to check for the presence of an irrelevant keyword. So this implementation simply ignores the `_do`. The complete implementation appears in Program 9.2:

```

/*****
/*
/* whileMacs.hla
/*
/* This program demonstrates how to use HLA's
/* "context-free" macros, along with the JT and
/* JF "medium-level" instructions to create
/* the basic WHILE statement.
/*
/*
/*****

program whileDemo;
#include("stdlib.hhf")

 // Emulate the while..endwhile loop here.
 //
 // Note that this code implements the WHILE
 // loop as a REPEAT..UNTIL loop for efficiency
 // (though it inserts an extra jump so the
 // semantics remain the same as the WHILE loop).

macro _while(whlexpr): repeatwhl, whltest, brkwhl;

 // Transfer control to the bottom of the loop
 // where the termination test takes place.

 jmp whltest;

 // Emit a label so we can jump back to the
 // top of the loop.

 repeatwhl:

 // Ignore the "_do" clause. Note that this
 // macro should really check to make sure
 // that "_do" follows the "_while" clause.
 // But it's not semantically important so
 // this code takes the lazy way out.

 keyword _do;

```

```

// If we encounter "_break" inside this
// loop, transfer control to the first statement
// beyond the loop.

keyword _break;
 jmp brkwhl;

// Ditto for "_breakif" except, of course, we
// only exit the loop if the corresponding
// boolean expression evaluates true.

keyword _breakif(biwExpr);
 jt(biwExpr) brkwhl;

// The "_continue" and "_continueif" statements
// should transfer control directly to the point
// where this loop tests for termination.

keyword _continue;
 jmp whltest;

keyword _continueif(ciwExpr);
 jt(ciwExpr) whltest;

// The "_endwhile" clause does most of the work.
// First, it must emit the target label used by the
// "_while", "_continue", and "_continueif" clauses
// above. Then it must emit the code that tests the
// loop termination condition and transfers control
// to the top of the loop (the "repeatwhl" label)
// if the expression evaluates false. Finally,
// this code must emit the "brkwhl" label the "_break"
// and "_breakif" statements reference.

terminator _endwhile;

 whltest:
 jt(whlexpr) repeatwhl;
 brkwhl:

endmacro;

begin whileDemo;

// Quick demo of the _while statement.
// Note that the _breakif in the nested
// _while statement only skips the
// inner-most _while, just as you should expect.

mov(0, eax);
_while(eax < 10) _do

 stdout.put("eax in loop = ", eax, " ebx=");
 inc(eax);
 mov(0, ebx);

```

```

 _while(ebx < 4) _do

 stdout.puti32(ebx);
 _breakif(ebx = 3);
 stdout.put(" ", ");
 inc(ebx);

 _endwhile;
 stdout.newln();

 _continueif(eax = 5);
 _breakif(eax = 8);
 _continue;
 _break;

_endwhile
end whileDemo;

```

---

---

### Program 9.2 Macro Implementation of the WHILE..ENDWHILE Loop

---

---

#### 9.2.1.3 The IF Statement

Simulating the HLA IF.THEN..ELSEIF..ELSE..ENDIF statement using macros is a little bit more involved than the simulation of FOREVER or WHILE. The semantics of the ELSEIF and ELSE clauses complicate the code generation and require careful thought. While it is easy to write KEYWORD macros for *\_elseif* and *\_else*, ensuring that these statements generate correct (and efficient) code is another matter altogether.

The basic *\_if..\_endif* statement, without the *\_elseif* and *\_else* clauses, is very easy to implement (even easier than the *\_while..\_endwhile* loop of the previous section). The complete implementation is

```

macro _if(ifExpr): onFalse;

 jf(ifExpr) onFalse;

keyword _then; // Just ignore _then.

terminator _endif;

 onFalse:

endmacro;

```

This macro generates code that tests the boolean expression you supply as a macro parameter. If the expression evaluates false, the code this macro emits immediately jumps to the point just beyond the *\_endif* terminating macro. So this is a simple and elegant implementation of the IF..ENDIF statement, assuming you don't need an ELSE or ELSEIF clause.

Adding an ELSE clause to this statement introduces some difficulties. First of all, we need some way to emit the target label of the JF pseudo-instruction in the *\_else* section if it is present and we need to emit this label in the terminator section if the *\_else* section is not present.

A related problem is that the code after the *\_if* clause must end with a JMP instruction that skips the *\_else* section if it is present. This JMP must transfer control to the same location as the current *onFalse* label.

Another problem that occurs when we use KEYWORD macros to implement the `_else` clause, is that we need some mechanism in place to ensure that at most one invocation of the `_else` macro appears in a given `_if.._endif` sequence.

We can easily solve these problems by introducing a compile-time variable (i.e., VAL object) into the macro. We will use this variable to indicate whether we've seen an `_else` section. This variable will tell us if we have more than one `_else` clause (which is an error) and it will tell us if we need to emit the `onFalse` label in the `_endif` macro. A reasonable implementation might be the following:

```
macro _if(ifExpr): onFalse, ifDone, hasElse;

 ?hasElse := False; // Haven't seen an _else clause yet.

 jf(ifExpr) onFalse;

keyword _then; // Just ignore _then.

keyword _else;

 // Check to see if this _if statement already has an _else clause:

 #if(hasElse)

 #error("Only one _else clause is legal in an _if statement")

 #endif

 ?hasElse := true; //Let the world know we've see an _else clause.

 // Since we've just encountered the _else clause, we've just finished
 // processing the statements in the _if section. The first thing we
 // need to do is emit a JMP instruction that will skip around the
 // _else statements (so the _if section doesn't fall in to the
 // _else code).

 jmp ifDone;

 // Okay, emit the onFalse label here so a false expression will transfer
 // control to the _else statements:

 onFalse:

terminator _endif;

 // If there was no _else section, we must emit the onFalse label
 // so that the former JF instruction has a proper destination.
 // If an _else section was present, we cannot emit this label
 // (since the _else code has already done so) but we must emit
 // the ifDone label.

 #if(hasElse)

 ifdone:

 #else

 onFalse:

 #endif

endmacro;
```

Adding the `_elseif` clause to the `_if._endif` statement complicates things considerably. The problem is that `_elseif` can appear zero or more times in an `_if` statement and each occurrence needs to generate a unique `onFalse` label. Worse, if at least one `_elseif` clause appears in the sequence, then the JF instruction in the `_if` clause must transfer control to the first `_elseif`, not to the `_else` clause. Also, the last `_elseif` clause must transfer control to the `_else` clause (or to the first statement beyond the `_endif` clause) if its expression evaluates false. A straight-forward implementation just isn't going to work here.

A clever solution is to create a string variable that contains the name of the previous JF target label. Whenever you encounter an `_elseif` or an `_else` clause you simply emit this string to the source file as the target label. Then the only trick is "how do we generate a unique label whenever we need one?". Well, let's suppose that we have a string that is unique on each invocation of the `_if` macro. This being the case, we can generate a (source file wide) unique string by concatenating a counter value to the end of this base string. Each time we need a unique string, we simply bump the value of the counter up by one and create a new string. Consider the following macro:

```
macro genLabel(base, number);

 @text(base + string(number));

endmacro;
```

If the `base` parameter is a string value holding a valid HLA identifier and the `number` parameter is an integer numeric operand, then this macro will emit a valid HLA identifier that consists of the `base` string followed by a string representing the numeric constant. For example, `'genLabel( "Hello", 52)'` emits the label `Hello52`. Since we can easily create an `uns32 VAL` object inside our `_if` macro and increment this each time we need a unique label, the only problem is to generate a unique base string on each invocation of the `_if` macro. Fortunately, HLA already does this for us.

Remember, HLA converts all local macro symbols to a unique identifier of the form `"_xxxx_"` where `xxxx` represents some four-digit hexadecimal value. Since local symbols are really nothing more than text constants initialized with these unique identifier strings, it's very easy to obtain a unique string in a macro invocation- just declare a local symbol (or use an existing local symbol) and apply the `@STRING:` operator to it to extract the unique name as a string. The following example demonstrates how to do this:

```
macro uniqueIDs: counter, base;

 ?counter := 0; // Increment this for each unique symbol you need.
 ?base := @string:base; // base holds the base name to use.
 .
 .
 .

 // Generate a unique label at this point:

 genLabel(base, counter): // Notice the colon. We're defining a
 ?counter := counter + 1; // label at this point!
 .
 .
 .
 genLabel(base, counter):
 ?counter := counter + 1;
 .
 .
 .
 etc.

endmacro;
```

Once we have the capability to generate a sequence of unique labels throughout a macro, implementing the `_elseif` clause simply becomes the task of emitting the last referenced label at the beginning of each

`_elseif` (or `_else`) clause and jumping if false to the next unique label in the series. Program 9.3 implements the `_if.._then.._elseif.._else.._endif` statement using exactly this technique.

```

/*****
/*
/* IFmacs.hla
/*
/* This program demonstrates how to use HLA's
/* "context-free" macros, along with the JT and
/* JF "medium-level" instructions to create
/* an IF statement.
/*
/*
*****/

program IFDemo;
#include("stdlib.hhf")

 // genlabel-
 //
 // This macro creates an HLA-compatible
 // identifier of the form "_xxxx_n" where
 // "_xxxx_" is the string associated with
 // the "base" parameter and "n" represents
 // some numeric value that the caller. The
 // combination of the base and the n values
 // will produce a unique label in the
 // program if base's string is unique for
 // each invocation of the "_if" macro.

macro genLabel(base, number);

 @text(base + string(number))

endmacro;

/*
** Emulate the if..elseif..else..endif statement here.
*/

macro _if(ifexpr):elseLbl, ifDone, hasElse, base;

 // This macro must create a unique ID string
 // in base. One sneaky way to do this is
 // to use the converted name HLA generates
 // for the "base" object (this is generally
 // a string of the form "_xxxx_" where "xxxx"
 // is a four-digit hexadecimal value).

 ?base := @string:base;

 // This macro may need to generate a large set
 // of different labels (one for each _elseif
 // clause). This macro uses the elseLbl
 // value, along with the value of "base" above,
 // to generate these unique labels.

 ?elseLbl := 0;

 // hasElse determines if we have an _else clause

```

```

// present in this statement. This macro uses
// this value to determine if it must emit a
// final else label when it encounters _endif.

?hasElse := false;

// For an IF statement, we must evaluate the
// boolean expression and jump to the current
// else label if the expression evaluates false.

jf(ifexpr) genLabel(base, elseLbl);

// Just ignore the _then keyword.
// A slightly better implementation would require
// this keyword, the current implementation lets
// you write an "_if" clause without the "_then"
// clause. For that matter, the current implementation
// lets you arbitrarily sprinkle "_then" clauses
// throughout the "_if" statement; we will ignore
// this for this example.

keyword _then;

// Handle the "_elseif" clause here.

keyword _elseif(elsex);

 // _elseif clauses are illegal after
 // an _else clause in the statement.
 // Enforce that here.

 #if(hasElse)

 #error("Unexpected '_elseif' clause")

 #endif

 // We've just finished the "_if" clause
 // or a previous "_elseif" clause. So
 // the first thing we have to do is jump
 // to the code just beyond this "_if"
 // statement.

 jmp ifDone;

 // Okay, this is where the previous "_if" or
 // "_elseif" statement must jump if its boolean
 // expression evaluates false. Emit the target
 // label. Next, because we're about to jump
 // to our own target label, bump up the elseLbl
 // value by one to prevent jumping back to the
 // label we're about to emit. Finally, emit
 // the code that tests the boolean expression and
 // transfers control to the next _elseif or _else
 // clause if the result is false.

genLabel(base, elseLbl);

```

```

?elseLbl := elseLbl+1;
jf(elsex) genLabel(base, elseLbl);

keyword _else;

// Only allow a single "_else" clause in this
// "_if" statement:

#if(hasElse)

 #error("Unexpected '_else' clause")

#endif

// As above, we've just finished the previous "_if"
// or "_elseif" clause, so jump directly to the end
// of the "_if" statement.

jmp ifDone;

// Okay, emit the current 'else' label so that
// the failure of the previous "_if" or "_elseif"
// test will transfer control here. Also set
// 'hasElse' to true to catch additional "_elseif"
// and "_else" clauses.

genLabel(base, elseLbl):
 ?hasElse := true;

terminator _endif;

// At the end of the _if statement we must emit the
// destination label that the _if and _elseif sections
// jump to. Also, if there was no _else section, this
// code has to emit the last deployed else label.

ifDone:
#if(!hasElse)

 genLabel(base, elseLbl);

#endif

endmacro;

begin IFDemo;

// Quick demo of the use of the above statements.

for(mov(0, eax); eax < 5; inc(eax)) do

 _if(eax = 0) _then

 stdout.put("in _if statement" nl);

 _elseif(eax = 1) _then

```

```

 stdout.put("in first _elseif clause" nl);

 _elseif(eax = 2) _then

 stdout.put("in second _elseif clause" nl);

 _else

 stdout.put("in _else clause" nl);
 _if(eax > 3) _then

 stdout.put("in second _if statement" nl);

 _endif;

 _endif;

endfor;

end IFDemo;

```

---

---

### Program 9.3 Macro Implementation of the IF..ENDIF Statement

---

---

## 9.2.2 The HLA SWITCH/CASE Statement

HLA doesn't support a selection statement (SWITCH or CASE statement). Instead, HLA's SWITCH..CASE..DEFAULT..ENDSWITCH statement exists only as a macro in the HLA Standard Library HLL.HHF file. This section discusses HLA's macro implementation of the SWITCH statement.

The SWITCH statement is very complex so it should come as no surprise that the macro implementation is long, involved, and complex. The example appearing in this section is slightly simplified over the standard HLA version, but not by much. This discussion assumes that you're familiar with the low-level implementation of the SWITCH..CASE..DEFAULT..ENDSWITCH statement. If you are not comfortable with that implementation, or feel a little rusty, you may want to take another look at "SWITCH/CASE Statements" on page 752 before attempting to read this section. The discussion in this section is somewhat advanced and assumes a fair amount of programming skill. If you have trouble following this discussion, you may want to skip this section until you gain some more experience.

There are several different ways to implement a SWITCH statement. In this section we will assume that the `_switch.._endswitch` macro we are writing will implement the SWITCH statement using a jump table. Implementation as a sequence of `if..elseif` statements is fairly trivial and is left as an exercise. Other schemes are possible as well, this section will not consider them.

A typical SWITCH statement implementation might look like the following:

```

readonly
 JmpTbl:dword[3] := [&Stmt5, &Stmt6, &Stmt7];
 .
 .
 .

// switch(i)

 mov(i, eax); // Check to see if "i" is outside the range
 cmp(eax, 5); // 5..7 and transfer control directly to the
 jb EndCase // DEFAULT case if it is.

```

```

 cmp(eax, 7);
 ja EndCase;
 jmp(JumpTbl[eax*4 - 5*@size(dword)]);

// case(5)
 Stmt5:
 stdout.put("I=5");
 jmp EndCase;

// Case(6)
 Stmt6:
 stdout.put("I=6");
 jmp EndCase;

// Case(7)
 Stmt7:
 stdout.put("I=7");

EndCase:

```

If you study this code carefully, with an eye to writing a macro to implement this statement, you'll discover a couple of major problems. First of all, it is exceedingly difficult to determine how many cases and the range of values those cases cover before actually processing each CASE in the SWITCH statement. Therefore, it is really difficult to emit the range check (for values outside the range 5..7) and the indirect jump before processing all the cases in the SWITCH statement. You can easily solve this problem, however, by moving the checks and the indirect jump to the bottom of the code and inserting a couple of extra JMP instructions. This produces the following implementation:

```

readonly
 JumpTbl:dword[3] := [&Stmt5, &Stmt6, &Stmt7];
 .
 .
 .

// switch(i)

 jmp DoSwitch; // First jump inserted into this code.

// case(5)
 Stmt5:
 stdout.put("I=5");
 jmp EndCase;

// Case(6)
 Stmt6:
 stdout.put("I=6");
 jmp EndCase;

// Case(7)
 Stmt7:
 stdout.put("I=7");
 jmp EndCase; // Second jump inserted into this code.

DoSwitch: // Insert this label and move the range
 mov(i, eax); // checks and indirect jump down here.
 cmp(eax, 5);
 jb EndCase
 cmp(eax, 7);
 ja EndCase;
 jmp(JumpTbl[eax*4 - 5*@size(dword)]);

```

```
// All the cases (including the default case) jump down here:
```

```
EndCase:
```

Since the range check code appears after all the cases, the macro can now process those cases and easily determine the bounds on the cases by the time it must emit the `CMP` instructions above that check the bounds of the `SWITCH` value. However, this implementation still has a problem. The entries in the *JumpTbl* table refer to labels that can only be determined by first processing all the cases in the `SWITCH` statement. Therefore, a macro cannot emit this table in a `READONLY` section that appears earlier in the source file than the `SWITCH` statement. Fortunately, HLA lets you embed data in the middle of the code section using the `READONLY..ENDREADONLY` and `STATIC..ENDSTATIC` directives<sup>1</sup>. Taking advantage of this feature allows use to rewrite the `SWITCH` implementation as follows:

```
// switch(i)

 jmp DoSwitch; // First jump inserted into this code.
// case(5)
 Stmt5:
 stdout.put("I=5");
 jmp EndCase;

// Case(6)
 Stmt6:
 stdout.put("I=6");
 jmp EndCase;

// Case(7)
 Stmt7:
 stdout.put("I=7");
 jmp EndCase; // Second jump inserted into this code.

DoSwitch: // Insert this label and move the range
 mov(i, eax); // checks and indirect jump down here.
 cmp(eax, 5);
 jb EndCase
 cmp(eax, 7);
 ja EndCase;
 jmp(JumpTbl[eax*4 - 5*@size(dword)]);

// All the cases (including the default case) jump down here:

EndCase:

readonly
 JumpTbl:dword[3] := [&Stmt5, &Stmt6, &Stmt7];
endreadonly;
```

HLA's macros can produce code like this when processing a `SWITCH` macro. So this is the type of code we will generate with a `_switch.._case.._default.._endswitch` macro.

Since we're going to need to know the minimum and maximum case values (in order to generate the appropriate operands for the `CMP` instructions above), the `_case` KEYWORD macro needs to compare the current case value(s) against the global minimum and maximum case values for all cases. If the current case value is less than the global minimum or greater than the global maximum, then the `_case` macro must update these global values accordingly. The `_endswitch` macro will use these global minimum and maximum values in the two `CMP` instructions it generates for the range checking sequence.

---

1. HLA actually moves the data to the appropriate segment in memory, the data is not stored directly in the `CODE` section.

For each case value appearing in a `_switch` statement, the `_case` macros must save the case value and an identifying label for that case value. This is necessary so that the `_endswitch` macro can generate the jump table. What is really needed is an arbitrary list of records, each record containing a value field and a label field. Unfortunately, the HLA compile-time language does not support arbitrary lists of objects, so we will have to implement the list using a (fixed size) array of record constants. The record declaration will take the following form:

```
caseRecord:
 record
 value:uns32;
 label:uns32;
 endrecord;
```

The *value* field will hold the current case value. The *label* field will hold a unique integer value for the corresponding `_case` that the macros can use to generate statement labels. The implementation of the `_switch` macro in this section will use a variant of the trick found in the section on the `_if` macro; it will convert a local macro symbol to a string and append an integer value to the end of that string to create a unique label. The integer value appended will be the value of the *label* field in the *caseRecord* list.

Processing the `_case` macro becomes fairly easy at this point. All the `_case` macro has to do is create an entry in the *caseRecord* list, bump a few counters, and emit an appropriate case label prior to the code emission. The implementation in this section uses Pascal semantics, so all but the first case in the `_switch.._endswitch` statement must first emit a jump to the statement following the `_endswitch` so the previous case's code doesn't fall into the current case.

The real work in implementing the `_switch.._endswitch` statement lies in the generation of the jump table. First of all, there is no requirement that the cases appear in ascending order in the `_switch.._endswitch` statement. However, the entries in the jump table must appear in ascending order. Second, there is no requirement that the cases in the `_switch.._endswitch` statement be consecutive. Yet the entries in the jump table must be consecutive case values<sup>2</sup>. The code that emits the jump table must handle these inconsistencies.

The first task is to sort the entries in the *caseRecord* list in ascending order. This is easily accomplished by writing a little *SortCases* macro to sort all the *caseRecord* entries once the `_switch.._endswitch` macro has processed all the cases. *SortCases* doesn't have to be fancy. In fact, a bubblesort algorithm is perfect for this because:

- Bubble sort is easy to implement
- Bubble sort is efficient when sorting small lists and most SWITCH statements only have a few cases.
- Bubble sort is especially efficient on nearly sorted data and most programmers put their cases in ascending order.

After sorting the cases, only one problem remains: there may be gaps in the case values. This problem is easily handled by stepping through the *caseRecord* elements one by one and synthesizing consecutive entries whenever a gap appears in the list. Program 9.4 provides the full `_switch.._case.._default.._endswitch` macro implementation.

---

```

/*****
/*
/* switch.hla-
/*
/* This program demonstrates how to implement the
/* _switch.._case.._default.._endswitch statement
/* using macros.
/*
/*
/*****
```

---

2. Of course, if there are gaps in the case values, the jump table entries for the missing items should contain the address of the default case.

```

program demoSwitch;
#include("stdlib.hhf")

const

 // Because this code uses an array to implement
 // the caseRecord list, we have to specify a fixed
 // number of cases. The following constant defines
 // the maximum number of possible cases in a
 // _switch statement.

 maxCases := 256;

type

 // The following data type hold the case value
 // and statement label information for each
 // case appearing in a _switch statement.

 caseRecord:
 record

 value:uns32;
 label:uns32;

 endrecord;

 // SortCases
 //
 // This routine does a bubble sort on an array
 // of caseRecord objects. It sorts in ascending
 // order using the "value" field as the key.
 //
 // This is a good old fashioned bubble sort which
 // turns out to be very efficient because:
 //
 // (1) The list of cases is usually quite small, and
 // (2) The data is usually already sorted (or mostly sorted).

macro SortCases(sort_array, sort_size):

Program 9.4 Macro Implementation of the SWITCH..ENDSWITCH Statement

---

---

### 9.2.3 A Modified WHILE Loop

The previous sections have shown you how to implement statements that are already available in HLA or the HLA Standard Library. While this approach lets you work with familiar statements that you should be comfortable with, it doesn't really demonstrate that you can create *new* control statements with HLA's compile-time language. In this section you will see how to create a variant of the WHILE statement that is not simply a rehash of HLA's WHILE statement. This should amply demonstrate that there are some useful control structures that HLA (and high level languages) don't provide and that you can easily use HLA compile-time language to implement specialized control structures as needed.

A common use of a WHILE loop is to search through a list and stop upon encountering some desired value or upon hitting the end of the list. A typical HLA example might take the following form:

```

while(<<There are more items in the list>>) do

 breakif(<<This was the item we're looking for>>);
 << select the next item in the list>>

endwhile;

```

The problem with this approach is that when the statement immediately following the ENDWHILE executes, that code doesn't know whether the loop terminated because it found the desired value or because it exhausted the list. The typical solution is to test to see if the loop exhausted the list and deal with that accordingly:

```

while(<<There are more items in the list>>) do

 breakif(<<This was the item we're looking for>>);
 << select the next item in the list>>

endwhile;
if(<<The list wasn't exhausted>>) then

 << do something with the item we found >>

endif;

```

The problem with this "solution" should be obvious if you think about it a moment. We've already tested to see if the loop is empty, immediately after leaving the loop we repeat this same test. This is somewhat inefficient. A better solution would be to have something like an "else" clause in the WHILE loop that

executes if you break out of the loop and doesn't execute if the loop terminates because the boolean expression evaluated false. Rather than use the keyword ELSE, let's invent a new (more readable) term: *onbreak*. The ONBREAK section of a WHILE loop executes (only once) if a BREAK or BREAKIF statement was the reason for the loop termination. With this ONBREAK clause, you could recode the previous WHILE loop a little bit more elegantly as follows:

```
while(<<There are more items in the list>>) do

 breakif(<<This was the item we're looking for>>);
 << select the next item in the list>>

onbreak

 << do something with the item we found >>

endwhile;
```

Note that if the ONBREAK clause is present, the WHILE's loop body ends at the ONBREAK keyword. The ONBREAK clause executes at most once per execution of this WHILE statement.

Implementing a `_while.._onbreak.._endwhile` statement is very easy using HLA's multi-part macros. Program 9.5 provides the complete implementation of this statement:

---

---

```

/*****
/*
/* while.hla
/*
/* This program demonstrates a variant of the
/* WHILE loop that provides a special "onbreak"
/* clause. The _onbreak clause executes if the
/* program executes a _break clause or it executes
/* a _breakif clause and the corresponding
/* boolean expression evaluates true. The _onbreak
/* section does not execute if the loop terminates
/* due to the _while boolean expression evaluating
/* false.
/*
/*
/*****

program Demo_while;
#include("stdlib.hhf")

// _while semantics:
//
// _while(expr)
//
// << stmts including optional _break, _breakif
// _continue, and _continueif statements >>
//
// _onbreak // This section is optional.
//
// << stmts that only execute if program executes
// a _break or _breakif (with true expression)
// statement. >>
//
// _endwhile;

macro _while(expr):falseLbl, breakLbl, topOfLoop, hasOnBreak;
```

```

// hasOnBreak keeps track of whether we've seen an _onbreak
// section.
?hasOnBreak:boolean:=false;

// Here's the top of the WHILE loop.
// Implement this as a straight-forward WHILE (test for
// loop termination at the top of the loop).

topOfLoop:
 jf(expr) falseLbl;

// Ignore the _do keyword.

keyword _do;

// _continue and _continueif (with a true expression)
// transfer control to the top of the loop where the
// _while code retests the loop termination condition.

keyword _continue;
 jmp topOfLoop;

keyword _continueif(expr1);
 jt(expr1) topOfLoop;

// Unlike the _break or _breakif in a standard WHILE
// statement, we don't immediately exit the WHILE.
// Instead, this code transfers control to the optional
// _onbreak section if it is present. If it is not
// present, control transfers to the first statement
// beyond the _endwhile.

keyword _break;
 jmp breakLbl;

keyword _breakif(expr2);
 jt(expr2) breakLbl;

// If we encounter an _onbreak section, this marks
// the end of the while loop body. Emit a jump that
// transfers control back to the top of the loop.
// This code also has to verify that there is only
// one _onbreak section present. Any code following
// this clause is going to execute only if the _break
// or _breakif statements execute and transfer control
// down here.

keyword _onbreak;
 #if(hasOnBreak)

 #error("Extra _onbreak clause encountered")

 #else

 jmp topOfLoop;
 ?hasOnBreak := true;

 breakLbl:

```

```

#endif

terminator _endwhile;

// If we didn't have an _onbreak section, then
// this is the bottom of the _while loop body.
// Emit the jump to the top of the loop and emit
// the "breakLbl" label so the execution of a
// _break or _breakif transfers control down here.

#if(!hasOnBreak)

 jmp topOfLoop;
 breakLbl:

#endif
falseLbl:

endmacro;

static
 i:int32;

begin Demo_while;

 // Demonstration of standard while loop

 mov(0, i);

### Program 9.5 The Implementation of `_while.._onbreak.._endwhile`

---

---

## 9.2.4 A Modified IF..ELSE..ENDIF Statement

The IF statement is another statement that doesn't always do exactly what you want. Like the `_while.._onbreak.._endwhile` example above, it's quite possible to redefine the IF statement so that it behaves the way we want it to. In this section you'll see how to implement a variant of the IF..ELSE..ENDIF statement that nests differently than the standard IF statement.

It is possible to simulate short-circuit boolean evaluation involving conjunction and disjunction without using the "&&" and "||" operators if you carefully structure your code. Consider the following example:

// "C" code employing logical-AND operator:

```

if(expr1 && expr2)
{
 << statements >>
}

```

// Equivalent HLA version:

```

if(expr1) then
 if(expr2) then
 << statements >>
 endif;
endif;

```

In both cases ("C" and HLA) the `<< statements >>` block executes only if both `expr1` and `expr2` evaluate true. So other than the extra typing involved, it is often very easy to simulate logical conjunction by using two IF statements in HLA.

There is one very big problem with this scheme. Consider what happens if you modify the "C" code to be the following:

// "C" code employing logical-AND operator:

```

if(expr1 && expr2)
{
 << 'true' statements >>
}
else
{
 << 'false' statements >>
}

```

The only way to convert this to HLA (using the standard HLA high level control constructs) is by duplicating the 'false' statements. This introduces a bit of inefficiency into your code. As a result, many HLA programmers will switch to low-level control constructs or HLA's hybrid control structures (see "Hybrid

Control Structures in HLA” on page 778) in order to avoid duplicating code. Unfortunately, dropping down into low-level code may make your program harder to read. It would be nice if you could efficiently handle this situation without making your code unreadable. Fortunately, you can do exactly this by creating a new version of the IF statement using HLA’s multi-part macro facilities.

Before describing how to create this new type of IF statement, we must digress for a moment and explore an interesting feature of HLA’s multi-part macro expansion: KEYWORD macros do not have to use unique names. Whenever you declare an HLA KEYWORD macro, HLA accepts whatever name you choose. If that name happens to be already defined, then the KEYWORD macro name takes precedence as long as the macro is active (that is, from the point you invoke the macro name until HLA encounters the TERMINATOR macro). Therefore, the KEYWORD macro name hides the previous definition of that name until the termination of the macro. This feature applies even to the original macro name; that is, it is possible to define a KEYWORD macro with the same name as the original macro to which the KEYWORD macro belongs. This is a very useful feature because it allows you to change the definition of the macro within the scope of the opening and terminating invocations of the macro.

Although not pertinent to the IF statement we are construction, you should note that parameter and local symbols in a macro also override any previously defined symbols of the same name. So if you use that symbol between the opening macro and the terminating macro, you will get the value of the local symbol, not the global symbol. E.g.,

```
var
 i:int32;
 j:int32;
 .
 .
 .
macro abc:i;
 ?i:text := "j";
 .
 .
 .
terminator xyz;
 .
 .
 .
endmacro
 .
 .
 .
 mov(25, i);
 mov(10, j);
 abc
 mov(i, eax); // Loads j's value (10), not 25 into eax.
 xyz;
```

The code above loads 10 into EAX because the "mov(i, eax);" instruction appears between the opening and terminating macros *abc..xyz*. Between those two macros the local definition of *i* takes precedence over the global definition. Since *i* is a text constant that expands to *j*, the aforementioned MOV statement is really equivalent to "mov(j, eax);" That statement, of course, loads 10 into EAX. Since this problem is difficult to see while reading your code, you should choose local symbols in multi-part macros very carefully. A good convention to adopt is to combine your local symbol name with the macro name, e.g.,

```
macro abc : i_abc;
```

You may wonder why HLA allows something to crazy to happen in your source code, in a moment you’ll see why this behavior is useful (and now, with this brief message out of the way, back to our regularly scheduled discussion).

Before we digressed to discuss this interesting feature in HLA multi-part macros, we were trying to figure out how to efficiently simulate the conjunction and disjunction operators in an IF statement without actually using this operators in our code. The problem in the example appearing earlier in this section is that you

would have to duplicate some code in order to convert the IF.ELSE statement properly. The following code shows this problem:

```
// "C" code employing logical-AND operator:

if(expr1 && expr2)
{
 << 'true' statements >>
}
else
{
 << 'false' statements >>
}

// Corresponding HLA code using the "nested-IF" algorithm:

if(expr1) then

 if(expr2) then

 << 'true' statements >>

 else

 << 'false' statements >>

 endif;

else

 << 'false' statements >>

endif;
```

Note that this code must duplicate the "<< 'false' statements >>" section if the logic is to exactly match the original "C" code. This means that the program will be larger and harder to read than is absolutely necessary.

One solution to this problem is to create a new kind of IF statement that doesn't nest the same way standard IF statements nest. In particular, if we define the statement such that all IF clauses nested with an outer IF.ENDIF block share the same ELSE and ENDIF clauses. If this were the case, then you could implement the code above as follows:

```
if(expr1) then

 if(expr2) then

 << 'true' statements >>

 else

 << 'false' statements >>

 endif;

endif;
```

If *expr1* is false, control immediately transfers to the ELSE clause. If the value of *expr1* is true, the control falls through to the next IF statement.

If *expr2* evaluates false, then the program jumps to the single ELSE clause that all IFs share in this statement. Notice that a single ELSE clause (and corresponding 'false' statements) appear in this code; hence the

code does not necessarily expand in size. If `expr2` evaluates true, then control falls through to the 'true' statements, exactly like a standard IF statement.

Notice that the nested IF statement above does not have a corresponding ENDIF. Like the ELSE clause, all nested IFs in this structure share the same ENDIF. Syntactically, there is no need to end the nested IF statement; the end of the THEN section ends with the ELSE clause, just as the outer IF statement's THEN block ends.

Of course, we can't actually define a new macro named "if" because you cannot redefine HLA reserved words. Nor would it be a good idea to do so even if these were legal (since it would make your programs very difficult to comprehend if the IF keyword had different semantics in different parts of the program. The following program uses the identifiers "\_if", "\_then", "\_else", and "\_endif" instead. It is questionable if these are good identifiers in production code (perhaps something a little more different would be appropriate). The following code example uses these particular identifiers so you can easily correlate them with the corresponding high level statements.

```

/*****
/*
/* if.hla
/*
/* This program demonstrates a modification of
/* the IF..ELSE..ENDIF statement using HLA's
/* multi-part macros.
/*
/*
/*****

program newIF;
#include("stdlib.hhf")

// Macro implementation of new form of if..then..else..endif.
//
// In this version, all nested IF statements transfer control
// to the same ELSE clause if any one of them have a false
// boolean expression. Syntax:
//
// _if(expression) _then
//
// <<statements including nested _if clauses>>
//
// _else // this is optional
//
// <<statements, but _if clauses are not allowed here>>
//
// _endif
//
// Note that nested _if clauses do not have a corresponding
// _endif clause. This is because the single _else and/or
// _endif clauses terminate all the nested _if clauses
// including the first one. Of course, once the code
// encounters an _endif another _if statement may begin.

// Macro to handle the main "_if" clause.
// This code just tests the expression and jumps to the _else
// clause if the expression evaluates false.

```

```

macro _if(ifExpr):elseLbl, hasElse, ifDone;

 ?hasElse := false;
 jf(ifExpr) elseLbl;

// Just ignore the _then keyword.

keyword _then;

// Nested _if clause (yes, HLA lets you replace the main
// macro name with a keyword macro). Identical to the
// above _if implementation except this one does not
// require a matching _endif clause. The single _endif
// (matching the first _if clause) terminates all nested
// _if clauses as well as the main _if clause.

keyword _if(nestedIfExpr);
 jf(nestedIfExpr) elseLbl;

 // If this appears within the _else section, report
 // an error (we don't allow _if clauses nested in
 // the else section, that would create a loop).

 #if(hasElse)

 #error("All _if clauses must appear before the _else clause")

 #endif

// Handle the _else clause here. All we need to is check to
// see if this is the only _else clause and then emit the
// jmp over the else section and output the elseLbl target.

keyword _else;
 #if(hasElse)

 #error("Only one _else clause is legal per _if.._endif")

 #else

 // Set hasElse true so we know that we've seen an _else
 // clause in this statement.

 ?hasElse := true;
 jmp ifDone;
 elseLbl:

 #endif

// _endif has two tasks. First, it outputs the "ifDone" label
// that _else uses as the target of its jump to skip over the
// else section. Second, if there was no else section, this
// code must emit the "elseLbl" label so that the false conditional(s)
// in the _if clause(s) have a legal target label.

terminator _endif;

 ifDone:

```

```

 #if(!hasElse)

 elseLbl:

 #endif

endmacro;

static
 tr:boolean := true;
 f:boolean := false;

begin newIF;

 // Real quick demo of the _if statement:

 _if(tr) _then

 _if(tr) _then
 _if(f) _then

 stdout.put("error" nl);

 _else

 stdout.put("Success");

 _endif

 _endif

end newIF;

```

---

### Program 9.6 Using Macros to Create a New IF Statement

---

Just in case you're wondering, this program prints "Success" and then quits. This is because the nested "\_if" statements are equivalent to the expression "true && true && false" which, of course, is false. Therefore, the "\_else" portion of this code should execute.

The only surprise in this macro is the fact that it redefines the *\_if* macro as a keyword macro upon invocation of the main *\_if* macro. The reason this code does this is so that any nested *\_if* clauses do not require a corresponding *\_endif* and don't support an *\_else* clause.

Implementing an ELSEIF clause introduces some difficulties, hence its absence in this example. The design and implementation of an ELSEIF clause is left to the more serious reader<sup>3</sup>.

---

## 9.3 Sample Program: A Simple Expression Compiler

This program's sample program is a bit complex. In fact, the theory behind this program is well beyond the scope of this text (since it involves compiler theory). However, this example is such a good demonstration of the capabilities of HLA's macro facilities and DSEL capabilities, it was too good not to include here. The following paragraphs will attempt to explain how this compile-time program operates. If you have difficulty understanding what's going on, don't feel too bad, this code isn't exactly the type of stuff that beginning assembly language programmers would normally develop on their own.

---

3. I.e., I don't even want to have to think about this problem!

This program presents a (very) simple *expression compiler*. This code includes a macro, *u32expr*, that emits a sequence of instructions that compute the value of an arithmetic expression and leave that result sitting in one of the 80x86's 32-bit registers. The syntax for the *u32expr* macro invocation is the following:

```
u32expr(reg32, uns32_expression);
```

This macro emits the code that computes the following (HLL) statement:

```
reg32 := uns32_expression;
```

For example, the macro invocation "u32expr( eax, ebx+ecx\*5 - edi );" computes the value of the expression "ebx+ecx\*5 - edi" and leaves the result of this expression sitting in the EAX register.

The *u32expr* macro places several restrictions on the expression. First of all, as the name implies, it only computes the result of an *uns32* expression. No other data types may appear within the expression. During computation, the macro uses the EAX and EDX registers, so expressions should not contain these registers as their values may be destroyed by the code that computes the expression (EAX or EDX may safely appear as the first operand of the expression, however). Finally, expressions may only contain the following operators:

```
<, <=, >, >=, <>, !=, =, ==
 +, -
 *, /
 (,)
```

The "<>" and "!=" operators are equivalent (not equals) and the "=" and "==" operators are also equivalent (equals). The operators above are listed in order of increasing precedence; i.e., "\*" has a higher precedence than "+" (as you would expect). You can override the precedence of an operator by using parentheses in the standard manner.

It is important to remember that *u32expr* is a macro, not a function. That is, the invocation of this macro results in a sequence of 80x86 assembly language instructions that computes the desired expression. The *u32expr* invocation is not a function call. to some routine that computes the result.

To understand how this macro works, it would be a good idea to review the section on "Converting Arithmetic Expressions to Postfix Notation" on page 613. That section discusses how to convert floating point expressions to reverse polish notation; although the *u32expr* macro works with *uns32* objects rather than floating point objects, the approach it uses to translate expressions into assembly language uses this same algorithm. So if you don't remember how to translate expressions into reverse polish notation, it might be worthwhile to review that section of this text.

Converting floating point expressions to reverse polish notation is especially easy because the 80x86's FPU uses a stack architecture. Alas, the integer instructions on the 80x86 use a register architecture and efficiently translating integer expression to assembly language is a bit more difficult (see "Arithmetic Expressions" on page 577). We'll solve this problem by translating the expressions to assembly code in a somewhat less than efficient manner; we'll simulate an integer stack architecture by using the 80x86's hardware stack to hold temporary results during an integer calculation.

To push an integer constant or variable onto the 80x86 hardware stack, we need only use a PUSH or PUSHFD instruction. This operation is trivial.

To add two values sitting on the top of stack together, leaving their sum on the stack, all we need do is pop those two values into registers, add the register values, and then push the result back onto the stack. We can do this operation slightly more efficiently, since addition is commutative, by using the following code:

```
// Compute X+Y where X is on NOS (next on stack) and Y is on TOS (top of stack):
 pop(eax); // Get Y's value.
 add(eax, [esp]); // Add with X's value and leave sum on TOS.
```

Subtraction is identical to addition. Although subtraction is not commutative the operands just happen to be on the stack in the proper order to efficiently compute their difference. To compute "X-Y" where X is on NOS and Y is on TOS, we can use code like the following:

```
// Compute X-y where X is on NOS and Y is on TOS:

 pop(eax);
 sub(eax, [esp]);
```

Multiplication of the two items on the top of stack is a little more complicated since we must use the MUL instruction (the only unsigned multiplication instruction available) and the destination operand must be the EDX:EAX register pair. Fortunately, multiplication is a commutative operation, so we can compute the product of NOS and TOS using code like the following:

```
// Compute X*Y where X is on NOS and Y is on TOS:

 pop(eax);
 mul([esp], eax); // Note that this wipes out the EDX register.
 mov(eax, [esp]);
```

Division is problematic because it is not a commutative operation and its operands on the stack are not in a convenient order. That is, to compute X/Y it would be really convenient if X was on TOS and Y was in the NOS position. Alas, as you'll soon see, it turns out that X is at NOS and Y is on the TOS. To resolve this issue requires slightly less efficient code than the sequences we've used above. Since the DIV instruction is so slow anyway, this will hardly matter.

```
// Compute X/Y where X is on NOS and Y is on TOS:

 mov([esp+4], eax); // Get X from NOS.
 xor(edx, edx); // Zero-extend EAX into EDX:EAX
 div([esp], edx:eax); // Compute their quotient.
 pop(edx); // Remove unneeded Y value from the stack.
 mov(eax, [esp]); // Store quotient to the TOS.
```

The remaining operators are the comparison operators. These operators compare the value on NOS with the value on TOS and leave true (1) or false (0) sitting on the stack based on the result of the comparison. While it is easy to work around the non-commutative aspect of many of the comparison operators, the big challenge is converting the result to true or false. The SETcc instructions are convenient for this purpose, but they only work on byte operands. Therefore, we will have to zero extend the result of the SETcc instructions to obtain an *uns32* result we can push onto the stack. Ultimately, the code we must emit for a comparison is similar to the following:

```
// Compute X <= Y where X is on NOS and Y is on TOS.

 pop(eax);
 cmp([esp], eax);
 setbe(al); // This instruction changes for other operators.
 movzx(al, eax);
 mov(eax, [esp]);
```

As it turns out, the appearance of parentheses in an expression only affects the order of the instructions appearing in the sequence, it does not affect the number of type of instructions that correspond to the calculation of an expression. As you'll soon see, handling parentheses is an especially trivial operation.

With this short description of how to emit code for each type of arithmetic operator, it's time to discuss exactly how we will write a macro to automate this translation. Once again, a complete discussion of this

topic is well beyond the scope of this text, however a simple introduction to compiler theory will certainly ease the understanding the *u32expr* macro.

For efficiency and reasons of convenience, most compilers are broken down into several components called *phases*. A compiler phase is collection of logically related activities that take place during compilation. There are three general compiler phases we are going to consider here: (1) *lexical analysis* (or *scanning*), (2) *parsing*, and (3) *code generation*. It is important to realize that these three activities occur concurrently during compilation; that is, they take place at the same time rather than as three separate, serial, activities. A compiler will typically run the lexical analysis phase for a short period, transfer control to the parsing phase, do a little code generation, and then, perhaps, do some more scanning and parsing and code generation (not necessarily in that order). Real compilers have additional phases, the *u32expr* macro will only use these three phases (and if you look at the macro, you'll discover that it's difficult to separate the parsing and code generation phases).

Lexical analysis is the process of breaking down a string of characters, representing the expression to compile, into a sequence of *tokens* for use by the parser. For example, an expression of the form "MaxVal - x <= \$1c" contains five distinct tokens:

- MaxVal
- -
- x
- <=
- \$1c

Breaking any one of these tokens into smaller objects would destroy the intent of the expression (e.g., converting MaxVal to "Max" and "Val" or converting "<=" into "<" and "="). The job of the lexical analyzer is to break the string down into a sequence of constituent tokens and return this sequence of tokens to the parser (generally one token at a time, as the parser requests new tokens). Another task for the lexical analyzer is to remove any extra white space from the string of symbols (since expressions may generally contain an arbitrary amount of white space).

Fortunately, it is easy to extract the next available token in the input string by skipping all white space characters and then look at the current character. Identifiers always begin with an alphabetic character or an underscore, numeric values always begin with a decimal digit, a dollar sign ("\$"), or a percent sign ("%"). Operators always begin with the corresponding punctuation character that represents the operator. There are only two major issues here: how do we classify these tokens and how do we differentiate two or more distinct tokens that start with the same character (e.g., "<", "<=", and "<>")? Fortunately, HLA's compile-time functions provide the tools we need to do this.

Consider the declaration of the *u32expr* macro:

```
macro u32expr(reg, expr):sexpr;
```

The *expr* parameter is a text object representing the expression to compile. The *sexpr* local symbol will contain the string equivalent of this text expression. The macro translates the text *expr* object to a string with the following statement:

```
?sexpr := @string:expr;
```

From this point forward, the macro works with the string in *sexpr*.

The *lexer* macro (compile-time function) handles the lexical analysis operation. This macro expects a single string parameter from which it extracts a single token and removes the string associated with that token from the front of the string. For example, the following macro invocation returns "2" as the function result and leaves "+3" in the parameter string (*str2Lex*):

```
?str2Lex := "2+3";
?TokenResult := lexer(str2Lex);
```

The *lexer* function actually returns a little more than the string it extracts from its parameter. The actual return value is a record constant that has the definition:

```
tokType:
 record
```

```

lexeme:string;
tokClass:tokEnum;

endrecord;

```

The *lexeme* field holds that actual string (e.g., "2" in this example) that the *lexer* macro returns. The *tokClass* field holds a small numeric value (see the *tokEnum* enumerated data type) that specifies that type of the token. In this example, the call to *lexer* stores the value *intconst* into the *tokClass* field. Having a single value (like *intconst*) when the *lexeme* could take on a large number of different forms (e.g., "2", "3", "4", ...) will help make the parser easier to write. The call to *lexer* in the previous example produces the following results:

```

str2lex : "+3"
TokenResult.lexeme: "2"
TokenResult.tokClass: intconst

```

A subsequent call to *lexer*, immediately after the call above, will process the next available character in the string and return the following values:

```

str2lex : "3"
TokenResult.lexeme: "+"
TokenResult.tokClass: plusOp

```

To see how *lexer* works, consider the first few lines of the *lexer* macro:

```

macro lexer(input):theLexeme,boolResult;

 ?theLexeme:string; // Holds the string we scan.
 ?boolResult:boolean; // Used only as a dummy value.

 // Check for an identifier.

 #if(@peekCset(input, tok1stIDChar))

 // If it began with a legal ID character, extract all
 // ID characters that follow. The extracted string
 // goes into "theLexeme" and this call also removes
 // those characters from the input string.

 ?boolResult := @oneOrMoreCset(input, tokIDChars, input, theLexeme);

 // Return a tokType constant with the identifier string and
 // the "identifier" token value:

 tokType:[theLexeme, identifier]

 // Check for a decimal numeric constant.

 #elseif(@peekCset(input, digits))
 .
 .
 .

```

The real work begins with the *#IF* statement where the code uses the *@peekCset* function to see if the first character of the *input* parameter is a member of the *tok1stIDChar* set (which is the alphabetic characters plus an underscore, i.e., the set of character that may appear as the first character of an identifier). If so, the

code executes the `@oneOrMoreCset` function to extract all legal identifier characters (alphanumerics plus underscore), storing the result in the `theLexeme` string variable. Note that this function call to `@oneOrMoreCset` also removes the string it matches from the front of the `input` string (see the description of `@oneOrMoreCset` for more details). This macro returns a `tokType` result by simply specifying a `tokType` constant containing `theLexeme` and the enum constant `identifier`.

If the first character of the input string is not in the `tok1stIDChar` set, then the `lexer` macro checks to see if the first character is a legal decimal digit. If so, then this macro processes that string of digits in a manner very similar to identifiers. The code handles hexadecimal and binary constants in a similar fashion. About the only thing exciting in the whole macro is the way it differentiates tokens that begin with the same symbol. Once it determines that a token begins with a character common to several lexemes, it calls `@matchStr` to attempt to match the longer tokens before settling on the shorter lexeme (i.e., `lexer` attempts to match "`<=`" or "`<>`" before it decides the lexeme is just "`<`"). Other than this complication, the operation of the `lexer` is really quite simple.

The operation of the parser/code generation phases is a bit more complex, especially since these macros are indirectly recursive; to simplify matters we will explore the parser/code generator in a bottom-up fashion.

The parser/code generator phases consist of four separate macros: `doTerms`, `doMulOps`, `doAddOps`, and `doCmpOps`. The reason for these four separate macros is to handle the different precedences of the arithmetic operators and the parentheses. An explanation of how these four macros handle the different arithmetic precedences is beyond the scope of this text; we'll just look at how these four macros do their job.

The `doTerms` macro is responsible for handling identifiers, numeric constants, and subexpressions surrounded by parentheses. The single parameter is the current input string whose first (non-blank) character sequence is an identifier, constant, or parenthetical expression. Here is the full text for this macro:

```
macro doTerms(expr):termToken;

 // Begin by removing any leading white space from the string:
 ?expr := @trim(expr, 0);

 // Okay, call the lexer to extract the next token from the input:
 ?termToken:tokType := lexer(expr);

 // See if the current token is an identifier. If so, assume that
 // it's an uns32 identifier and emit the code to push its value onto
 // the stack.

 #if(termToken.tokClass = identifier)

 // If we've got an identifier, emit the code to
 // push that identifier onto the stack.

 push(@text(termToken.lexeme));

 // If it wasn't an identifier, see if it's a numeric constant.
 // If so, emit the code that will push this value onto the stack.

 #elseif(termToken.tokClass = intconst)

 // If we've got a constant, emit the code to push
 // that constant onto the stack.

 pushd(@text(termToken.lexeme));

 // If it's not an identifier or an integer constant, see if it's
 // a parenthesized subexpression. If so, invoke the doCmpOps macro
 // to do the real work of code generation for the subexpression.
 // The call to the doCmpOps macro emits all the code needed to push
```

```

// the result of the subexpression onto the stack; note that this
// macro doesn't need to emit any code for the parenthetical expression,
// all the code emission is handled by doCmpOps.

#elseif(termToken.tokClass = lparen)

 // If we've got a parenthetical expression, emit
 // the code to leave the parenthesized expression
 // sitting on the stack.

 doCmpOps(expr);

 // We must have a closing right parentheses after the subexpression.
 // Skip any white space and check for the closing ")" here.

 ?expr := @trim(expr, 0);
 ?termToken:tokType := lexer(expr);
 #if(termToken.tokClass <> rparen)

 #error("Expected closing parenthesis: " + termToken.lexeme)

 #endif

// If we get to this point, then the lexer encountered something besides
// an identifier, a numeric constant, or a parenthetical expression.

#else

 #error("Unexpected term: '" + termToken.lexeme + "'")

#endif

endmacro;

```

The *doTerms* macro is responsible for leaving a single item sitting on the top of the 80x86 hardware stack. That stack item is either the value of an *uns32* identifier, the value of an *uns32* expression, or the value left on the stack via a parenthesized subexpression. The important thing to remember is that you can think of *doTerms* as a function that emits code that leaves a single item on the top of the 80x86 stack.

The *doMulOps* macro handles expressions consisting of a single term (items handled by the *doTerms* macro) optionally followed by zero or more pairs consisting of a multiplicative operator ("\*" or "/") and a second term. It is especially important to remember that the *doMulOps* macro does not require the presence of a multiplicative operator; it will legally process a single term (identifier, numeric constant, or parenthetical expression). If one or more multiplicative operator and term pairs are present, the *doMulOps* macro will emit the code that will multiply the values of the two terms together and push the result onto the stack. E.g., consider the following:

$$X * 5$$

Since there is a multiplicative operator present ("\*"), the *doMulOps* macro will call *doTerms* to process the two terms (pushing *X* and then *Y* onto the stack) and then the *doMulOps* macro will emit the code to multiply the two values on the stack leaving their product on the stack. The complete code for the *doMulOps* macro is the following:

```

macro doMulOps(sexpr):opToken;

 // Process the leading term (not optional). Note that
 // this expansion leaves an item sitting on the stack.

 doTerms(sexpr);

```

```

// Process all the MULOPs at the current precedence level.
// (these are optional, there may be zero or more of them.)
// Begin by removing any leading white space.

?sexpr := @trim(sexpr, 0);
#while(@peekCset(sexpr, MulOps)

 // Save the operator so we know what code we should
 // generate later.

 ?opToken := lexer(sexpr);

 // Get the term following the operator.

 doTerms(sexpr);

 // Okay, the code for the two terms is sitting on
 // the top of the stack (left operand at [esp+4] and
 // the right operand at [esp]). Emit the code to
 // perform the specified operation.

 #if(opToken.lexeme = "*")

 // For multiplication, compute
 // [esp+4] = [esp] * [esp+4] and
 // then pop the junk off the top of stack.

 pop(eax);
 mul((type dword [esp]));
 mov(eax, [esp]);

 #elseif(opToken.lexeme = "/")

 // For division, compute
 // [esp+4] = [esp+4] / [esp] and
 // then pop the junk off the top of stack.

 mov([esp+4], eax);
 xor(edx, edx);
 div([esp], edx:eax);
 pop(edx);
 mov(eax, [esp]);

 #endif
 ?sexpr := @trim(sexpr, 0);

#endwhile

endmacro;

```

Note the simplicity of the code generation. This macro assumes that *doTerms* has done its job leaving two values sitting on the top of the stack. Therefore, the only code this macro has to generate is the code to pop these two values off the stack and then multiply or divide them, depending on the actual operator that is present. The code generation uses the sequences appearing earlier in this section.

The *doAddOps* and *doCmpOps* macros work in a manner nearly identical to *doMulOps*. The only difference is the operators these macros handle (and, of course, the code that they generate). See Program 9.7, below, for details concerning these macros.

Once we've got the lexer and the four parser/code generation macros written, writing the *u32expr* macro is quite easy. All that *u32expr* needs to do is call the *doCmpOps* macro to compile the expression and then pop the result off the stack and store it into the destination register appearing as the first operand. This requires little more than a single POP instruction.

About the only thing interesting in the *u32expr* macro is the presence of the RETURNS statement. This HLA statement takes the following form:

```
returns({ statements }, string_expression)
```

This statement simply compiles the sequence of statements appearing between the braces in the first operand and then it uses the second *string\_expression* operand as the "returns" value for this statement. As you may recall from the discussion of instruction composition ( see "Instruction Composition in HLA" on page 538), HLA substitutes the "returns" value of a statement in place of that statement if it appears as an operand to another expression. The RETURNS statement appearing in the *u32expr* macro returns the register you specify as the first parameter as the "returns" value for the macro invocation. This lets you invoke the *u32expr* macro as an operand to many different instructions (that accept a 32-bit register as an operand). For example, the following *u32expr* macro invocations are all legal:

```
mov(u32expr(eax, i*j+k/15 - 2), m);
if(u32expr(edx, eax < (ebx-2)*ecx) then ... endif;
funcCall(u32expr(eax, (x*x + y*y)/z*z), 16, 2);
```

Well, without further ado, here's the complete code for the *u32expr* compiler and some test code that checks out the operation of this macro:

---

---

```
// u32expr.hla
//
// This program demonstrates how to write an "expression compiler"
// using the HLA compile-time language. This code defines a macro
// (u32expr) that accepts an arithmetic expression as a parameter.
// This macro compiles that expression into a sequence of HLA
// machine language instructions that will compute the result of
// that expression at run-time.
//
// The u32expr macro does have some severe limitations.
// First of all, it only support uns32 operands.
// Second, it only supports the following arithmetic
// operations:
//
// +, -, *, /, <, <=, >, >=, =, <>.
//
// The comparison operators produce zero (false) or
// one (true) depending upon the result of the (unsigned)
// comparison.
//
// The syntax for a call to u32expr is
//
// u32expr(register, expression)
//
// The macro computes the result of the expression and
// leaves this result sitting in the register specified
// as the first operand. This register overwrites the
// values in the EAX and EDX registers (though these
// two registers are fine as the destination for the
// result).
//
// This macro also returns the first (register) parameter
// as its "returns" value, so you may use u32expr anywhere
```

```
// a 32-bit register is legal, e.g.,
//
// if(u32expr(eax, (i*3-2) < j)) then
//
// << do something if (i*3-2) < j >>
//
// endif;
//
// The statement above computes true or false in EAX and the
// "if" statement processes this result accordingly.
```

```
program TestExpr;
#include("stdlib.hhf")

// Some special character classifications the lexical analyzer uses.
```

```
const
```

```
 // tok1stIDChar is the set of legal characters that
 // can begin an identifier. tokIDChars is the set
 // of characters that may follow the first character
 // of an identifier.
```

```
 tok1stIDChar := { 'a'..'z', 'A'..'Z', '_' };
 tokIDChars := { 'a'..'z', 'A'..'Z', '0'..'9', '_' };
```

```
 // digits, hexDigits, and binDigits are the sets
 // of characters that are legal in integer constants.
 // Note that these definitions don't allow underscores
 // in numbers, although it would be a simple fix to
 // allow this.
```

```
 digits := { '0'..'9' };
 hexDigits := { '0'..'9', 'a'..'f', 'A'..'F' };
 binDigits := { '0'..'1' };
```

```
 // CmpOps, PlusOps, and MulOps are the sets of
 // operator characters legal at three levels
 // of precedence that this parser supports.
```

```
 CmpOps := { '>', '<', '=', '!' };
 PlusOps := { '+', '-' };
 MulOps := { '*', '/' };
```

```
type
```

```
 // tokEnum-
 //
 // Data values the lexical analyzer returns to quickly
 // determine the classification of a lexeme. By
 // classifying the token with one of these values, the
 // parser can more quickly process the current token.
 // I.e., rather than having to compare a scanned item
 // against the two strings "+" and "-", the parser can
 // simply check to see if the current item is a "plusOp"
```

```

// (which indicates that the lexeme is "+" or "-").
// This speeds up the compilation of the expression since
// only half the comparisons are needed and they are
// simple integer comparisons rather than string comparisons.

tokEnum: enum
 {
 identifier,
 intconst,
 lparen,
 rparen,
 plusOp,
 mulOp,
 cmpOp
 };

// tokType-
//
// This is the "token" type returned by the lexical analyzer.
// The "lexeme" field contains the string that matches the
// current item scanned by the lexer. The "tokClass" field
// contains a generic classification for the symbol (see the
// "tokEnum" type above).

tokType:
 record

 lexeme:string;
 tokClass:tokEnum;

 endrecord;

// lexer-
//
// This is the lexical analyzer. On each call it extracts a
// lexical item from the front of the string passed to it as a
// parameter (it also removes this item from the front of the
// string). If it successfully matches a token, this macro
// returns a tokType constant as its return value.

macro lexer(input):theLexeme,boolResult;

 ?theLexeme:string; // Holds the string we scan.
 ?boolResult:boolean; // Used only as a dummy value.

 // Check for an identifier.

 #if(@peekCset(input, tok1stIDChar))

 // If it began with a legal ID character, extract all
 // ID characters that follow. The extracted string
 // goes into "theLexeme" and this call also removes
 // those characters from the input string.

 ?boolResult := @oneOrMoreCset(input, tokIDChars, input, theLexeme);

 // Return a tokType constant with the identifier string and
 // the "identifier" token value:

```

```

tokType:[theLexeme, identifier]

// Check for a decimal numeric constant.

#elseif(@peekCset(input, digits))

 // If the current item began with a decimal digit, extract
 // all the following digits and put them into "theLexeme".
 // Also remove these characters from the input string.

 ?boolResult := @oneOrMoreCset(input, digits, input, theLexeme);

 // Return an integer constant as the current token.

 tokType:[theLexeme, intconst]

// Check for a hexadecimal numeric constant.

#elseif(@peekChar(input, '$'))

 // If we had a "$" symbol, grab it and any following
 // hexadecimal digits. Set boolResult true if there
 // is at least one hexadecimal digit. As usual, extract
 // the hex value to "theLexeme" and remove the value
 // from the input string:

 ?boolResult := @oneChar(input, '$', input) &
 @oneOrMoreCset(input, hexDigits, input, theLexeme);

 // Returns the hex constant string as an intconst object:

 tokType:['$' + theLexeme, intconst]

// Check for a binary numeric constant.

#elseif(@peekChar(input, '%'))

 // See the comments for hexadecimal constants. This boolean
 // constant scanner works the same way.

 ?boolResult := @oneChar(input, '%', input) &
 @oneOrMoreCset(input, binDigits, input, theLexeme);
 tokType:['%' + theLexeme, intconst]

// Handle the "+" and "-" operators here.

#elseif(@peekCset(input, PlusOps))

 // If it was a "+" or "-" sign, extract it from the input
 // and return it as a "plusOp" token.

 ?boolResult := @oneCset(input, PlusOps, input, theLexeme);
 tokType:[theLexeme, plusOp]

```

```

// Handle the "*" and "/" operators here.

#elseif(@peekCset(input, MulOps))

 // If it was a "*" or "/" sign, extract it from the input
 // and return it as a "mulOp" token.

 ?boolResult := @oneCset(input, MulOps, input, theLexeme);
 tokType:[theLexeme, mulOp]

// Handle the "=" ("=="), "<>" ("!="), "<", "<=", ">", and ">="
// operators here.

#elseif(@peekCset(input, CmpOps))

 // Note that we must check for two-character operators
 // first so we don't confuse them with the single
 // character operators:

 #if
 (
 @matchStr(input, ">=", input, theLexeme)
 | @matchStr(input, "<=", input, theLexeme)
 | @matchStr(input, "<>", input, theLexeme)
)

 tokType:[theLexeme, cmpOp]

 #elseif(@matchStr(input, "!=", input, theLexeme))

 tokType:["<>", cmpOp]

 #elseif(@matchStr(input, "==", input, theLexeme))

 tokType:["=", cmpOp]

 #elseif(@oneCset(input, {'>', '<', '='}, input, theLexeme))

 tokType:[theLexeme, cmpOp]

 #else

 #error("Illegal comparison operator: " + input)

 #endif

// Handle the parentheses down here.

#elseif(@oneChar(input, '(', input, theLexeme))

 tokType:["(", lparen]

#elseif(@oneChar(input, ')', input, theLexeme))

## 9.4 Putting It All Together

The ability to extend the HLA language is one of the most powerful features of the HLA language. In this chapter you got to explore the use of several tools that allow you to extend the base language. Although a complete treatise on language design and implementation is beyond the scope of this chapter, further study in the area of compiler construction will help you learn new techniques for extending the HLA language. Later volumes in this text, including the volume on advanced string handling, will cover additional topics of interest to those who want to design and implement their own language constructs.

---

# Classes and Objects

# Chapter Ten

---

## 10.1 Chapter Overview

Many modern imperative high level languages now support the notion of classes and objects in their programming paradigm. C++ (an object version of C) and Delphi (an object version of Pascal) are two good examples. Of course, these high level language compilers translate their high level source code into low-level machine code, so it should be pretty obvious that some mechanism exists in machine code for implementing classes and objects.

Although it has always been possible to implement classes and objects in machine code, most assemblers provide poor support for writing object-oriented assembly language programs. Of course, HLA does not suffer from this drawback as it provides good support for writing object-oriented assembly language programs. This chapter discusses the general principles behind object-oriented programming (OOP) and how HLA supports OOP.

---

## 10.2 General Principles

Before discussing the mechanisms behind OOP, it is probably a good idea to take a step back and explore the benefits of using OOP (especially in assembly language programs). Most texts describing the benefits of OOP will mention buzz-words like “code reuse,” “abstract data types,” “improved development efficiency,” and so on. While all of these features are nice and are good attributes for a programming paradigm, a good software engineer would question the use of assembly language in an environment where “improved development efficiency” is an important goal. After all, you can probably obtain far better efficiency by using a high level language (even in a non-OOP fashion) than you can by using objects in assembly language. If the purported features of OOP don’t seem to apply to assembly language programming, why bother using OOP in assembly? This section will explore some of those reasons.

The first thing you should realize is that the use of assembly language does not negate the aforementioned OOP benefits. OOP in assembly language does promote code reuse, it provides a good method for implementing abstract data types, and it can improve development efficiency *in assembly language*. In other words, if you’re dead set on using assembly language, there are benefits to using OOP.

To understand one of the principle benefits of OOP, consider the concept of a global variable. Most programming texts strongly recommend against the use of global variables in a program (as does this text). Interprocedural communication through global variables is dangerous because it is difficult to keep track of all the possible places in a large program that modify a given global object. Worse, it is very easy when making enhancements to accidentally reuse a global object for something other than its intended purpose; this tends to introduce defects into the system.

Despite the well-understood problems with global variables, the semantics of global objects (extended lifetimes and accessibility from different procedures) are absolutely necessary in various situations. Objects solve this problem by letting the programmer decide on the lifetime of an object<sup>1</sup> as well as allow access to data fields from different procedures. Objects have several advantages over simple global variables insofar as objects can control access to their data fields (making it difficult for procedures to accidentally access the data) and you can also create multiple *instances* of an object allowing two separate sections of your program to use their own unique “global” object without interference from the other section.

Of course, objects have many other valuable attributes. One could write several volumes on the benefits of objects and OOP; this single chapter cannot do this subject justice. The following subsections present objects with an eye towards using them in HLA/assembly programs. However, if you are a beginning to

---

1. That is, the time during which the system allocates memory for an object.

OOP or wish more information about the object-oriented paradigm, you should consult other texts on this subject.

An important use for classes and objects is to create *abstract data types* (ADTs). An abstract data type is a collection of data objects and the functions (which we'll call *methods*) that operate on the data. In a pure abstract data type, the ADT's methods are the only code that has access to the data fields of the ADT; external code may only access the data using function calls to get or set data field values (these are the ADT's *accessor* methods). In real life, for efficiency reasons, most languages that support ADTs allow, at least, limited access to the data fields of an ADT by external code.

Assembly language is not a language most people associate with ADTs. Nevertheless, HLA provides several features to allow the creation of rudimentary ADTs. While some might argue that HLA's facilities are not as complete as those in a language such as C++ or Java, keep in mind that these differences exist because HLA is assembly language.

True ADTs should support *information hiding*. This means that the ADT does not allow the user of an ADT access to internal data structures and routines which manipulate those structures. In essence, information hiding restricts access to an ADT to only the accessor methods provided by the ADT. Assembly language, of course, provides very few restrictions. If you are dead set on accessing an object directly, there is very little HLA can do to prevent you from doing this. However, HLA has some facilities which will provide a small amount of information hiding capabilities. Combined with some care on your part, you will be able to enjoy many of the benefits of information hiding within your programs.

The primary facility HLA provides to support information hiding is separate compilation, linkable modules, and the `#INCLUDE/#INCLUDEONCE` directives. For our purposes, an abstract data type definition will consist of two sections: an *interface* section and an *implementation* section.

The interface section contains the definitions which must be visible to the application program. In general, it should not contain any specific information which would allow the application program to violate the information hiding principle, but this is often impossible given the nature of assembly language. Nevertheless, you should attempt to only reveal what is absolutely necessary within the interface section.

The implementation section contains the code, data structures, etc., to actually implement the ADT. While some of the methods and data types appearing in the implementation section may be public (by virtue of appearance within the interface section), many of the subroutines, data items, and so on will be private to the implementation code. The implementation section is where you hide all the details from the application program.

If you wish to modify the abstract data type at some point in the future, you will only have to change the interface and implementation sections. Unless you delete some previously visible object which the applications use, there will be no need to modify the applications at all.

Although you could place the interface and implementation sections directly in an application program, this would not promote information hiding or maintainability, especially if you have to include the code in several different applications. The best approach is to place the implementation section in an include file that any interested application reads using the HLA `#INCLUDE` directive and to place the implementation section in a separate module that you link with your applications.

The include file would contain `EXTERNAL` directives, any necessary macros, and other definitions you want made public. It generally would not contain 80x86 code except, perhaps, in some macros. When an application wants to make use of an ADT it would include this file.

The separate assembly file containing the implementation section would contain all the procedures, functions, data objects, etc., to actually implement the ADT. Those names which you want to be public should appear in the interface include file and have the `EXTERNAL` attribute. You should also include the interface include file in the implementation file so you do not have to maintain two sets of `EXTERNAL` directives.

One problem with using procedures for data access methods is the fact that many accessor methods are especially trivial (typically just a `MOV` instruction) and the overhead of the call and return instructions is expensive for such trivial operations. For example, suppose you have an ADT whose data object is a structure, but you do not want to make the field names visible to the application and you really do not want to allow the application to access the fields of the data structure directly (because the data structure may change in the future). The normal way to handle this is to supply a method *GetField* which returns the desired field

of the object. However, as pointed out above, this can be very slow. An alternative, for simple access methods is to use a macro to emit the code to access the desired field. Although code to directly access the data object appears in the application program (via macro expansion), it will be automatically updated if you ever change the macro in the interface section by simply assembling your application.

Although it is quite possible to create ADTs using nothing more than separate compilation and, perhaps, RECORDs, HLA does provide a better solution: the class. Read on to find out about HLA's support for classes and objects as well as how to use these to create ADTs.

---

## 10.3 Classes in HLA

HLA's classes provide a good mechanism for creating abstract data types. Fundamentally, a class is little more than a RECORD declaration that allows the definition of fields other than data fields (e.g., procedures, constants, and macros). The inclusion of other program declaration objects in the class definition dramatically expands the capabilities of a class over that of a record. For example, with a class it is now possible to easily define an ADT since classes may include data and methods that operate on that data (procedures).

The principle way to create an abstract data type in HLA is to declare a class data type. Classes in HLA always appear in the TYPE section and use the following syntax:

```
classname : class

 << Class declaration section >>

endclass;
```

The class declaration section is very similar to the local declaration section for a procedure insofar as it allows CONST, VAL, VAR, and STATIC variable declaration sections. Classes also let you define macros and specify procedure, iterator, and *method* prototypes (method declarations are legal only in classes). Conspicuously absent from this list is the TYPE declaration section. You cannot declare new types within a class.

A method is a special type of procedure that appears only within a class. A little later you will see the difference between procedures and methods, for now you can treat them as being one and the same. Other than a few subtle details regarding class initialization and the use of pointers to classes, their semantics are identical<sup>2</sup>. Generally, if you don't know whether to use a procedure or method in a class, the safest bet is to use a method.

You do not place procedure/iterator/method code within a class. Instead you simply supply *prototypes* for these routines. A routine prototype consists of the PROCEDURE, ITERATOR, or METHOD reserved word, the routine name, any parameters, and a couple of optional procedure attributes (RETURNS and EXTERNAL). The actual routine definition (i.e., the body of the routine and any local declarations it needs) appears outside the class.

The following example demonstrates a typical class declaration appearing in the TYPE section:

```
TYPE
 TypicalClass: class

 const
 TCconst := 5;

 val
 TCval := 6;

 var
 TCvar : uns32; // Private field used only by TCproc.
```

---

2. Note, however, that the difference between procedures and methods makes all the difference in the world to the object-oriented programming paradigm. Hence the inclusion of methods in HLA's class definitions.

```

static
 TCstatic : int32;

procedure TCproc(u:uns32); returns("eax");
iterator TCiter(i:int32); external;
method TCmethod(c:char);

endclass;

```

As you can see, classes are very similar to records in HLA. Indeed, you can think of a record as being a class that only allows VAR declarations. HLA implements classes in a fashion quite similar to records insofar as it allocates sequential data fields in sequential memory locations. In fact, with only one minor exception, there is almost no difference between a RECORD declaration and a CLASS declaration that only has a VAR declaration section. Later you'll see exactly how HLA implements classes, but for now you can assume that HLA implements them the same as it does records and you won't be too far off the mark.

You can access the *TCvar* and *TCstatic* fields (in the class above) just like a record's fields. You access the CONST and VAL fields in a similar manner. If a variable of type *TypicalClass* has the name *obj*, you can access the fields of *obj* as follows:

```

mov (obj.TCconst, eax);
mov(obj.TCval, ebx);
add(obj.TCvar, eax);
add(obj.TCstatic, ebx);
obj.TCproc(20); // Calls the TCproc procedure in TypicalClass.
etc.

```

If an application program includes the class declaration above, it can create variables using the *TypicalClass* type and perform operations using the above methods. Unfortunately, the application program can also access the fields of the ADT data type with impunity. For example, if a program created a variable *MyClass* of type *TypicalClass*, then it could easily execute instructions like "MOV( MyClass.TCvar, eax );" even though this field might be private to the implementation section. Unfortunately, if you are going to allow an application to declare a variable of type *TypicalClass*, the field names will have to be visible. While there are some tricks we could play with HLA's class definitions to help hide the private fields, the best solution is to thoroughly comment the private fields and then exercise some restraint when accessing the fields of that class. Specifically, this means that ADTs you create using HLA's classes cannot be "pure" ADTs since HLA allows direct access to the data fields. However, with a little discipline, you can simulate a pure ADT by simply electing not to access such fields outside the class' methods, procedures, and iterators.

Prototypes appearing in a class are effectively FORWARD declarations. Like normal forward declarations, all procedures, iterators, and methods you define in a class must have an actual implementation later in the code. Alternately, you may attach the EXTERNAL keyword to the end of a procedure, iterator, or method declaration within a class to inform HLA that the actual code appears in a separate module. As a general rule, class declarations appear in header files and represent the interface section of an ADT. The procedure, iterator, and method bodies appear in the implementation section which is usually a separate source file that you compile separately and link with the modules that use the class.

The following is an example of a sample class procedure implementation:

```

procedure TypicalClass.TCproc(u:uns32); nodisplay;
 << Local declarations for this procedure >>
begin TCproc;

 << Code to implement whatever this procedure does >>

end TCProc;

```

There are several differences between a standard procedure declaration and a class procedure declaration. First, and most obvious, the procedure name includes the class name (e.g., *TypicalClass.TCproc*). This differentiates this class procedure definition from a regular procedure that just happens to have the name

*TCproc*. Note, however, that you do not have to repeat the class name before the procedure name in the BEGIN and END clauses of the procedure.

A second difference between class procedures and non-class procedures is not obvious. Some procedure attributes (EXTERNAL, RETURNS, CDECL, PASCAL, and STDCALL) are legal only in the prototype declaration appearing within the class while other attributes (NOFRAME, NODISPLAY, NOALIGNSTK, and ALIGN) are legal only within the procedure definition and not within the class. Fortunately, HLA provides helpful error messages if you stick the option in the wrong place, so you don't have to memorize this rule.

If a class routine's prototype does not have the EXTERNAL option, the compilation unit (that is, the PROGRAM or UNIT) containing the class declaration must also contain the routine's definition or HLA will generate an error at the end of the compilation. For small, local, classes (i.e., when you're embedding the class declaration and routine definitions in the same compilation unit) the convention is to place the class' procedure, iterator, and method definitions in the source file shortly after the class declaration. For larger systems (i.e., when separately compiling a class' routines), the convention is to place the class declaration in a header file by itself and place all the procedure, iterator, and method definitions in a separate HLA unit and compile them by themselves.

## 10.4 Objects

Remember, a class definition is just a type. Therefore, when you declare a class type you haven't created a variable whose fields you can manipulate. An *object* is an *instance* of a class; that is, an object is a variable whose type is some class type. You declare objects (i.e., class variables) the same way you declare other variables: in a VAR, STATIC, or STORAGE section<sup>3</sup>. A pair of sample object declarations follow:

```
var
 T1: TypicalClass;
 T2: TypicalClass;
```

For a given class object, HLA allocates storage for each variable appearing in the VAR section of the class declaration. If you have two objects, *T1* and *T2*, of type *TypicalClass* then *T1.TCvar* is unique as is *T2.TCvar*. This is the intuitive result (similar to RECORD declarations); most data fields you define in a class will appear in the VAR declaration section.

Static data objects (e.g., those you declare in the STATIC section of a class declaration) are not unique among the objects of that class; that is, HLA allocates only a single static variable that all variables of that class share. For example, consider the following (partial) class declaration and object declarations:

```
type
 sc: class

 var
 i: int32;

 static
 s: int32;
 .
 .
 .
 endclass;

var
 s1: sc;
 s2: sc;
```

In this example, *s1.i* and *s2.i* are different variables. However, *s1.s* and *s2.s* are aliases of one another. Therefore, an instruction like "mov( 5, s1.s);" also stores five into *s2.s*. Generally you use static class vari-

3. Technically, you could also declare an object in a READONLY section, but HLA does not allow you to define class constants, so there is little utility in declaring class objects in the READONLY section.

ables to maintain information about the whole class while you use class VAR objects to maintain information about the specific object. Since keeping track of class information is relatively rare, you will probably declare most class data fields in a VAR section.

You can also create dynamic instances of a class and refer to those dynamic objects via pointers. In fact, this is probably the most common form of object storage and access. The following code shows how to create pointers to objects and how you can dynamically allocate storage for an object:

```
var
 pSC: pointer to sc;
 .
 .
 .
 malloc(@size(sc));
 mov(eax, pSC);
 .
 .
 .
 mov(pSC, ebx);
 mov((type sc [ebx]).i, eax);
```

Note the use of type coercion to cast the pointer in EBX as type *sc*.

## 10.5 Inheritance

Inheritance is one of the most fundamental ideas behind object-oriented programming. The basic idea behind inheritance is that a class inherits, or copies, all the fields from some class and then possibly expands the number of fields in the new data type. For example, suppose you created a data type *point* which describes a point in the planar (two dimensional) space. The class for this point might look like the following:

```
type
 point: class

 var
 x:int32;
 y:int32;
 method distance;

 endclass;
```

Suppose you want to create a point in 3D space rather than 2D space. You can easily build such a data type as follows:

```
type
 point3D: class inherits(point)

 var
 z:int32;

 endclass;
```

The INHERITS option on the CLASS declaration tells HLA to insert the fields of *point* at the beginning of the class. In this case, *point3D* inherits the fields of *point*. HLA always places the inherited fields at the beginning of a class object. The reason for this will become clear a little later. If you have an instance of *point3D* which you call *P3*, then the following 80x86 instructions are all legal:

```
mov(P3.x, eax);
add(P3.y, eax);
mov(eax, P3.z);
```

```
P3.distance();
```

Note that the *P3.distance* method invocation in this example calls the *point.distance* method. You do not have to write a separate *distance* method for the *point3D* class unless you really want to do so (see the next section for details). Just like the *x* and *y* fields, *point3D* objects inherit *point*'s methods.

---

## 10.6 Overriding

*Overriding* is the process of replacing an existing method in an inherited class with one more suitable for the new class. In the *point* and *point3D* examples appearing in the previous section, the *distance* method (presumably) computes the distance from the origin to the specified point. For a point on a two-dimensional plane, you can compute the distance using the function:

$$\text{dist} = \sqrt{x^2+y^2}$$

However, the distance for a point in 3D space is given by the equation:

$$\text{dist} = \sqrt{x^2+y^2+z^2}$$

Clearly, if you call the *distance* function for *point* for a *point3D* object you will get an incorrect answer. In the previous section, however, you saw that the *P3* object calls the distance function inherited from the *point* class. Therefore, this would produce an incorrect result.

In this situation the *point3D* data type must override the *distance* method with one that computes the correct value. You cannot simply redefine the *point3D* class by adding a *distance* method prototype:

```
type
 point3D: class inherits(point)

 var
 z:int32;

 method distance; // This doesn't work!

endclass;
```

The problem with the *distance* method declaration above is that *point3D* already has a distance method – the one that it inherits from the *point* class. HLA will complain because it doesn't like two methods with the same name in a single class.

To solve this problem, we need some mechanism by which we can override the declaration of *point.distance* and replace it with a declaration for *point3D.distance*. To do this, you use the **OVERRIDE** keyword before the method declaration:

```
type
 point3D: class inherits(point)

 var
 z:int32;

 override method distance; // This will work!

endclass;
```

The **OVERRIDE** prefix tells HLA to ignore the fact that *point3D* inherits a method named *distance* from the *point* class. Now, any call to the *distance* method via a *point3D* object will call the *point3D.distance* method rather than *point.distance*. Of course, once you override a method using the **OVERRIDE** prefix, you must supply the method in the implementation section of your code, e.g.,

```
method point3D.distance; nodisplay;

 << local declarations for the distance function >>
```

```
begin distance;

 << Code to implement the distance function >>

end distance;
```

---

## 10.7 Virtual Methods vs. Static Procedures

A little earlier, this chapter suggested that you could treat class methods and class procedures the same. There are, in fact, some major differences between the two (after all, why have methods if they're the same as procedures?). As it turns out, the differences between methods and procedures is crucial if you want to develop object-oriented programs. Methods provide the second feature necessary to support true polymorphism: virtual procedure calls<sup>4</sup>. A virtual procedure call is just a fancy name for an indirect procedure call (using a pointer associated with the object). The key benefit of virtual procedures is that the system automatically calls the right method when using pointers to generic objects.

Consider the following declarations using the *point* class from the previous sections:

```
var
 P2: point;
 p: pointer to point;
```

Given the declarations above, the following assembly statements are all legal:

```
mov(P2.x, eax);
mov(P2.y, ecx);
P2.distance(); // Calls point3D.distance.

lea(ebx, P2); // Store address of P2 into P.
mov(ebx, P);
P.distance(); // Calls point.distance.
```

Note that HLA lets you call a method via a pointer to an object rather than directly via an object variable. This is a crucial feature of objects in HLA and a key to implementing *virtual method calls*.

The magic behind polymorphism and inheritance is that object pointers are *generic*. In general, when your program references data indirectly through a pointer, the value of the pointer should be the address of the underlying data type associated with that pointer. For example, if you have a pointer to a 16-bit unsigned integer, you wouldn't normally use that pointer to access a 32-bit signed integer value. Similarly, if you have a pointer to some record, you would not normally cast that pointer to some other record type and access the fields of that other type<sup>5</sup>. With pointers to class objects, however, we can lift this restriction a bit. Pointers to objects may legally contain the address of the object's type *or the address of any object that inherits the fields of that type*. Consider the following declarations that use the *point* and *point3D* types from the previous examples:

```
var
 P2: point;
 P3: point3D;
 p: pointer to point;
 .
 .
 .
 lea(ebx, P2);
 mov(ebx, p);
```

---

4. Polymorphism literally means “many-faced.” In the context of object-oriented programming polymorphism means that the same method name, e.g., *distance*, and refer to one of several different methods.

5. Of course, assembly language programmers break rules like this all the time. For now, let's assume we're playing by the rules and only access the data using the data type associated with the pointer.

```

p.distance(); // Calls the point.distance method.
.
.
.
lea(ebx, P3);
mov(ebx, p); // Yes, this is semantically legal.
p.distance(); // Surprise, this calls point3D.distance.

```

Since  $p$  is a pointer to a *point* object, it might seem intuitive for  $p.distance$  to call the *point.distance* method. However, methods are *polymorphic*. If you've got a pointer to an object and you call a method associated with that object, the system will call the actual (overridden) method associated with the object, not the method specifically associated with the pointer's class type.

Class procedures behave differently than methods with respect to overridden procedures. When you call a class procedure indirectly through an object pointer, the system will always call the procedure associated with the underlying class associated with the pointer. So had *distance* been a procedure rather than a method in the previous examples, the "p.distance();" invocation would always call *point.distance*, even if  $p$  is pointing at a *point3D* object. The section on Object Initialization, later in this chapter, explains why methods and procedures are different (see "Object Implementation" on page 1040).

Note that iterators are also virtual; so like methods an object iterator invocation will always call the (overridden) iterator associated with the actual object whose address the pointer contains. To differentiate the semantics of methods and iterators from procedures, we will refer to the method/iterator calling semantics as *virtual procedures* and the calling semantics of a class procedure as a *static procedure*.

## 10.8 Writing Class Methods, Iterators, and Procedures

For each class procedure, method, and iterator prototype appearing in a class definition, there must be a corresponding procedure, method, or iterator appearing within the program (for the sake of brevity, this section will use the term *routine* to mean procedure, method, or iterator from this point forward). If the prototype does not contain the EXTERNAL option, then the code must appear in the same compilation unit as the class declaration. If the EXTERNAL option does follow the prototype, then the code may appear in the same compilation unit or a different compilation unit (as long as you link the resulting object file with the code containing the class declaration). Like external (non-class) procedures and iterators, if you fail to provide the code the linker will complain when you attempt to create an executable file. To reduce the size of the following examples, they will all define their routines in the same source file as the class declaration.

HLA class routines must always follow the class declaration in a compilation unit. If you are compiling your routines in a separate unit, the class declarations must still precede the code with the class declaration (usually via an #INCLUDE file). If you haven't defined the class by the time you define a routine like *point.distance*, HLA doesn't know that *point* is a class and, therefore, doesn't know how to handle the routine's definition.

Consider the following declarations for a point2D class:

```

type
point2D: class

 const
 UnitDistance: real32 := 1.0;

 var
 x: real32;
 y: real32;

 static
 LastDistance: real32;

 method distance(fromX: real32; fromY:real32); returns("st0");
 procedure InitLastDistance;

```

```
endclass;
```

The distance function for this class should compute the distance from the object's point to (fromX,fromY). The following formula describes this computation:

$$\sqrt{(x - \text{fromX})^2 + (y - \text{fromY})^2}$$

A first pass at writing the distance method might produce the following code:

```
method point2D.distance(fromX:real32; fromY:real32); nodisplay;
begin distance;

 fld(x); // Note: this doesn't work!
 fld(fromX); // Compute (x-fromX)
 fsub();
 fld(st0); // Duplicate value on TOS.
 fmul(); // Compute square of difference.

 fld(y); // This doesn't work either.
 fld(fromY); // Compute (y-fromY)
 fsub();
 fld(st0); // Compute the square of the difference.
 fmul();

 fsqrt();

end distance;
```

This code probably looks like it should work to someone who is familiar with an object-oriented programming language like C++ or Delphi. However, as the comments indicate, the instructions that push the *x* and *y* variables onto the FPU stack don't work – HLA doesn't automatically define the symbols associated with the data fields of a class within that class' routines.

To learn how to access the data fields of a class within that class' routines, we need to back up a moment and discover some very important implementation details concerning HLA's classes. To do this, consider the following variable declarations:

```
var
 Origin: point2D;
 PtInSpace: point2D;
```

Remember, whenever you create two objects like *Origin* and *PtInSpace*, HLA reserves storage for the *x* and *y* data fields for both of these objects. However, there is only one copy of the *point2D.distance* method in memory. Therefore, were you to call *Origin.distance* and *PtInSpace.distance*, the system would call the same routine for both method invocations. Once inside that method, one has to wonder what an instruction like “fld( *x* );” would do. How does it associate *x* with *Origin.x* or *PtInSpace.x*? Worse still, how would this code differentiate between the data field *x* and a global object *x*? In HLA, the answer is “it doesn't.” You do not specify the data field names within a class routine by simply using their names as though they were common variables.

To differentiate *Origin.x* from *PtInSpace.x* within class routines, HLA automatically passes a pointer to an object's data fields whenever you call a class routine. Therefore, you can reference the data fields indirectly off this pointer. HLA passes this object pointer in the ESI register. This is one of the few places where HLA-generated code will modify one of the 80x86 registers behind your back: **anytime you call a class routine, HLA automatically loads the ESI register with the object's address.** Obviously, you cannot count on ESI's value being preserved across class routine class nor can you pass parameters to the class routine in the ESI register. For class methods and iterators (but not procedures), HLA will also load the EDI register with the address of the class' *virtual method table* (see “Virtual Method Tables” on page 1043).

While the virtual method table address isn't as interesting as the object address, keep in mind that **HLA-generated code will overwrite any value in the EDI register when you call a method or an iterator.**

Upon entry into a class routine, ESI contains a pointer to the (non-static) data fields associated with the class. Therefore, to access fields like *x* and *y* (in our *point2D* example), you could use an address expression like the following:

```
(type point2D [esi]).x
```

Since you use ESI as the base address of the object's data fields, it's a good idea not to disturb ESI's value within the class routines (or, at least, preserve ESI's value if you need to access the objects data fields after some point where you must use ESI for some other purpose). Note that if you call an iterator or a method you do not have to preserve EDI (unless, for some reason, you need access to the virtual method table, which is unlikely).

Accessing the fields of a data object within a class' routines is such a common operation that HLA provides a shorthand notation for casting ESI as a pointer to the class object: **THIS**. Within a class in HLA, the reserved word **THIS** automatically expands to a string of the form "(type *classname* [esi])" substituting, of course, the appropriate class name for *classname*. Using the **THIS** keyword, we can (correctly) rewrite the previous distance method as follows:

```
method point2D.distance(fromX:real32; fromY:real32); nodisplay;
begin distance;

 fld(this.x);
 fld(fromX); // Compute (x-fromX)
 fsub();
 fld(st0); // Duplicate value on TOS.
 fmul(); // Compute square of difference.

 fld(this.y);
 fld(fromY); // Compute (y-fromY)
 fsub();
 fld(st0); // Compute the square of the difference.
 fmul();

 fsqrt();

end distance;
```

Don't forget that calling a class routine wipes out the value in the ESI register. This isn't obvious from the syntax of the routine's invocation. It is especially easy to forget this when calling some class routine from inside some other class routine; don't forget that if you do this the internal call wipes out the value in ESI and on return from that call ESI no longer points at the original object. Always push and pop ESI (or otherwise preserve ESI's value) in this situation, e.g.,

```
.
.
.
fld(this.x); // ESI points at current object.
.
.
.
push(esi); // Preserve ESI across this method call.
SomeObject.SomeMethod();
pop(esi);
.
.
.
lea(ebx, this.x); // ESI points at original object here.
```

The `THIS` keyword provides access to the class variables you declare in the `VAR` section of a class. You can also use `THIS` to call other class routines associated with the current object, e.g.,

```
 this.distance(5.0, 6.0);
```

To access class constants and `STATIC` data fields you generally do not use the `THIS` pointer. HLA associates constant and static data fields with the whole class, not a specific object. To access these class members, just use the class name in place of the object name. For example, to access the `UnitDistance` constant in the `point2D` class you could use a statement like the following:

```
 fld(point2D.UnitDistance);
```

As another example, if you wanted to update the `LastDistance` field in the `point2D` class each time you computed a distance, you could rewrite the `point2D.distance` method as follows:

```
method point2D.distance(fromX:real32; fromY:real32); nodisplay;
begin distance;

 fld(this.x);
 fld(fromX); // Compute (x-fromX)
 fsub();
 fld(st0); // Duplicate value on TOS.
 fmul(); // Compute square of difference.

 fld(this.y);
 fld(fromY); // Compute (y-fromY)
 fsub();
 fld(st0); // Compute the square of the difference.
 fmul();

 fsqrt();

 fst(point2D.LastDistance); // Update shared (STATIC) field.

end distance;
```

To understand why you use the class name when referring to constants and static objects but you use `THIS` to access `VAR` objects, check out the next section.

Class procedures are also static objects, so it is possible to call a class procedure by specifying the class name rather than an object name in the procedure invocation, e.g., both of the following are legal:

```
Origin.InitLastDistance();
point2D.InitLastDistance();
```

There is, however, a subtle difference between these two class procedure calls. The first call above loads `ESI` with the address of the `Origin` object prior to actually calling the `InitLastDistance` procedure. The second call, however, is a direct call to the class procedure without referencing an object; therefore, HLA doesn't know what object address to load into the `ESI` register. In this case, HLA loads `NULL` (zero) into `ESI` prior to calling the `InitLastDistance` procedure. Because you can call class procedures in this manner, it's always a good idea to check the value in `ESI` within your class procedures to verify that HLA contains an object address. Checking the value in `ESI` is a good way to determine which calling mechanism is in use. Later, this chapter will discuss constructors and object initialization; there you will see a good use for static procedures and calling those procedures directly (rather than through the use of an object).

## 10.9 Object Implementation

In a high level object-oriented language like C++ or Delphi, it is quite possible to master the use of objects without really understanding how the machine implements them. One of the reasons for learning assembly language programming is to fully comprehend low-level implementation details so one can make

educated decisions concerning the use of programming constructs like objects. Further, since assembly language allows you to poke around with data structures at a very low-level, knowing how HLA implements objects can help you create certain algorithms that would not be possible without a detailed knowledge of object implementation. Therefore, this section, and its corresponding subsections, explains the low-level implementation details you will need to know in order to write object-oriented HLA programs.

HLA implements objects in a manner quite similar to records. In particular, HLA allocates storage for all VAR objects in a class in a sequential fashion, just like records. Indeed, if a class consists of only VAR data fields, the memory representation of that class is nearly identical to that of a corresponding RECORD declaration. Consider the Student record declaration taken from Volume Three and the corresponding class:

```

type
 student: record
 Name: char[65];
 Major: int16;
 SSN: char[12];
 Midterm1: int16;
 Midterm2: int16;
 Final: int16;
 Homework: int16;
 Projects: int16;
 endrecord;

student2: class
 Name: char[65];
 Major: int16;
 SSN: char[12];
 Midterm1: int16;
 Midterm2: int16;
 Final: int16;
 Homework: int16;
 Projects: int16;
 endclass;

```

**Figure 10.1 Student RECORD Implementation in Memory**

**Figure 10.2 Student CLASS Implementation in Memory**

If you look carefully at these two figures, you'll discover that the only difference between the class and the record implementations is the inclusion of the VMT (virtual method table) pointer field at the beginning of the class object. This field, which is always present in a class, contains the address of the class' virtual method table which, in turn, contains the addresses of all the class' methods and iterators. The VMT field, by the way, is present even if a class doesn't contain any methods or iterators.

As pointed out in previous sections, HLA does not allocate storage for STATIC objects within the object's storage. Instead, HLA allocates a single instance of each static data field that all objects share. As an example, consider the following class and object declarations:

```
type
 tHasStatic: class

 var
 i:int32;
 j:int32;
 r:real32;

 static
 c:char[2];
 b:byte;

 endclass;

var
 hs1: tHasStatic;
 hs2: tHasStatic;
```

Figure 10.3 shows the storage allocation for these two objects in memory.

**Figure 10.3** Object Allocation with Static Data Fields

Of course, `CONST`, `VAL`, and `MACRO` objects do not have any run-time memory requirements associated with them, so HLA does not allocate any storage for these fields. Like the `STATIC` data fields, you may access `CONST`, `VAL`, and `MACRO` fields using the class name as well as an object name. Hence, even if

*tHasStatic* has these types of fields, the memory organization for *tHasStatic* objects would still be the same as shown in Figure 10.3.

Other than the presence of the virtual method table pointer (VMT), the presence of methods, iterators, and procedures has no impact on the storage allocation of an object. Of course, the machine instructions associated with these routines does appear somewhere in memory. So in a sense the code for the routines is quite similar to static data fields insofar as all the objects share a single instance of the routine.

### 10.9.1 Virtual Method Tables

When HLA calls a class procedure, it directly calls that procedure using a CALL instruction, just like any normal non-class procedure call. Methods and iterators are another story altogether. Each object in the system carries a pointer to a virtual method table which is an array of pointers to all the methods and iterators appearing within the object's class.

**Figure 10.4 Virtual Method Table Organization**

Each iterator or method you declare in a class has a corresponding entry in the virtual method table. That *dword* entry contains the address of the first instruction of that iterator or method. To call a class method or iterator is a bit more work than calling a class procedure (it requires one additional instruction plus the use of the EDI register). Here is a typical calling sequence for a method:

```

mov(ObjectAdrs, ESI); // All class routines do this.
mov([esi], edi); // Get the address of the VMT into EDI
call((type dword [edi+n])); // "n" is the offset of the method's entry
 // in the VMT.

```

For a given class there is only one copy of the VMT in memory. This is a static object so all objects of a given class type share the same VMT. This is reasonable since all objects of the same class type have exactly the same methods and iterators (see Figure 10.5).

Note: Objects are all the same class type

**Figure 10.5 All Objects That are the Same Class Type Share the Same VMT**

Although HLA builds the VMT record structure as it encounters methods and iterators within a class, HLA does not automatically create the actual run-time virtual method table for you. You must explicitly declare this table in your program. To do this, you include a statement like the following in a `STATIC` or `READONLY` declaration section of your program, e.g.,

```
readonly
 VMT(classname);
```

Since the addresses in a virtual method table should never change during program execution, the `READONLY` section is probably the best choice for declaring VMTs. It should go without saying that changing the pointers in a VMT is, in general, a really bad idea. So putting VMTs in a `STATIC` section is usually not a good idea.

A declaration like the one above defines the variable `classname._VMT_`. In section 10.10 (see “Constructors and Object Initialization” on page 1048) you see that you’ll need this name when initializing object variables. The class declaration automatically defines the `classname._VMT_` symbol as an external static variable. The declaration above just provides the actual definition of this external symbol.

The declaration of a VMT uses a somewhat strange syntax because you aren’t actually declaring a new symbol with this declaration, you’re simply supplying the data for a symbol that you previously declared implicitly by defining a class. That is, the class declaration defines the static table variable `classname._VMT_`, all you’re doing with the VMT declaration is telling HLA to emit the actual data for the table. If, for some reason, you would like to refer to this table using a name other than `classname._VMT_`, HLA does allow you to prefix the declaration above with a variable name, e.g.,

```
readonly
 myVMT: VMT(classname);
```

In this declaration, `myVMT` is an alias of `classname._VMT_`. As a general rule, you should avoid aliases in a program because they make the program more difficult to read and understand. Therefore, it is unlikely that you would ever really need to use this type of declaration.

Like any other global static variable, there should be only one instance of a VMT for a given class in a program. The best place to put the VMT declaration is in the same source file as the class’ method, iterator, and procedure code (assuming they all appear in a single file). This way you will automatically link in the VMT whenever you link in the routines for a given class.

## 10.9.2 Object Representation with Inheritance

Up to this point, the discussion of the implementation of class objects has ignored the possibility of inheritance. Inheritance only affects the memory representation of an object by adding fields that are not explicitly stated in the class declaration.

Adding inherited fields from a *base class* to another class must be done carefully. Remember, an important attribute of a class that inherits fields from a base class is that you can use a pointer to the base class to access the inherited fields from that base class in another class. As an example, consider the following classes:

```
type
 tBaseClass: class
 var
 i:uns32;
 j:uns32;
 r:real32;

 method mBase;
 endclass;

 tChildClassA: class inherits(tBaseClass)
 var
 c:char;
 b:boolean;
 w:word;

 method mA;
 endclass;

 tChildClassB: class inherits(tBaseClass)
 var
 d:dword;
 c:char;
 a:byte[3];
 endclass;
```

Since both *tChildClassA* and *tChildClassB* inherit the fields of *tBaseClass*, these two child classes include the *i*, *j*, and *r* fields as well as their own specific fields. Furthermore, whenever you have a pointer variable whose base type is *tBaseClass*, it is legal to load this pointer with the address of any child class of *tBaseClass*; therefore, it is perfectly reasonable to load such a pointer with the address of a *tChildClassA* or *tChildClassB* variable, e.g.,

```
var
 B1: tBaseClass;
 CA: tChildClassA;
 CB: tChildClassB;
 ptr: pointer to tBaseClass;
 .
 .
 .
 lea(ebx, B1);
 mov(ebx, ptr);
 << Use ptr >>
 .
 .
 .
 lea(eax, CA);
 mov(ebx, ptr);
 << Use ptr >>
```

```

.
.
.
lea(eax, CB);
mov(eax, ptr);
<< Use ptr >>

```

Since *ptr* points at an object of *tBaseClass*, you may legally (from a semantic sense) access the *i*, *j*, and *r* fields of the object where *ptr* is pointing. It is not legal to access the *c*, *b*, *w*, or *d* fields of the *tChildClassA* or *tChildClassB* objects since at any one given moment the program may not know exactly what object type *ptr* references.

In order for inheritance to work properly, the *i*, *j*, and *r* fields must appear at the same offsets all child classes as they do in *tBaseClass*. This way, an instruction of the form “mov((type tBaseClass [ebx]).i, eax);” will correct access the *i* field even if EBX points at an object of type *tChildClassA* or *tChildClassB*. Figure 10.6 shows the layout of the child and base classes:

Derived (child) classes locate their inherited fields at the same offsets as those fields in the base class.

**Figure 10.6** Layout of Base and Child Class Objects in Memory

Note that the new fields in the two child classes bear no relation to one another, even if they have the same name (e.g., field *c* in the two child classes does not lie at the same offset). Although the two child classes share the fields they inherit from their common base class, any new fields they add are unique and separate. Two fields in different classes share the same offset only by coincidence.

All classes (even those that aren't related to one another) place the pointer to the virtual method table at offset zero within the object. There is a single VMT associated with each class in a program; even classes that inherit fields from some base class have a VMT that is (generally) different than the base class' VMT. shows how objects of type *tBaseClass*, *tChildClassA* and *tChildClassB* point at their specific VMTs:

```

var
 B1: tBaseClass;
 CA: tChildClassA;
 CB: tChildClassB;
 CB2: tChildClassB;
 CA2: tChildClassA;

```

**Figure 10.7 Virtual Method Table References from Objects**

A virtual method table is nothing more than an array of pointers to the methods and iterators associated with a class. The address of the first method or iterator appearing in a class is at offset zero, the address of the second appears at offset four, etc. You can determine the offset value for a given iterator or method by using the `@offset` function. If you want to call a method or iterator directly (using 80x86 syntax rather than HLA's high level syntax), you code use code like the following:

```

var
 sc: tBaseClass;
 .
 .
 .
 lea(esi, sc); // Get the address of the object (& VMT).
 mov([esi], edi); // Put address of VMT into EDI.
 call((type dword [edi+@offset(tBaseClass.mBase)]));

```

Of course, if the method has any parameters, you must push them onto the stack before executing the code above. Don't forget, when making direct calls to a method, that you must load ESI with the address of the object. Any field references within the method will probably depend upon ESI containing this address. The choice of EDI to contain the VMT address is nearly arbitrary. Unless you're doing something tricky (like using EDI to obtain run-time type information), you could use any register you please here. As a general rule, you should use EDI when simulating class iterator/method calls because this is the convention that HLA employs and most programmers will expect this.

Whenever a child class inherits fields from some base class, the child class' VMT also inherits entries from the base class' VMT. For example, the VMT for class *tBaseClass* contains only a single entry – a pointer to method *tBaseClass.mBase*. The VMT for class *tChildClassA* contains two entries: a pointer to *tBaseClass.mBase* and *tChildClassA.mA*. Since *tChildClassB* doesn't define any new methods or iterators, *tChildClassB*'s VMT contains only a single entry, a pointer to the *tBaseClass.mBase* method. Note that *tChildClassB*'s VMT is identical to *tBaseClass*' VMT. Nevertheless, HLA produces two distinct VMTs. This is a critical fact that we will make use of a little later. Figure 10.8 shows the relationship between these VMTs:

### Virtual Method Tables for Derived (inherited) Classes

**Figure 10.8** Virtual Method Tables for Inherited Classes

Although the VMT always appears at offset zero in an object (and, therefore, you can access the VMT using the address expression “[ESI]” if ESI points at an object), HLA actually inserts a symbol into the symbol table so you may refer to the VMT symbolically. The symbol *\_pVMT\_* (pointer to Virtual Method Table) provides this capability. So a more readable way to access the VMT pointer (as in the previous code example) is

```
lea(esi, sc);
mov((type tBaseClass [esi])._pVMT_, edi);
call((type dword [edi+@offset(tBaseClass.mBase)]));
```

If you need to access the VMT directly, there are a couple ways to do this. Whenever you declare a class object, HLA automatically includes a field named *\_VMT\_* as part of that class. *\_VMT\_* is a static array of double word objects. Therefore, you may refer to the VMT using an identifier of the form *class-name.\_VMT\_*. Generally, you shouldn't access the VMT directly, but as you'll see shortly, there are some good reasons why you need to know the address of this object in memory.

## 10.10 Constructors and Object Initialization

If you've tried to get a little ahead of the game and write a program that uses objects prior to this point, you've probably discovered that the program inexplicably crashes whenever you attempt to run it. We've covered a lot of material in this chapter thus far, but you are still missing one crucial piece of information – how to properly initialize objects prior to use. This section will put the final piece into the puzzle and allow you to begin writing programs that use classes.

Consider the following object declaration and code fragment:

```
var
 bc: tBaseClass;
 .
 .
 .
 bc.mBase();
```

Remember that variables you declare in the VAR section are uninitialized at run-time. Therefore, when the program containing these statements gets around to executing *bc.mBase*, it executes the three-statement sequence you've seen several times already:

```
lea(esi, sbc);
mov([esi], edi);
call((type dword [edi+@offset(tBaseClass.mBase)]));
```

The problem with this sequence is that it loads EDI with an undefined value assuming you haven't previously initialized the *bc* object. Since EDI contains a garbage value, attempting to call a subroutine at address “[EDI+@offset(tBaseClass.mBase)]” will likely crash the system. Therefore, before using an object, you must initialize the *\_pVMT\_* field with the address of that object's VMT. One easy way to do this is with the following statement:

```
mov(&tBaseClass._VMT_, bc._pVMT_);
```

Always remember, **before using an object, be sure to initialize the virtual method table pointer for that field.**

Although you must initialize the virtual method table pointer for all objects you use, this may not be the only field you need to initialize in those objects. Each specific class may have its own application-specific initialization that is necessary. Although the initialization may vary by class, you need to perform the same initialization on each object of a specific class that you use. If you ever create more than a single object from a given class, it is probably a good idea to create a procedure to do this initialization for you. This is such a common operation that object-oriented programmers have given these initialization procedures a special name: *constructors*.

Some object-oriented languages (e.g., C++) use a special syntax to declare a constructor. Others (e.g., Delphi) simply use existing procedure declarations to define a constructor. One advantage to employing a special syntax is that the language knows when you define a constructor and can automatically generate code to call that constructor for you (whenever you declare an object). Languages, like Delphi, require that you explicitly call the constructor; this can be a minor inconvenience and a source of defects in your programs. HLA does not use a special syntax to declare constructors – you define constructors using standard class procedures. As such, you will need to explicitly call the constructors in your program; however, you'll see an easy method for automating this in a later section of this chapter.

Perhaps the most important fact you must remember is that **constructors must be class procedures**. You must not define constructors as methods (or iterators). The reason is quite simple: one of the tasks of the constructor is to initialize the pointer to the virtual method table and you cannot call a class method or iterator until after you've initialized the VMT pointer. Since class procedures don't use the virtual method table, you can call a class procedure prior to initializing the VMT pointer for an object.

By convention, HLA programmers use the name *Create* for the class constructor. There is no requirement that you use this name, but by doing so you will make your programs easier to read and follow by other programmers.

As you may recall, you can call a class procedure via an object reference or a class reference. E.g., if *clsProc* is a class procedure of class *tClass* and *Obj* is an object of type *tClass*, then the following two class procedure invocations are both legal:

```
tClass.clsProc();
Obj.clsProc();
```

There is a big difference between these two calls. The first one calls *clsProc* with ESI containing zero (NULL) while the second invocation loads the address of *Obj* into ESI before the call. We can use this fact to determine within a method the particular calling mechanism.

---

### 10.10.1 Dynamic Object Allocation Within the Constructor

As it turns out, most programs allocated object dynamically using *malloc* and refer to those objects indirectly using pointers. This adds one more step to the initialization process – allocating storage for the object. The constructor is the perfect place to allocate this storage. Since you probably won't need to allocate all objects dynamically, you'll need two types of constructors: one that allocates storage and then initializes the object, and another that simply initializes an object that already has storage.

Another constructor convention is to merge these two constructors into a single constructor and differentiate the type of constructor call by the value in ESI. On entry into the class' *Create* procedure, the program checks the value in ESI to see if it contains NULL (zero). If so, the constructor calls *malloc* to allocate storage for the object and returns a pointer to the object in ESI. If ESI does not contain NULL upon entry into the procedure, then the constructor assumes that ESI points at a valid object and skips over the memory allocation statements. At the very least, a constructor initializes the pointer to the VMT; therefore, the minimalist constructor will look like the following:

```
procedure tBaseClass.mBase; nodisplay;
begin mBase;

 if(ESI = 0) then

 push(EAX); // Malloc returns its result here, so save it.
 malloc(@size(tBaseClass));
 mov(eax, esi); // Put pointer into ESI;
 pop(eax);

 endif;

 // Initialize the pointer to the VMT:
 // (remember, "this" is shorthand for (type tBaseClass [esi])"

 mov(&tBaseClass._VMT_, this._pVMT_);

 // Other class initialization would go here.

end mBase;
```

After you write a constructor like the one above, you choose an appropriate calling mechanism based on whether your object's storage is already allocated. For pre-allocated objects (i.e., those you've declared in VAR, STATIC, or STORAGE sections<sup>6</sup> or those you've previously allocated storage for via *malloc*) you simply load the address of the object into ESI and call the constructor. For those objects you declare as a variable, this is very easy – just call the appropriate *Create* constructor:

```
var
 bc0: tBaseClass;
 bcp: pointer to tBaseClass;
 .
 .
 .
 bc0.Create(); // Initializes pre-allocated bc0 object.
 .
 .
 .
 malloc(@size(tBaseClass)); // Allocate storage for bcp object.
 mov(eax, bcp);
 .
 .
 .
 bcp.Create(); // Initializes pre-allocated bcp object.
```

Note that although *bcp* is a pointer to a *tBaseClass* object, the *Create* method does not automatically allocate storage for this object. The program already allocates the storage earlier. Therefore, when the program calls *bcp.Create* it loads ESI with the address contained within *bcp*; since this is not NULL, the *tBaseClass.Create* procedure does not allocate storage for a new object. By the way, the call to *bcp.Create* emits the following sequence of machine instructions:

```
mov(bcp, esi);
```

---

6. You generally do not declare objects in READONLY sections because you cannot initialize them.

```
call tBaseClass.Create;
```

Until now, the code examples for a class procedure call always began with an LEA instruction. This is because all the examples to this point have used object variables rather than pointers to object variables. Remember, a class procedure (method/iterator) call passes the address of the object in the ESI register. For object variables HLA emits an LEA instruction to obtain this address. For pointers to objects, however, the actual object address is the *value* of the pointer variable; therefore, to load the address of the object into ESI, HLA emits a MOV instruction that copies the value of the pointer into the ESI register.

In the example above, the program preallocates the storage for an object prior to calling the object constructor. While there are several reasons for preallocating object storage (e.g., you're creating a dynamic array of objects), you can achieve most simple object allocations like the one above by calling a standard *Create* method (i.e., one that allocates storage for an object if ESI contains NULL). The following example demonstrates this:

```
var
 bcp2: pointer to tBaseClass;
 .
 .
 .
 tBaseClass.Create(); // Calls Create with ESI=NULL.
 mov(esi, bcp2); // Save pointer to new class object in bcp2.
```

Remember, a call to a *tBaseClass.Create* constructor returns a pointer to the new object in the ESI register. It is the caller's responsibility to save the pointer this function returns into the appropriate pointer variable; the constructor does not automatically do this for you.

## 10.10.2 Constructors and Inheritance

Constructors for derived (child) classes that inherit fields from a base class represent a special case. Each class must have its own constructor but needs the ability to call the base class constructor. This section explains the reasons for this and how to do this.

A derived class inherits the *Create* procedure from its base class. However, you must override this procedure in a derived class because the derived class probably requires more storage than the base class and, therefore, you will probably need to use a different call to *malloc* to allocate storage for a dynamic object. Hence, it is very unusual for a derived class not to override the definition of the *Create* procedure.

However, overriding a base class' *Create* procedure has problems of its own. When you override the base class' *Create* procedure, you take the full responsibility of initializing the (entire) object, including all the initialization required by the base class. At the very least, this involves putting duplicate code in the overridden procedure to handle the initialization usually done by the base class constructor. In addition to make your program larger (by duplicating code already present in the base class constructor), this also violates information hiding principles since the derived class must be aware of all the fields in the base class (including those that are logically private to the base class). What we need here is the ability to call a base class' constructor from within the derived class' destructor and let that call do the lower-level initialization of the base class' fields. Fortunately, this is an easy thing to do in HLA.

Consider the following class declarations (which does things the hard way):

```
type
 tBase: class
 var
 i:uns32;
 j:int32;

 procedure Create(); returns("esi");
 endclass;

 tDerived: class inherits(tBase)
 var
```

```

 r: real64;

 override procedure Create(); returns("esi");
 endclass;

 procedure tBase.Create; nodisplay;
 begin Create;

 if(esi = 0) then

 push(eax);
 mov(malloc(@size(tBase)), esi);
 pop(eax);

 endif;
 mov(&tBase._VMT_, this._pVMT_);
 mov(0, this.i);
 mov(-1, this.j);

 end Create;

 procedure tDerived.Create; nodisplay;
 begin Create;

 if(esi = 0) then

 push(eax);
 mov(malloc(@size(tDerived)), esi);
 pop(eax);

 endif;

 // Initialize the VMT pointer for this object:

 mov(&tDerived._VMT_, this._pVMT_);

 // Initialize the "r" field of this particular object:

 fldz();
 fstp(this.r);

 // Duplicate the initialization required by tBase.Create:

 mov(0, this.i);
 mov(-1, this.j);

 end Create;

```

Let's take a closer look at the *tDerived.Create* procedure above. Like a conventional constructor, it begins by checking ESI and allocates storage for a new object if ESI contains NULL. Note that the size of a *tDerived* object includes the size required by the inherited fields, so this properly allocates the necessary storage for all fields in a *tDerived* object.

Next, the *tDerived.Create* procedure initializes the VMT pointer field of the object. Remember, each class has its own VMT and, specifically, derived classes do not use the VMT of their base class. Therefore, this constructor must initialize the *\_pVMT\_* field with the address of the *tDerived* VMT.

After initializing the VMT pointer, the *tDerived* constructor initializes the value of the *r* field to 0.0 (remember, FLDZ loads zero onto the FPU stack). This concludes the *tDerived*-specific initialization.

The remaining instructions in *tDerived.Create* are the problem. These statements duplicate some of the code appearing in the *tBase.Create* procedure. The problem with code duplication becomes really apparent

when you decide to modify the initial values of these fields; if you've duplicated the initialization code in derived classes, you will need to change the initialization code in more than one *Create* procedure. More often than not, this results in defects in the derived class *Create* procedures, especially if those derived classes appear in different source files than the base class.

Another problem with burying base class initialization in derived class constructors is the violation of the information hiding principle. Some fields of the base class may be *logically private*. Although HLA does not explicitly support the concept of public and private fields in a class (as, say, C++ does), well-disciplined programmers will still partition the fields as private or public and then only use the private fields in class routines belonging to that class. Initializing these private fields in derived classes is not acceptable to such programmers. Doing so will make it very difficult to change the definition and implementation of some base class at a later date.

Fortunately, HLA provides an easy mechanism for calling the inherited constructor within a derived class' constructor. All you have to do is call the base constructor using the classname syntax, e.g., you could call *tBase.Create* directly from within *tDerived.Create*. By calling the base class constructor, your derived class constructors can initialize the base class fields without worrying about the exact implementation (or initial values) of the base class.

Unfortunately, there are two types of initialization that every (conventional) constructor does that will affect the way you call a base class constructor: all conventional constructors allocate memory for the class if ESI contains zero and all conventional constructors initialize the VMT pointer. Fortunately, it is very easy to deal with these two problems

The memory required by an object of some most base class is usually less than the memory required for an object of a class you derive from that base class (because the derived classes usually add more fields). Therefore, you cannot allow the base class constructor to allocate the storage when you call it from inside the derived class' constructor. This problem is easily solved by checking ESI within the derived class constructor and allocating any necessary storage for the object *before* calling the base class constructor.

The second problem is the initialization of the VMT pointer. When you call the base class' constructor, it will initialize the VMT pointer with the address of the base class' virtual method table. A derived class object's *\_pVMT\_* field, however, must point at the virtual method table for the derived class. Calling the base class constructor will always initialize the *\_pVMT\_* field with the wrong pointer; to properly initialize the *\_pVMT\_* field with the appropriate value, the derived class constructor must store the address of the derived class' virtual method table into the *\_pVMT\_* field after the call to the base class constructor (so that it overwrites the value written by the base class constructor).

The *tDerived.Create* constructor, rewritten to call the *tBase.Create* constructors, follows:

```
procedure tDerived.Create; nodisplay;
begin Create;

 if(esi = 0) then

 push(eax);
 mov(malloc(@size(tDerived)), esi);
 pop(eax);

 endif;

 // Call the base class constructor to do any initialization
 // needed by the base class. Note that this call must follow
 // the object allocation code above (so ESI will always contain
 // a pointer to an object at this point and tBase.Create will
 // never allocate storage).

 tBase.Create();

 // Initialize the VMT pointer for this object. This code
 // must always follow the call to the base class constructor
 // because the base class constructor also initializes this
 // field and we don't want the initial value supplied by
```

```

// tBase.Create.

mov(&tDerived._VMT_, this._pVMT_);

// Initialize the "r" field of this particular object:

fldz();
fstp(this.r);

end Create;

```

This solution solves all the above concerns with derived class constructors.

---

### 10.10.3 Constructor Parameters and Procedure Overloading

All the constructor examples to this point have not had any parameters. However, there is nothing special about constructors that prevent the use of parameters. Constructors are procedures therefore you can specify any number and types of parameters you choose. You can use these parameter values to initialize certain fields or control how the constructor initializes the fields. Of course, you may use constructor parameters for any purpose you'd use parameters in any other procedure. In fact, about the only issue you need concern yourself with is the use of parameters whenever you have a derived class. This section deals with those issues.

The first, and probably most important, problem with parameters in derived class constructors actually applies to all overridden procedures, iterators, and methods: the parameter list of an overridden routine must exactly match the parameter list of the corresponding routine in the base class. In fact, HLA doesn't even give you the chance to violate this rule because `OVERRIDE` routine prototypes don't allow parameter list declarations – they automatically inherit the parameter list of the base routine. Therefore, you cannot use a special parameter list in the constructor prototype for one class and a different parameter list for the constructors appearing in base or derived classes. Sometimes it would be nice if this weren't the case, but there are some sound and logical reasons why HLA does not support this<sup>7</sup>.

Some languages, like C++, support function overloading letting you specify several different constructors whose parameter list specifies which constructor to use. HLA does not directly support procedure overloading in this manner, but you can use macros to simulate this language feature (see “Simulating Function Overloading with Macros” on page 962). To use this trick with constructors you would create a macro with the name *Create*. The actual constructors could have names that describe their differences (e.g., *CreateDefault*, *CreateSetIJ*, etc.). The *Create* macro would parse the actual parameter list to determine which routine to call.

HLA does not support macro overloading. Therefore, you cannot override a macro in a derived class to call a constructor unique to that derived class. In certain circumstances you can create a small workaround by defining empty procedures in your base class that you intend to override in some derived class (this is similar to an abstract method, see “Abstract Methods” on page 1060). Presumably, you would never call the procedure in the base class (in fact, you would probably want to put an error message in the body of the procedure just in case you accidentally call it). By putting the empty procedure declaration in the base class, the macro that simulates function overloading can refer to that procedure and you can use that in derived classes later on.

---

7. Calling virtual methods and iterators would be a real problem since you don't really know which routine a pointer references. Therefore, you couldn't know the proper parameter list. While the problems with procedures aren't quite as drastic, there are some subtle problems that could creep into your code if base or derived classes allowed overridden procedures with different parameter lists.

---

## 10.11 Destructors

A destructor is a class routine that cleans up an object once a program finishes using that object. Like constructors, HLA does not provide a special syntax for creating destructors nor does HLA automatically call a destructor; unlike constructors, a destructor is usually a method rather than a procedure (since virtual destructors make a lot of sense while virtual constructors do not).

A typical destructor will close any files opened by the object, free the memory allocated during the use of the object, and, finally, free the object itself if it was created dynamically. The destructor also handles any other clean-up chores the object may require before it ceases to exist.

By convention, most HLA programmers name their destructors *Destroy*. Destructors generally do not have any parameters, so the issue of overloading the parameter list rarely arises. About the only code that most destructors have in common is the code to free the storage associated with the object. The following destructor demonstrates how to do this:

```
procedure tBase.Destroy; nodisplay;
begin Destroy;

 push(eax); // isInHeap uses this

 // Place any other clean up code here.
 // The code to free dynamic objects should always appear last
 // in the destructor.

 /*****/

 // The following code assumes that ESI still contains the address
 // of the object.

 if(isInHeap(esi)) then

 free(esi);

 endif;
 pop(eax);

end Destroy;
```

The HLA Standard Library routine *isInHeap* returns true if its parameter is an address that *malloc* returned. Therefore, this code automatically frees the storage associated with the object if the program originally allocated storage for the object by calling *malloc*. Obviously, on return from this method call, ESI will no longer point at a legal object in memory if you allocated it dynamically. Note that this code will not affect the value in ESI nor will it modify the object if the object wasn't one you've previously allocated via a call to *malloc*.

---

## 10.12 HLA's “\_initialize\_” and “\_finalize\_” Strings

Although HLA does not automatically call constructors and destructors associated with your classes, HLA does provide a mechanism whereby you can cause these calls to happen automatically: by using the *\_initialize\_* and *\_finalize\_* compile-time string variables (i.e., VAL constants) HLA automatically declares in every procedure.

Whenever you write a procedure, iterator, or method, HLA automatically declares several local symbols in that routine. Two such symbols are *\_initialize\_* and *\_finalize\_*. HLA declares these symbols as follows:

```
val
 initialize: string := "";
 finalize: string := "";
```

HLA emits the `_initialize_` string as text at the very beginning of the routine's body, i.e., immediately after the routine's `BEGIN` clause<sup>8</sup>. Similarly, HLA emits the `_finalize_` string at the very end of the routine's body, just before the `END` clause. This is comparable to the following:

```
procedure SomeProc;
 << declarations >>
begin SomeProc;

 @text(_initialize_);

 << procedure body >>

 @text(_finalize_);

end SomeProc;
```

Since `_initialize_` and `_finalize_` initially contain the empty string, these expansions have no effect on the code that HLA generates unless you explicitly modify the value of `_initialize_` prior to the `BEGIN` clause or you modify `_finalize_` prior to the `END` clause of the procedure. So if you modify either of these string objects to contain a machine instruction, HLA will compile that instruction at the beginning or end of the procedure. The following example demonstrates how to use this technique:

```
procedure SomeProc;
 ?_initialize_ := "mov(0, eax);";
 ?_finalize_ := "stdout.put(eax);";
begin SomeProc;

 // HLA emits "mov(0, eax);" here in response to the _initialize_
 // string constant.

 add(5, eax);

 // HLA emits "stdout.put(eax);" here.

end SomeProc;
```

Of course, these examples don't save you much. It would be easier to type the actual statements at the beginning and end of the procedure than assign a string containing these statements to the `_initialize_` and `_finalize_` compile-time variables. However, if we could automate the assignment of some string to these variables, so that you don't have to explicitly assign them in each procedure, then this feature might be useful. In a moment, you'll see how we can automate the assignment of values to the `_initialize_` and `_finalize_` strings. For the time being, consider the case where we load the name of a constructor into the `_initialize_` string and we load the name of a destructor in to the `_finalize_` string. By doing this, the routine will "automatically" call the constructor and destructor for that particular object.

The example above has a minor problem. If we can automate the assignment of some value to `_initialize_` or `_finalize_`, what happens if these variables already contain some value? For example, suppose we have two objects we use in a routine and the first one loads the name of its constructor into the `_initialize_` string; what happens when the second object attempts to do the same thing? The solution is simple: don't directly assign any string to the `_initialize_` or `_finalize_` compile-time variables, instead, always concatenate your strings to the end of the existing string in these variables. The following is a modification to the above example that demonstrates how to do this:

```
procedure SomeProc;
 ?_initialize_ := _initialize_ + "mov(0, eax);";
 ?_finalize_ := _finalize_ + "stdout.put(eax);";
begin SomeProc;
```

---

8. If the routine automatically emits code to construct the activation record, HLA emits `_initialize_`'s text after the code that builds the activation record.

```

// HLA emits "mov(0, eax);" here in response to the _initialize_
// string constant.

add(5, eax);

// HLA emits "stdout.put(eax);" here.

end SomeProc;

```

When you assign values to the \_initialize\_ and \_finalize\_ strings, HLA almost guarantees that the \_initialize\_ sequence will execute upon entry into the routine. Sadly, the same is not true for the \_finalize\_ string upon exit. HLA simply emits the code for the \_finalize\_ string at the end of the routine, immediately before the code that cleans up the activation record and returns. Unfortunately, “falling off the end of the routine” is not the only way that one could return from that routine. One could explicitly return from somewhere in the middle of the code by executing a RET instruction. Since HLA only emits the \_finalize\_ string at the very end of the routine, returning from that routine in this manner bypassing the \_finalize\_ code. Unfortunately, other than manually emitting the \_finalize\_ code, there is nothing you can do about this<sup>9</sup>. Fortunately, this mechanism for exiting a routine is completely under your control; if you never exit a routine except by “falling off the end” then you won’t have to worry about this problem (note that you can use the EXIT control structure to transfer control to the end of a routine if you really want to return from that routine from somewhere in the middle of the code).

Another way to prematurely exit a routine which, unfortunately, you have no control over, is by raising an exception. Your routine could call some other routine (e.g., a standard library routine) that raises an exception and then transfers control immediately to whomever called your routine. Fortunately, you can easily trap and handle exceptions by putting a TRY..ENDTRY block in your procedure. Here is an example that demonstrates this:

```

procedure SomeProc;
 << declarations that modify _initialize_ and _finalize_ >>
begin SomeProc;

 << HLA emits the code for the _initialize_ string here. >>

 try // Catch any exceptions that occur:

 << Procedure Body Goes Here >>

 anyexception

 push(eax); // Save the exception #.
 @text(_finalize_); // Execute the _finalize_ code here.
 pop(eax); // Restore the exception #.
 raise(eax); // Reraise the exception.

 endtry;

 // HLA automatically emits the _finalize_ code here.

end SomeProc;

```

Although the code above handles some problems that exist with \_finalize\_, by no means that this handle every possible case. Always be on the look out for ways your program could inadvertently exit a routine without executing the code found in the \_finalize\_ string. You should explicitly expand \_finalize\_ if you encounter such a situation.

---

9. Note that you can manually emit the \_finalize\_ code using the statement “@text( \_finalize\_);”.

There is one important place you can get into trouble with respect to exceptions: within the code the routine emits for the `_initialize_` string. If you modify the `_initialize_` string so that it contains a constructor call and the execution of that constructor raises an exception, this will probably force an exit from that routine without executing the corresponding `_finalize_` code. You could bury the TRY.ENDTRY statement directly into the `_initialize_` and `_finalize_` strings but this approach has several problems, not the least of which is the fact that one of the first constructors you call might raise an exception that transfers control to the exception handler that calls the destructors for all objects in that routine (including those objects whose constructors you have yet to call). Although no single solution that handles all problems exists, probably the best approach is to put a TRY.ENDTRY block around each constructor call if it is possible for that constructor to raise some exception that is possible to handle (i.e., doesn't require the immediate termination of the program).

Thus far this discussion of `_initialize_` and `_finalize_` has failed to address one important point: why use this feature to implement the "automatic" calling of constructors and destructors since it apparently involves more work than simply calling the constructors and destructors directly? Clearly there must be a way to automate the assignment of the `_initialize_` and `_finalize_` strings or this section wouldn't exist. The way to accomplish this is by using a macro to define the class type. So now it's time to take a look at another HLA feature that makes it possible to automate this activity: the FORWARD keyword.

You've seen how to use the FORWARD reserved word to create procedure and iterator prototypes (see "Forward Procedures" on page 546), it turns out that you can declare forward CONST, VAL, TYPE, and variable declarations as well. The syntax for such declarations takes the following form:

```
ForwardSymbolName: forward(undefinedID);
```

This declaration is completely equivalent to the following:

```
?undefinedID: text := "ForwardSymbolName";
```

Especially note that this expansion does not actually define the symbol `ForwardSymbolName`. It just converts this symbol to a string and assigns this string to the specified TEXT object (`undefinedID` in this example).

Now you're probably wonder how something like the above is equivalent to a forward declaration. The truth is, it isn't. However, FORWARD declarations let you create macros that simulate type names by allowing you to defer the actual declaration of an object's type until some later point in the code. Consider the following example:

```
type
 myClass: class
 var
 i:int32;

 procedure Create; returns("esi");
 procedure Destroy;
 endclass;

macro _myClass: varID;
 forward(varID);
 ?_initialize_ := _initialize_ + @string:varID + ".Create(); ";
 ?_finalize_ := _finalize_ + @string:varID + ".Destroy(); ";
 varID: myClass
endmacro;
```

Note, and this is very important, that a semicolon does not follow the "varID: myClass" declaration at the end of this macro. You'll find out why this semicolon is missing in a little bit.

If you have the class and macro declarations above in your program, you can now declare variables of type `_myClass` that automatically invoke the constructor and destructor upon entry and exit of the routine containing the variable declarations. To see how, take a look at the following procedure shell:

```
procedure HasmyClassObject;
var
```

```

 mco: _myClass;
begin HasmyClassObject;

 << do stuff with mco here >>

end HasmyClassObject;

```

Since *\_myClass* is a macro, the procedure above expands to the following text during compilation:

```

procedure HasmyClassObject;
var
 mco: // Expansion of the _myClass macro:
 forward(_0103_); // _0103_ symbol is and HLA supplied text symbol
 // that expands to "mco".

 ?_initialize_ := _initialize_ + "mco" + ".Create(); ";
 ?_finalize_ := _finalize_ + "mco" + ".Destroy(); ";
 mco: myClass;

begin HasmyClassObject;

 mco.Create(); // Expansion of the _initialize_ string.

 << do stuff with mco here >>

 mco.Destroy(); // Expansion of the _finalize_ string.

end HasmyClassObject;

```

You might notice that a semicolon appears after “mco: myClass” declaration in the example above. This semicolon is not actually a part of the macro, instead it is the semicolon that follows the “mco: \_myClass;” declaration in the original code.

If you want to create an array of objects, you could legally declare that array as follows:

```

var
 mcoArray: _myClass[10];

```

Because the last statement in the *\_myClass* macro doesn't end with a semicolon, the declaration above will expand to something like the following (almost correct) code:

```

mcoArray: // Expansion of the _myClass macro:
 forward(_0103_); // _0103_ symbol is and HLA supplied text symbol
 // that expands to "mcoArray".

 ?_initialize_ := _initialize_ + "mcoArray" + ".Create(); ";
 ?_finalize_ := _finalize_ + "mcoArray" + ".Destroy(); ";
 mcoArray: myClass[10];

```

The only problem with this expansion is that it only calls the constructor for the first object of the array. There are several ways to solve this problem; one is to append a macro name to the end of *\_initialize\_* and *\_finalize\_* rather than the constructor name. That macro would check the object's name (*mcoArray* in this example) to determine if it is an array. If so, that macro could expand to a loop that calls the constructor for each element of the array (the implementation appears as a programming project at the end of this chapter).

Another solution to this problem is to use a macro parameter to specify the dimensions for arrays of *myClass*. This scheme is easier to implement than the one above, but it does have the drawback of requiring a different syntax for declaring object arrays (you have to use parentheses around the array dimension rather than square brackets).

The FORWARD directive is quite powerful and lets you achieve all kinds of tricks. However, there are a few problems of which you should be aware. First, since HLA emits the *\_initialize\_* and *\_finalize\_* code transparently, you can be easily confused if there are any errors in the code appearing within these strings. If

you start getting error messages associated with the BEGIN or END statements in a routine, you might want to take a look at the `_initialize_` and `_finalize_` strings within that routine. The best defense here is to always append very simple statements to these strings so that you reduce the likelihood of an error.

Fundamentally, HLA doesn't support automatic constructor and destructor calls. This section has presented several tricks to attempt to automate the calls to these routines. However, the automation isn't perfect and, indeed, the aforementioned problems with the `_finalize_` strings limit the applicability of this approach. The mechanism this section presents is probably fine for simple classes and simple programs. However, one piece of advice is probably worth following: if your code is complex or correctness is critical, it's probably a good idea to explicitly call the constructors and destructors manually.

## 10.13 Abstract Methods

An *abstract base class* is one that exists solely to supply a set of common fields to its derived classes. You never declare variables whose type is an abstract base class, you always use one of the derived classes. The purpose of an abstract base class is to provide a template for creating other classes, nothing more. As it turns out, the only difference in syntax between a standard base class and an abstract base class is the presence of at least one *abstract method* declaration. An abstract method is a special method that does not have an actual implementation in the abstract base class. Any attempt to call that method will raise an exception. If you're wondering what possible good an abstract method could be, well, keep on reading...

Suppose you want to create a set of classes to hold numeric values. One class could represent unsigned integers, another class could represent signed integers, a third could implement BCD values, and a fourth could support *real64* values. While you could create four separate classes that function independently of one another, doing so passes up an opportunity to make this set of classes more convenient to use. To understand why, consider the following possible class declarations:

```
type
uint: class
 var
 TheValue: dword;

 method put;
 << other methods for this class >>
endclass;

sint: class
 var
 TheValue: dword;

 method put;
 << other methods for this class >>
endclass;

r64: class
 var
 TheValue: real64;

 method put;
 << other methods for this class >>
endclass;
```

The implementation of these classes is not unreasonable. They have fields for the data, they have a *put* method (which, presumably, writes the data to the standard output device). Presumably they have other methods and procedures to implement various operations on the data. There is, however, two problems with these classes, one minor and one major, both occurring because these classes do not inherit any fields from a common base class.

The first problem, which is relatively minor, is that you have to repeat the declaration of several common fields in these classes. For example, the *put* method declaration appears in each of these classes<sup>10</sup>. This duplication of effort involves results in a harder to maintain program because it doesn't encourage you to use a common name for a common function since it's easy to use a different name in each of the classes.

A bigger problem with this approach is that it is not generic. That is, you can't create a generic pointer to a "numeric" object and perform operations like addition, subtraction, and output on that value (regardless of the underlying numeric representation).

We can easily solve these two problems by turning the previous class declarations into a set of derived classes. The following code demonstrates an easy way to do this:

```
type
numeric: class
 procedure put;
 << Other common methods shared by all the classes >>
endclass;

uint: class inherits(numeric)
 var
 TheValue: dword;

 override method put;
 << other methods for this class >>
endclass;

sint: class inherits(numeric)
 var
 TheValue: dword;

 override method put;
 << other methods for this class >>
endclass;

r64: class inherits(numeric)
 var
 TheValue: real64;

 override method put;
 << other methods for this class >>
endclass;
```

This scheme solves both the problems. First, by inheriting the *put* method from *numeric*, this code encourages the derived classes to always use the name *put* thereby making the program easier to maintain. Second, because this example uses derived classes, it's possible to create a pointer to the *numeric* type and load this pointer with the address of a *uint*, *sint*, or *r64* object. That pointer can invoke the methods found in the *numeric* class to do functions like addition, subtraction, or numeric output. Therefore, the application that uses this pointer doesn't need to know the exact data type, it only deals with numeric values in a generic fashion.

One problem with this scheme is that it's possible to declare and use variables of type *numeric*. Unfortunately, such numeric variables don't have the ability to represent any type of number (notice that the data storage for the numeric fields actually appears in the derived classes). Worse, because you've declared the *put* method in the *numeric* class, you've actually got to write some code to implement that method even though one should never really call it; the actual implementation should only occur in the derived classes. While you could write a dummy method that prints an error message (or, better yet, raises an exception), there shouldn't be any need to write "dummy" procedures like this. Fortunately, there *is* no reason to do so – if you use *abstract* methods.

---

10. Note, by the way, that *TheValue* is not a common class because this field has a different type in the *r64* class.

The `ABSTRACT` keyword, when it follows a method declaration, tells HLA that you are not going to provide an implementation of the method for this class. Instead, it is the responsibility of all derived class to provide a concrete implementation for the abstract method. HLA will raise an exception if you attempt to call an abstract method directly. The following is the modification to the *numeric* class to convert *put* to an abstract method:

```
type
 numeric: class
 method put; abstract;
 << Other common methods shared by all the classes >>
 endclass;
```

An abstract base class is a class that has at least one abstract method. Note that you don't have to make all methods abstract in an abstract base class; it is perfectly legal to declare some standard methods (and, of course, provide their implementation) within the abstract base class.

Abstract method declarations provide a mechanism by which a base class enforces the methods that the derived classes must implement. In theory, all derived classes must provide concrete implementations of all abstract methods or those derived classes are themselves abstract base classes. In practice, it's possible to bend the rules a little and use abstract methods for a slightly different purpose.

A little earlier, you read that one should never create variables whose type is an abstract base class. For if you attempt to execute an abstract method the program would immediately raise an exception to complain about this illegal method call. In practice, you actually can declare variables of an abstract base type and get away with this as long as you don't call any abstract methods. We can use this fact to provide a better form of method overloading (that is, providing several different routines with the same name but different parameter lists). Remember, the standard trick in HLA to overload a routine is to write several different routines and then use a macro to parse the parameter list and determine which actual routine to call (see "Simulating Function Overloading with Macros" on page 962). The problem with this technique is that you cannot override a macro definition in a class, so if you want to use a macro to override a routine's syntax, then that macro must appear in the base class. Unfortunately, you may not need a routine with a specific parameter list in the base class (for that matter, you may only need that particular version of the routine in a single derived class), so implementing that routine in the base class and in all the other derived classes is a waste of effort. This isn't a big problem. Just go ahead and define the abstract method in the base class and only implement it in the derived class that needs that particular method. As long as you don't call that method in the base class or in the other derived classes that don't override the method, everything will work fine.

One problem with using abstract methods to support overloading is that this trick does not apply to procedures - only methods and iterators. However, you can achieve the same effect with procedures by declaring a (non-abstract) procedure in the base class and overriding that procedure only in the class that actually uses it. You will have to provide an implementation of the procedure in the base class, but that is a minor issue (the procedure's body, by the way, should simply raise an exception to indicate that you should have never called it).

An example of routine overloading in a class appears in this chapter's sample program.

---

## 10.14 Run-time Type Information (RTTI)

When working with an object variable (as opposed to a pointer to an object), the type of that object is obvious: it's the variable's declared type. Therefore, at both compile-time and run-time the program trivially knows the type of the object. When working with pointers to objects you cannot, in the general case, determine the type of an object a pointer references. However, at run-time it is possible to determine the object's actual type. This section discusses how to detect the underlying object's type and how to use this information.

If you have a pointer to an object and that pointer's type is some base class, at run-time the pointer could point at an object of the base class or any derived type. At compile-time it is not possible to determine the exact type of an object at any instant. To see why, consider the following short example:

```
ReturnSomeObject(); // Returns a pointer to some class in ESI.
mov(esi, ptrToObject);
```

The routine *ReturnSomeObject* returns a pointer to an object in ESI. This could be the address of some base class object or a derived class object. At compile-time there is no way for the program to know what type of object this function returns. For example, *ReturnSomeObject* could ask the user what value to return so the exact type could not be determined until the program actually runs and the user makes a selection.

In a perfectly designed program, there probably is no need to know a generic object's actual type. After all, the whole purpose of object-oriented programming and inheritance is to produce general programs that work with lots of different objects without having to make substantial changes to the program. In the real world, however, programs may not have a perfect design and sometimes it's nice to know the exact object type a pointer references. Run-time type information, or RTTI, gives you the capability of determining an object's type at run-time, even if you are referencing that object using a pointer to some base class of that object.

Perhaps the most fundamental RTTI operation you need is the ability to ask if a pointer contains the address of some specific object type. Many object-oriented languages (e.g., Delphi) provide an *IS* operator that provides this functionality. *IS* is a boolean operator that returns true if its left operand (a pointer) points to an object whose type matches the left operand (which must be a type identifier). The typical syntax is generally the following:

```
ObjectPointerOrVar is ClassType
```

This operator would return true if the variable is of the specified class, it returns false otherwise. Here is a typical use of this operator (in the Delphi language)

```
if(ptrToNumeric is uint) then begin
.
.
.
end;
```

It's actually quite simple to implement this functionality in HLA. As you may recall, each class is given its own virtual method table. Whenever you create an object, you must initialize the pointer to the VMT with the address of that class' VMT. Therefore, the VMT pointer field of all objects of a given class type contain the same pointer value and this pointer value is different than the VMT pointer field of all other classes. We can use this fact to see if an object is some specific type. The following code demonstrates how to implement the Delphi statement above in HLA:

```
mov(ptrToNumeric, esi);
if((type uint [esi])._pVMT_ = &uint._VMT_) then
.
.
.
endif;
```

This IF statement simply compares the object's *\_pVMT\_* field (the pointer to the VMT) against the address of the desired class' VMT. If they are equal, then the *ptrToNumeric* variable points at an object of type *uint*.

Within the body of a class method or iterator, there is a slightly easier way to see if the object is a certain class. Remember, upon entry into a method or an iterator, the EDI register contains the address of the virtual method table. Therefore, assuming you haven't modified EDI's value, you can easily test to see if THIS (ESI) is a specific class type using an IF statement like the following:

```
if(EDI = &uint._VMT_) then
.
.
.
endif;
```

## 10.15 Calling Base Class Methods

In the section on constructors you saw that it is possible to call an ancestor class' procedure within the derived class' overridden procedure. To do this, all you needed to do was to invoke the procedure using the call "classname.procedureName( parameters);". On occasion you may want to do this same operation with a class' methods as well as its procedures (that is, have an overridden method call the corresponding base class method in order to do some computation you'd rather not repeat in the derived class' method). Unfortunately, HLA does not let you directly call methods as it does procedures. You will need to use an indirect mechanism to achieve this; specifically, you will have to call the function using the address in the base class' virtual method table. This section describes how to do this.

Whenever your program calls a method it does so indirectly, using the address found in the virtual method table for the method's class. The virtual method table is nothing more than an array of 32-bit pointers with each entry containing the address of one of that class' methods. So to call a method, all you need is the index into this array (or, more properly, the offset into the array) of the address of the method you wish to call. The HLA compile-time function *@offset* comes to the rescue- it will return the offset into the virtual method table of the method whose name you supply as a parameter. Combined with the CALL instruction, you can easily call any method associated with a class. Here's an example of how you would do this:

```
type
 myCls: class
 .
 .
 .
 method m;
 .
 .
 .
 endclass;
 .
 .
 .
 call(myCls._VMT_[@offset(myCls.m)]);
```

The CALL instruction above calls the method whose address appears at the specified entry in the virtual method table for *myCls*. The *@offset* function call returns the offset (i.e., index times four) of the address of *myCls.m* within the virtual method table. Hence, this code indirectly calls the *m* method by using the virtual method table entry for *m*.

There is one major drawback to calling methods using this scheme: you don't get to use the high level syntax for procedure/method calls. Instead, you must use the low-level CALL instruction. In the example above, this isn't much of an issue because the *m* procedure doesn't have any parameters. If it did have parameters, you would have to manually push those parameters onto the stack yourself (see "Passing Parameters on the Stack" on page 798). Fortunately, you'll rarely need to call ancestor class methods from a derived class, so this won't be much of an issue in real-world programs.

## 10.16 Sample Program

This chapter's sample program will present what is probably the epitome of object-oriented programs: a simple "drawing" program that uses objects to represent shapes to draw on the display. While limited to a demonstration program, this program does demonstrate important object-oriented concepts in assembly language.

This is an unusual drawing program insofar as it draws shapes using ASCII characters. While the shapes it draws are very rough (compared to a graphics-based drawing program), the output of this program could be quite useful for creating rudimentary diagrams to include as comments in your HLA (or other lan-

guage) programs. This sample program does not provide a “user interface” for drawing images (something you would need to effectively use this program) because the user interface represents a lot of code that won’t improve your appreciation of object-oriented programming (not to mention, this book is long enough already). Providing a mouse-based user interface to this program is left as an exercise to the interested reader.

This program consists of three source files: the class definitions in a header file, the implementation of the class’ procedures and methods in an HLA source file, and a main program that demonstrates a simple use of the class’ objects. The following listings are for these three files.

```

type
 // Generic shape class:

 shape: class

 const

 maxX: uns16 := 80;
 maxY: uns16 := 25;

 var

 x: uns16;
 y: uns16;
 width: uns16;
 height: uns16;
 fillShape: boolean;

 procedure create; returns("esi"); external;

 method draw; abstract;
 method fill(f:boolean); external;
 method moveTo(x:uns16; y:uns16); external;
 method resize(width: uns16; height: uns16); external;

 endclass;

 // Class for a rectangle shape
 //
 // +-----+
 // | |
 // +-----+

 rect: class inherits(shape)

 override procedure create; external;
 override method draw; external;

 endclass;

 // Class for a rounded rectangle shape
 //
 // -----
 // / \
 // | |

```

```

// \ /
// -----

roundrect: class inherits(shape)

 override procedure create; external;
 override method draw; external;

endclass;

// Class for a diamond shape
//
// /\
// / \
// \ /
// \ /

diamond: class inherits(shape)

 override procedure create; external;
 override method resize; external;
 override method draw; external;

endclass;

```

---

---

### Program 10.1 Shapes.hhf - The Shape Class Header Files

---

---

```

unit Shapes;
#includeonce("stdlib.hhf")
#includeonce("shapes.hhf")

// Emit the virtual method tables for the classes:

static
 vmt(shape);
 vmt(rect);
 vmt(roundrect);
 vmt(diamond);

/*****/

// Generic shape methods and procedures

// Constructor for the shape class.
//
// Note: this should really be an abstract procedure, but since
// HLA doesn't support abstract procedures we'll fake it by
// raising an exception if somebody tries to call this proc.

```

```

procedure shape.create; nodisplay; noframe;
begin create;

 // This should really be an abstract procedure,
 // but such things don't exist, so we will fake it.

 raise(ex.ExecutedAbstract);

end create;

// Generic shape.fill method.
// This is an accessor function that sets the "fill" field
// to the value of the parameter.

method shape.fill(f:boolean); nodisplay;
begin fill;

 push(eax);
 mov(f, al);
 mov(al, this.fillShape);
 pop(eax);

end fill;

// Generic shape.moveTo method.
// Checks the coordinates passed as a parameter and
// then sets the (X,Y) coordinates of the underlying
// shape object to these values.

method shape.moveTo(x:uns16; y:uns16); nodisplay;
begin moveTo;

 push(eax);
 push(ebx);

 mov(x, ax);
 assert(ax < shape.maxX);
 mov(ax, this.x);

 mov(y, ax);
 assert(ax < shape.maxY);
 mov(ax, this.y);

 pop(ebx);
 pop(eax);

end moveTo;

// Generic shape.resize method.
// Sets the width and height fields of the underlying object
// to the values passed as parameters.
//
// Note: Ignores resize request if the size is less than 2x2.

method shape.resize(width:uns16; height:uns16); nodisplay;
begin resize;

 push(eax);

```

```

assert(width <= shape.maxX);
assert(height <= shape.maxY);

if(width > 2) then

 if(height > 2) then

 mov(width, ax);
 mov(ax, this.width);

 mov(height, ax);
 mov(ax, this.height);

 endif;

endif;

pop(eax);

end resize;

/*****
/*
/* rect's methods:

## 10.17 Putting It All Together

HLA's class declarations provide a powerful tool for creating object-oriented assembly language programs. Although object-oriented programming is not as popular in assembly as in high level languages, part of the reason has been the lack of assemblers that support object-oriented programming in a reasonable fashion and an even greater lack of tutorial information on object-oriented programming in assembly language.

While this chapter cannot go into great detail about the object-oriented programming paradigm (space limitations prevent this), this chapter does explain the object-oriented facilities that HLA provides and supplies several example programs that use those facilities. From here on, it's up to you to utilize these facilities in your programs and gain experience writing object oriented assembly code.

---

# The MMX Instruction Set

# Chapter Eleven

---

## 11.1 Chapter Overview

While working on the Pentium and Pentium Pro processors, Intel was also developing an instruction set architecture extension for multimedia applications. By studying several existing multimedia applications, developing lots of multimedia related algorithms, and through simulation, Intel developed 57 instructions that would greatly accelerate the execution of multimedia applications. The end result was their multimedia extensions to the Pentium processor that Intel calls the MMX Technology Instructions.

Prior to the invention of the MMX enhancements, good quality multimedia systems required separate digital signal processors and special electronics to handle much of the multimedia workload<sup>1</sup>. The introduction of the MMX instruction set allowed later Pentium processors to handle these multimedia tasks without these expensive digital signal processors (DSPs), thus lowering the cost of multimedia systems. So later Pentiums, Pentium II, Pentium III, and Pentium IV processors all have the MMX instruction set. Earlier Pentiums (and CPUs prior to the Pentium) and the Pentium Pro do not have these instructions available. Since the instruction set has been available for quite some time, you can probably use the MMX instructions without worrying about your software failing on many machines.

In this chapter we will discuss the MMX Technology instructions and how to use them in your assembly language programs. The use of MMX instructions, while not completely limited to assembly language, is one area where assembly language truly shines since most high level languages do not make good use of MMX instructions except in library routines. Therefore, writing fast code that uses MMX instructions is mainly the domain of the assembly language programmer. Hence, it's a good idea to learn these instructions if you're going to write much assembly code.

---

## 11.2 Determining if a CPU Supports the MMX Instruction Set

While it's almost a given that any modern CPU your software will run on will support the MMX extended instruction set, there may be times when you want to write software that will run on a machine even in the absence of MMX instructions. There are two ways to handle this problem – either provide two versions of the program, one with MMX support and one without (and let the user choose which program they wish to run), or the program can dynamically determine whether a processor supports the MMX instruction set and skip the MMX instructions if they are not available.

The first situation, providing two different programs, is the easiest solution from a software development point of view. You don't actually create two source files, of course; what you do is use conditional compilation statements (i.e., #IF..#ELSE..#ENDIF) to selectively compile MMX or standard instructions depending on the presence of an identifier or value of a boolean constant in your program. See “Conditional Compilation (Compile-Time Decisions)” on page 934 for more details.

Another solution is to dynamically determine the CPU type at run-time and use program logic to skip over the MMX instructions and execute equivalent standard code if the CPU doesn't support the MMX instruction set. If you're expecting the software to run on an Intel Pentium or later CPU, you can use the CPUID instruction to determine whether the processor supports the MMX instruction set. The CPUID instruction will return bit 23 as a one in the feature flags return result.

The following code illustrates how to use the CPUID instruction. This example does not demonstrate the entire CPUID sequence, but shows the portion used for detection of MMX technology.

---

1. A good example was the Apple Quadra 660AV and 840AV computer systems; they were built around the Motorola 68040 processor rather than a Pentium, but the 68040 was no more capable of handling multimedia applications than the Pentium. However, an on-board DSP (digital signal processor) CPU allowed the Quodras to easily handle audio applications that the 68040 could not.

```
// For a perfectly general routine, you should determine if this
// is a Pentium or later processor. We'll assume at least a Pentium
// for now, since most Win32 OSes expect a Pentium or better processor.

 mov(1, eax); // Request for CPUID feature flags.
 CPUID(); // Get the feature flags into EDX.
 test($80_0000, edx); // Is bit 23 set?
 jnz HasMMX;
```

This code assumes at least the presence of a Pentium Processor. If your code needs to run on a 486 or 386 processor, you will have to detect that the system is using one of these processors. There is tons of code on the net that detects different processors, but most of it will not run under Windows since that code typically uses protected (non-user-mode) instructions. There is also a Windows API call (`Get_Machine_Info`) that will return this status. We'll not go into the details here because 99% of the users out there that are running modern versions of Windows have a CPU that supports the MMX instruction set or, at least, the CPUID instruction.

---

## 11.3 The MMX Programming Environment

The MMX architecture extends the Pentium architecture by adding the following:

- Eight MMX registers (MM0..MM7).
- Four MMX data types (packed bytes, packed words, packed double words, and quad word).
- 57 MMX Instructions.

---

### 11.3.1 The MMX Registers

The MMX architecture adds eight 64-bit registers to the Pentium. The MMX instructions refer to these registers as MM0, MM1, MM2, MM3, MM4, MM5, MM6, and MM7. These are strictly data registers, you cannot use them to hold addresses nor are they suitable for calculations involving addresses.

Although MM0..MM7 appear as separate registers in the Intel Architecture, the Pentium processors alias these registers with the FPU's registers (ST0..ST7). Each of the eight MMX 64-bit registers is physically equivalent to the L.O. 64-bits of each of the FPU's registers (see Figure 11.1). The MMX registers overlay the FPU registers in much the same way that the 16-bit general purpose registers overlay the 32-bit general purpose registers.

**Figure 11.1 MMX and FPU Register Aliasing**

Because the MMX registers overlay the FPU registers, you cannot mix FPU and MMX instructions in the same computation sequence. You can begin executing an MMX instruction sequence at any time; however, once you execute an MMX instruction you cannot execute another FPU instruction until you execute a special MMX instruction, EMMS (Exit MMX Machine State). This instruction resets the FPU so you may begin a new sequence of FPU calculations. The CPU does not save the FPU state across the execution of the MMX instructions; executing EMMS clears all the FPU registers. Because saving FPU state is very expensive, and the EMMS instruction is quite slow, it's not a good idea to frequently switch between MMX and FPU calculations. Instead, you should attempt to execute the MMX and FPU instructions at different times during your program's execution.

You're probably wondering why Intel chose to alias the MMX registers with the FPU registers. Intel, in their literature, brags constantly about what a great idea this was. You see, by aliasing the MMX registers with the FPU registers, Microsoft and other multitasking OS vendors did not have to write special code to save the MMX state when the CPU switched from one process to another. The fact that the OS automatically saved the FPU state means that the CPU would automatically save the MMX state as well. This meant that the new Pentium chips with MMX technology that Intel created were automatically compatible with Windows 95, Windows NT, and Linux without any changes to the operating system code.

Of course, those operating systems have long since been upgraded and Microsoft (and Linux developers) could have easily provided a "service pack" to handle the new registers (had Intel chosen not to alias the FPU and MMX registers). So while aliasing MMX with the FPU provided a very short-lived and temporary benefit, in retrospect Intel made a big mistake with this decision. They've obviously realized their mistake, because as they've introduced new "streaming" instructions (the floating point equivalent of the MMX instruction set) they've added new registers (XMM0..XMM7) without using this trick. It's too bad they

don't fix the problem in their current CPUs (there is no technical reason why they can't create separate MMX and FPU registers at this point). Oh well, you'll just have to live with the fact that you can't execute interleaved FPU and MMX instructions.

### 11.3.2 The MMX Data Types

The MMX instruction set supports four different data types: an eight-byte array, a four-word array, a two element double word array, and a quadword object. Each MMX register processes one of these four data types (see Figure 11.2).

**Figure 11.2** The MMX Data Types

Despite the presence of 64-bit registers, the MMX instruction set does not extend the 32-bit Pentium processor to 64-bits. Instead, after careful study Intel added only those 64-bit instructions that were useful for multimedia operations. For example, you cannot add or subtract two 64-bit integers with the MMX instruction set. In fact, only the logical and shift operations directly manipulate 64 bits.

The MMX instruction set was not designed to provide general 64-bit capabilities to the Pentium. Instead, the MMX instruction set provides the Pentium with the capability of performing multiple eight-, sixteen-, or thirty-two bit operations simultaneously. In other words, the MMX instructions are generally SIMD (Single Instruction Multiple Data) instructions (see “Parallel Processing” on page 258 for an explanation of SIMD). For example, a single MMX instruction can add eight separate pairs of byte values together. This is not the same as adding two 64-bit values since the overflow from the individual bytes does not carry over into the higher order bytes. This can accelerate a program that needs to add a long string of bytes together since a single MMX instruction can do the work of eight regular Pentium instructions. This is how the MMX instruction set speeds up multimedia applications – by processing multiple data objects in parallel with a single instruction. Given the data types the MMX instruction set supports, you can process up to eight byte objects in parallel, four word objects in parallel, or two double words in parallel.

---

## 11.4 The Purpose of the MMX Instruction Set

The Single Instruction Multiple Data model the MMX architecture supports may not look all that impressive when viewed with a SISD (Single Instruction, Single Data) bias. Once you’ve mastered the basic integer instructions on the 80x86, it’s difficult to see the application of the MMX’s SIMD instruction set. However, the MMX instructions directly address the needs of modern media, communications, and graphics applications, which often use sophisticated algorithms that perform the same operations on a large number of small data types (bytes, words, and double words).

For example, most programs use a stream of bytes or words to represent audio and video data. The MMX instructions can operate on eight bytes or four words with a single instruction, thus accelerating the program by almost a factor of four or eight.

One drawback to the MMX instruction set is that it is not general purpose. Intel’s research that led to the development of these new instructions specifically targeted audio, video, graphics, and another multimedia applications. Although some of the instructions are applicable in many general programs, you’ll find that many of the instructions have very little application outside their limited domain. Although, with a lot of deep thought, you can probably dream up some novel uses of many of these instructions that have nothing whatsoever at all to do with multimedia, you shouldn’t get too frustrated if you cannot figure out why you would want to use a particular instruction; that instruction probably has a specific purpose and if you’re not trying to code a solution for that problem, you may not be able to use the instruction. If you’re questioning why Intel would put such limited instructions in their instruction set, just keep in mind that although you can use the instruction(s) for lots of different purposes, they are invaluable for the few purposes they are uniquely suited.

---

## 11.5 Saturation Arithmetic and Wraparound Mode

The MMX instruction set supports saturating arithmetic (see “Sign Extension, Zero Extension, Contraction, and Saturation” on page 63). When manipulating standard integer values and an overflow occurs, the integer instructions maintain the correct L.O. bits of the value in the integer while truncating any overflow<sup>2</sup>. This form of arithmetic is known as *wraparound* mode since the L.O. bits wrap back around to zero. For example, if you add the two eight-bit values \$02 and \$FF you wind up with a carry and the result \$01. The actual sum is \$101, but the operation truncates the ninth bit and the L.O. byte wraps around to \$01.

In saturation mode, results of an operation that overflow or underflow are clipped (saturated) to some maximum or minimum value depending on the size of the object and whether it is signed or unsigned. The

---

2. For some instructions the overflow may appear in another register or the carry flag, but in the destination register the high order bits are lost.

result of an operation that exceeds the range of a data-type saturates to the maximum value of the range. A result that is less than the range of a data type saturates to the minimum value of the range.

**Table 1:**

| Data Type     | Decimal     |             | Hexadecimal |             |
|---------------|-------------|-------------|-------------|-------------|
|               | Lower Limit | Upper Limit | Lower Limit | Upper Limit |
| Signed Byte   | -128        | +127        | \$80        | \$7f        |
| Unsigned Byte | 0           | 255         | 0           | \$ff        |
| Signed Word   | -32768      | +32767      | \$8000      | \$7fff      |
| Unsigned Word | 0           | 65535       | 0           | \$ffff      |

For example, when the result exceeds the data range limit for signed bytes, it is saturated to \$7f; if a value is less than the data range limit, it is saturated to \$80 for signed bytes. If a value exceeds the range for unsigned bytes, it is saturated to \$ff or \$00.

This saturation effect is very useful for audio and video data. For example, if you are amplifying an audio signal by multiplying the words in the 44.1 kHz audio stream by 1.5, clipping the value at +32767, while introducing distortion, sounds far better than allowing the waveform to wrap around to -32768. Similarly, if you are mixing colors in a 24-bit graphic or video image, saturating to white produces much more meaningful results than wrap-around.

Since Intel created the MMX architecture to support audio, graphics, and video, it should come as no surprise that the MMX instruction set supports saturating arithmetic. For those applications that require saturating arithmetic, having the CPU automatically handle this process (rather than having to explicitly check after each calculation) is another way the MMX architecture speeds up multimedia applications.

## 11.6 MMX Instruction Operands

Most MMX instructions operate on two operands, a source and a destination operand. A few instructions have three operands with the third operand being a small immediate (constant) value. In this section we'll take a look at the common MMX instruction operands.

The destination operand is almost always an MMX register. In fact, the only exceptions are those instructions that store an MMX register into memory. The MMX instructions always leave the result of MMX calculations in an MMX register.

The source operand can be an MMX register or a memory location. The memory location is usually a quad word entity, but certain instructions operate on double word objects. Note that, in this context, "quad word" and "double word" mean eight or four consecutive bytes in memory; they do not necessarily imply that the MMX instruction is operating on a qword or dword object. For example, if you add eight bytes together using the PADDB (packed add bytes) instruction, PADDB references a qword object in memory, but actually adds together eight separate bytes.

For most MMX instructions, the generic HLA syntax is one of the following:

```
mmxInstr(source, dest);
```

The specific forms are

```
mmxInstr(mmi, mmi); // i=0..7
mmxInstr(mem, mmi); // i=0..7
```

MMX instructions access memory using the same addressing modes as the standard integer instructions. Therefore, any legal 80x86 addressing mode is usable in an MMX instruction. For those instructions that reference a 64-bit memory location, HLA requires that you specify an anonymous memory object (e.g., “[ebx]” or “[ebp+esi\*8+6]”) or a *qword* variable.

A few instructions require a small immediate value (or constant). For example, the shift instructions let you specify a shift count as an immediate value in the range 0..63. Another instruction uses the immediate value to specify a set of four different count values in the range 0..3 (i.e., four two-bit count values). These instructions generally take the following form:

```
mmxInstr(imm8, source, dest);
```

Note that, in general, MMX instructions do not allow you to specify immediate constants as operands except for a few special cases (such as shift counts). In particular, the source operand to an MMX instruction has to be a register or a quad word variable, it cannot be a 64-bit constant. To achieve the same effect as specifying a constant as the source operand, you must initialize a quad word variable in the READONLY (or STATIC) section of your program and specify this variable as the source operand. Unfortunately, HLA does not support 64-bit constants, so initializing the value is going to be a bit of a problem. There are two solutions to this problem: break the constant into smaller pieces (bytes, words, or double words) and emit the constant in pieces that HLA can process; or you can write your own numeric conversion routine(s) using the HLA compile-time language to allow the emission of a 64-bit constant. We'll explore both of those approaches here.

The first approach is the one you will most commonly use. Very few MMX instructions actually operate on 64-bit data operands; instead, they typically operate on a (small) array of bytes, words, or double words. Since HLA provides good support for byte, word, and double word constant expressions, specifying a 64-bit MMX memory operand as a short array of objects is probably the best way to create this data. Since the MMX instructions that fetch a source value from memory expect a 64-bit operand, you must declare such objects as *qword* variables, e.g.,

```
static
 mmxVar:qword;
```

The big problem with this declaration is that the *qword* type does not allow an initializer (since HLA cannot handle 64-bit constant expressions). Since this declaration occurs in the STATIC segment, HLA will initialize *mmxVar* with zero; probably not the value you're interested in supplying here.

There are two ways to solve this problem. The first way is to attach the NOSTORAGE option to the MMX variable declarations in the STATIC segment. The data declarations that immediately follow the variable definition provide the initial data for that variable. Here's an example of such a declaration:

```
static
 mmxDVar: qword; nostorage;
 dword $1234_5678, $90ab_cdef;
```

Note that the DWORD directive above stores the double word constants in successive memory locations. Therefore, \$1234\_5678 will appear in the L.O. double word of the 64-bit value and \$90ab\_cdef will appear in the H.O. double word of the 64-bit value. Always keep in mind that the L.O. objects come first in the list following the DWORD (or BYTE, or WORD, or ???) directive; this appears to be opposite of the way you're used to reading values.

The example above used a DWORD directive to provide the initialization constant. However, you can use any data declaration directive, or even a combination of directives, as long as you allocate at least eight bytes (64-bits) for each *qword* constant. The following data declaration, for example, initializes eight eight-bit constants for an MMX operand; this would be perfect for a PADDB instruction or some other instruction that operates on eight bytes in parallel:

```
static
 eightBytes: qword; nostorage;
 byte 0, 1, 2, 3, 4, 5, 6, 7;
```

Although most MMX instructions operate on small arrays of bytes, words, or double words, a few actually do operate on 64-bit quantities. For such memory operands you would probably prefer to specify a 64-bit constant rather than break it up into its constituent double word values. This way, you don't have to remember to put the L.O. double word first and perform other mental adjustments.

Although HLA does not support 64-bit constants in the compile time language, HLA is flexible enough to allow you to extend the language to handle such declarations. Program 11.1 demonstrates how to write a macro to accept a 64-bit hexadecimal constant. This macro will automatically emit two DWORD declarations containing the L.O. and H.O. components of the 64-bit value you specify as the *qword16* (quadword constant, base 16) macro parameter. You would typically use the *qword16* macro as follows:

```
static
 H0Ones: qword; nostorage;
 qword16($FFFF_FFFF_0000_0000);
```

The *qword16* macro would emit the following:

```
 dword 0;
 dword $FFFF_FFFF;
```

Without further ado, here's the macro (and a sample test program):

```
program qwordConstType;
#include("stdlib.hhf")

// The following macro accepts a 64-bit hexadecimal constant
// and emits two dword objects in place of the constant.

macro qword16(theHexVal):hs, len, dwval, mplier, curch, didLO;

 // Remove whitespace around the macro parameter (shouldn't
 // be any, but just in case something weird is going on) and
 // convert all lower case characters to upper case.

 ?hs := @uppercase(@trim(@string:theHexVal, 0), 0);

 // If there is a leading "$" symbol, strip it from the string.

 #if(@substr(hs, 0, 1) = "$")

 ?hs := @substr(hs, 1, 256);

 #endif

 // Process each character in the string from the L.O. digit
 // through to the H.O. digit. Add the digit, multiplied by
 // some successive power of 16, to the current sum we're
 // accumulating in dwval. When we cross a dword boundary,
 // emit the L.O. dword and start over.

 ?len := @length(hs); // Number of characters to process.
 ?dwval:dword := 0; // Accumulate value here.
 ?mplier:dword := 1; // Power of 16 to multiply by.
 ?didLO:boolean := false; // Checks for overflow.
 #while(len > 0) // Repeat for each char in string.

 // For each character in the string, verify that it is
 // a legal hexadecimal character and merge it in with the
 // current accumulated value if it is. Print an error message
 // if we come across an illegal character.
```

```

?len := len - 1; // Next available char.
?curch := char(@substr(hs, len, 1)); // Get the character.
#if(curch in { '0'..'9' }) // See if valid decimal digit.

 // Accumulate result if decimal digit.

 ?dwval := dwval +
 (uns8(curch) - uns8('0')) * mplier;

#elseif(curch in { 'A'..'F' }) // See if valid hex digit.

 // Accumulate result if a hexadecimal digit.

 ?dwval := dwval +
 (uns8(curch) - uns8('A') + 10) * mplier;

// Ignore underscore characters and report an error for anything
// else we find in the string.

#elseif(curch <> '_')

 #error("Illegal character in 64-bit hexadecimal constant")
 #print("Character = '", curch, "' Rest of string: '", hs, "'")

#endif

// If it's not an underscore character, adjust the multiplier value.
// If we cross a dword boundary, emit the L.O. value as a dword
// and reset everything for the H.O. dword.

#if(curch <> '_')

 // If the current value fits in 32 bits, process this
 // as though it were a dword object.

 #if(mplier < $1000_0000)

 ?mplier := mplier * 16;

 #elseif(len > 0)

 // Down here we've just processed the last hex
 // digit that will fit into 32 bits. So emit the
 // L.O. dword and reset the mplier and dwval constants.

 ?mplier := 1;
 dword dwval;
 ?dwval := 0;

 // If we've been this way before, we've got an
 // overflow.

 #if(didLO)

 #error("64-bit overflow in constant");

 #endif
 ?didLO := true;

```

```

 #endif

 #endif

#endwhile

// Emit the H.O. dword here.

dword dwval;

// If the constant only consumed 32 bits, we've got to emit a zero
// for the H.O. dword at this point.

#if(!didLO)

 dword 0;

#endif

endmacro;

static
 x:qword; nostorage;
 qword16($1234_5678_90ab_cdef);
 qword16(100);

begin qwordConstType;

 stdout.put("64-bit value of x = $");
 stdout.putqw(x);
 stdout.newln();

end qwordConstType;

```

---

### Program 11.1 qword16 Macro to Process 64-bit Hexadecimal Constants

---

Although it's a little bit more difficult, you could also write a *qword10* macro that lets you specify decimal constants as the macro operand rather than hexadecimal constants. The implementation of *qword10* is left as a programming exercise at the end of this volume.

---

## 11.7 MMX Technology Instructions

The following subsections describe each of the MMX instructions in detail. The organization is as follows:

- Data Transfer Instructions,
- Conversion Instructions,
- Packed Arithmetic Instructions,
- Comparisons,
- Logical Instructions,
- Shift and Rotate Instructions,
- the EMMS Instruction.

These sections describe *what* these instructions do, not *how* you would use them. Later sections will provide examples of how you can use several of these instructions.

---

### 11.7.1 MMX Data Transfer Instructions

```

movd(reg32, mmi);
movd(mem32, mmi);
movd(mmi, reg32);
movd(mmi, mem32);

movq(mem64, mmi);
movq(mmi, mem64);
movq(mmi, mmi);

```

The MOVD (move double word) instruction copies data between a 32-bit integer register or double word memory location and an MMX register. If the destination is an MMX register, this instruction zero-extends the value while moving it. If the destination is a 32-bit register or memory location, this instruction copies the L.O. 32-bits of the MMX register to the destination.

The MOVQ (move quadword) instruction copies data between two MMX registers or between an MMX register and memory. If either the source or destination operand is a memory object, it must be a *qword* variable or HLA will complain.

---

### 11.7.2 MMX Conversion Instructions

```

packssdw(mem64, mmi);
packssdw(mmi, mmi);

packsswb(mem64, mmi);
packsswb(mmi, mmi);

packusdw(mem64, mmi);
packusdw(mmi, mmi);

packuswb(mem64, mmi);
packuswb(mmi, mmi);

punpckhbw(mem64, mmi);
punpckhbw(mmi, mmi);

punpckhdq(mem64, mmi);
punpckhdq(mmi, mmi);

punpckhwd(mem64, mmi);
punpckhwd(mmi, mmi);

punpcklbw(mem64, mmi);
punpcklbw(mmi, mmi);

punpckldq(mem64, mmi);
punpckldq(mmi, mmi);

punpcklwd(mem64, mmi);
punpcklwd(mmi, mmi);

```

The `PACKSSxx` instructions pack and saturate signed values. They convert a sequence of larger values to a sequence of smaller values via saturation. Those instructions with the *dw* suffix pack four double words into four words; those with the *wb* suffix saturate and pack eight signed words into eight signed bytes.

The `PACKSSDW` instruction takes the two double words in the source operand and the two double words in the destination operand and converts these to four signed words via saturation. The instruction packs these four words together and stores the result in the destination MMX register. See Figure 11.3 for details.

The `PACKSSWB` instruction takes the four words from the source operand and the four signed words from the destination operand and converts, via signed saturation, these values to eight signed bytes. This instruction leaves the eight bytes in the destination MMX register. See Figure 11.4 for details.

One application for these pack instructions is to convert UNICODE to ASCII (ANSI). You can convert UNICODE (16-bit) character to ANSI (8-bit) character if the H.O. eight bits of each UNICODE character is zero. The `PACKUSWB` instruction will take eight UNICODE characters and pack them into a string that is eight bytes long with a single instruction. If the H.O. byte of any UNICODE character contains a non-zero value, then the `PACKUSWB` instruction will store \$FF in the respective byte; therefore, you can use \$FF as a conversion error indication.

Another use for the `PACKSSWB` instruction is to translate a 16-bit audio stream to an eight-bit stream. Assuming you've scaled your sixteen-bit values to produce a sequence of values in the range -128..+127, you can use the `PACKSSWB` instruction to convert that sequence of 16-bit values into a packed sequence of eight bit values.

**Figure 11.3** `PACKSSDW` Instruction

**Figure 11.4** PACKSSWB Instruction

The unpack instructions (PUNPCKxxx) provide the converse operation to the pack instructions. The unpack instructions take a sequence of smaller, packed, values and translate them into larger values. There is one problem with this conversion, however. Unlike the pack instructions, where it took two 64-bit operands to generate a single 64-bit result, the unpack operations will produce a 64-bit result from a single 32-bit result. Therefore, these instructions cannot operate directly on full 64-bit source operands. To overcome this limitation, there are two sets of unpack instructions: one set unpacks the data from the L.O. double word of a 64-bit object, the other set of instructions unpacks the H.O. double word of a 64-bit object. By executing one instruction from each set you can unpack a 64-bit object into a 128-bit object.

The PUNPCKLBW, PUNPCKLWD, and PUNPCKLDQ instructions merge (unpack) the L.O. double words of their source and destination operands and store the 64-bit result into their destination operand.

The PUNPCKLBW instruction unpacks and interleaves the low-order four bytes of the source (first) and destination (second) operands. It places the L.O. four bytes of the destination operand at the even byte positions in the destination and it places the L.O. four bytes of the source operand in the odd byte positions of the destination operand.(see Figure 11.5).

**Figure 11.5 UNPCKLBW Instruction**

The PUNPCKLWD instruction unpacks and interleaves the low-order two words of the source (first) and destination (second) operands. It places the L.O. two words of the destination operand at the even word positions in the destination and it places the L.O. words of the source operand in the odd word positions of the destination operand (see Figure 11.6).

**Figure 11.6 The PUNPCKLWD Instruction**

The PUNPCKDQ instruction copies the L.O. dword of the source operand to the L.O. dword of the destination operand and it copies the (original) L.O. dword of the destination operand to the L.O. dword of the destination (i.e., it doesn't change the L.O. dword of the destination, see Figure 11.7).

**Figure 11.7 PUNPCKLDQ Instruction**

The PUNPCKHBW instruction is quite similar to the PUNPCKLBW instruction. The difference is that it unpacks and interleaves the high-order four bytes of the source (first) and destination (second) operands. It places the H.O. four bytes of the destination operand at the even byte positions in the destination and it places the H.O. four bytes of the source operand in the odd byte positions of the destination operand (see Figure 11.8).

**Figure 11.8 PUNPCKHBW Instruction**

The PUNPCKHWD instruction unpacks and interleaves the low-order two words of the source (first) and destination (second) operands. It places the L.O. two words of the destination operand at the even word positions in the destination operand and it places the L.O. words of the source operand in the odd word positions of the destination operand (see Figure 11.9)

**Figure 11.9 PUNPCKHWD Instruction**

The PUNPCKHDQ instruction copies the H.O. dword of the source operand to the H.O. dword of the destination operand and it copies the (original) H.O. dword of the destination operand to the L.O. dword of the destination (see Figure 11.10).

**Figure 11.10 PUNPCKDQ Instruction**

Since the unpack instructions provide the converse operation of the pack instructions, it should come as no surprise that you can use these instructions to perform the inverse algorithms of the examples given earlier for the pack instructions. For example, if you have a string of eight-bit ANSI characters, you can convert them to their UNICODE equivalents by setting one MMX register (the source) to all zeros. You can convert each four characters of the ANSI string to UNICODE by loading those four characters into the L.O. double word of an MMX register and executing the PUNPCKLBW instruction. This will interleave each of the characters with a zero byte, thus converting them from ANSI to UNICODE.

Of course, the unpack instructions are quite valuable any time you need to interleave data. For example, if you have three separate images containing the blue, red, and green components of a 24-bit image, it is possible to merge these three bytes together using the PUNPCKLBW instruction<sup>3</sup>.

psubusw(mmi, mmi);

```

---

3. Typically you would merge in a fourth byte of zero and then store the resulting double word every three bytes in memory to overwrite the zeros.

```

pmulhuw(mem64, mmi);
pmulhuw(mmi, mmi);

pmulhw(mem64, mmi);
pmulhw(mmi, mmi);

pmullw(mem64, mmi);
pmullw(mmi, mmi);

pmaddwd(mem64, mmi);
pmaddwd(mmi, mmi);

```

The packed arithmetic instructions operate on a set of bytes, words, or double words within a 64-bit block. For example, the PADDW instruction computes four 16-bit sums of two operand simultaneously. None of these instructions affect the CPU's FLAGS register. Therefore, there is no indication of overflow, underflow, zero result, negative result, etc. If you need to test a result after a packed arithmetic computation, you will need to use one of the packed compare instructions (see "MMX Comparison Instructions" on page 1103).

The PADDB, PADDW, and PADDD instructions add the individual bytes, words, or double words in the two 64-bit operands using a wrap-around (i.e., non-saturating) addition. Any carry out of a sum is lost; it is your responsibility to ensure that overflow never occurs. As for the integer instructions, these packed add instructions add the values in the source operand to the destination operand, leaving the sum in the destination operand. These instructions produce correct results for signed or unsigned operands (assuming overflow/underflow does not occur).

The PADDSB and PADDSW instructions add the eight eight-bit or four 16-bit operands in the source and destination locations together using signed saturation arithmetic. The PADDUSB and PADDUSW instructions add their eight eight-bit or four 16-bit operands together using unsigned saturation arithmetic. Notice that you must use different instructions for signed and unsigned value since saturation arithmetic is different depending upon whether you are manipulating signed or unsigned operands. Also note that the instruction set does not support the saturated addition of double word values.

The PSUBB, PSUBW, and PSUBD instructions work just like their addition counterparts, except of course, they compute the wrap-around difference rather than the sum. These instructions compute  $dest=dest-src$ . Likewise, the PSUBSB, PSUBSW, PSUBUSB, and PSUBUSW instruction compute the difference of the destination and source operands using saturation arithmetic.

While addition and subtraction can produce a one-bit carry or borrow, multiplication of two n-bit operands can produce as large as a  $2*n$  bit result. Since overflow is far more likely in multiplication than in addition or subtraction, the MMX packed multiply instructions work a little differently than their addition and subtraction counterparts. To successfully multiply two packed values requires two instructions - one to compute the L.O. component of the result and one to produce the H.O. component of the result. The PMULLW, PMULHW, and PMULHUW instructions handle this task.

The PMULLW instruction multiplies the four words of the source operand by the four words of the destination operand and stores the four L.O. words of the four double word results into the destination operand. This instruction ignores the H.O. words of the results. Used by itself, this instruction computes the wrap-around product of an unsigned or signed set of operands; this is also the L.O. words of the four products.

The PMULHW and PMULHUW instructions complete the calculation. After computing the L.O. words of the four products with the PMULLW instruction, you use either the PMULHW or PMULHUW instruction to compute the H.O. words of the products. These two instruction multiply the four words in the source by the four words in the destination and then store the H.O. words of the results in the destination MMX register. The difference between the two is that you use PMULHW for signed operands and PMULHUW for unsigned operands. If you compute the full product by using a PMULLW and a PMULHW (or PMULHUW) instruction pair, then there is no overflow possible, hence you don't have to worry about wrap-around or saturation arithmetic.

The PMADDWD instruction multiplies the four words in the source operand by the four words in the destination operand to produce four double word products. Then it adds the two L.O. double words together

and stores the result in the L.O. double word of the destination MMX register; it also adds together the two H.O. double words and stores their sum in the H.O. word of the destination MMX register.

## 11.7.4 MMX Logic Instructions

```
pand(mem64, mmi);
pand(mmi, mmi);
```

```
pandn(mem64, mmi);
pandn(mmi, mmi);
```

```
por(mem64, mmi);
por(mmi, mmi);
```

```
pxor(mem64, mmi);
pxor(mmi, mmi);
```

The packed logic instructions are some examples of MMX instructions that actually operate on 64-bit values. There are no packed byte, packed word, or packed double word versions of these instructions. Of course, there is no need for special byte, word, or double word versions of these instructions since they would all be equivalent to the 64-bit logic instruction. Hence, if you want to logically AND eight bytes together in parallel, you use the PAND instruction; likewise, if you want to logically AND four words or two double words together, you just use the PAND instruction.

The PAND, POR, and PXOR instructions do the same thing as their 32-bit integer instruction counterparts (AND, OR, XOR) except, of course, they operate on two 64-bit MMX operands. Hence, no further discussion of these instructions is really necessary here. The PANDN (AND NOT) instruction is a new logic instruction, so it bears a little bit of a discussion. The PANDN instruction computes the following result:

```
dest := dest and (not source);
```

As you may recall from the chapter on Introduction to Digital Design, this is the inhibition function. If the destination operand is B and the source operand is A, this function computes  $B = BA'$ . (see “Boolean Functions and Truth Tables” on page 197 for details of the inhibition function). If you’re wondering why Intel chose to include such a weird function in the MMX instruction set, well, this instruction has one very useful property: it forces bits to zero in the destination operand everywhere there is a one bit in the source operand. This is an extremely useful function for merging to 64-bit quantities together. The following code sequence demonstrates this:

```
readonly
AlternateNibbles: qword; nostorage;
 qword16($F0F0_F0F0_F0F0_F0F0); // Note: needs qword16 macro!
 .
 .
 .
// Create a 64-bit value in MM0 containing the Odd nibbles from MM1 and
// the even nibbles from MM0:

pandn(AlternateNibbles, mm0); // Clear the odd numbered nibbles.
pand(AlternateNibbles, mm1); // Clear the even numbered nibbles.
por(mm1, mm0); // Merge the two.
```

The PANDN operation is also useful for compute the set difference of two character sets. You could implement the *cs.difference* function using only six MMX instructions:

```
// Compute csdest := csdest - cssrc;

movq((type qword csdest), mm0);
pandn((type qword cssrc), mm0);
movq(mm0, (type qword csdest));
```

```

movq((type qword cdest[8]), mm0);
pandn((type qword cssrc[8]), mm0);
movq(mm0, (type qword cdest[8]));

```

Of course, if you want to improve the performance of the HLA Standard Library character set functions, you can use the MMX logic instructions throughout that module. Examples of such code appear later in this chapter.

---

## 11.7.5 MMX Comparison Instructions

```

pcmpeqb(mem64, mmi);
pcmpeqb(mmi, mmi);

pcmpeqw(mem64, mmi);
pcmpeqw(mmi, mmi);

pcmpeqd(mem64, mmi);
pcmpeqd(mmi, mmi);

pcmpgtb(mem64, mmi);
pcmpgtb(mmi, mmi);

pcmpgtw(mem64, mmi);
pcmpgtw(mmi, mmi);

pcmpgtd(mem64, mmi);
pcmpgtd(mmi, mmi);

```

The packed comparison instructions compare the destination (second) operand to the source (first) operand and test for equality or greater than. These instructions compare eight pairs of bytes (PCMPEQB, PCMPGTB), four pairs of words (PCMPEQW, PCMPGTW), or two pairs of double words (PCMPEQD, PCMPGTD).

The first big difference to notice about these packed comparison instructions is that they compare the second operand to the first operand. This is exactly opposite of the standard CMP instruction (that compares the first operand to the second operand). The reason for this will become clear in a moment; however, you do have to keep in mind when using these instructions that the operands are opposite what you would normally expect. If this ordering bothers you, you can create macros to reverse the operands; we will explore this possibility a little later in this section.

The second big difference between the packed comparisons and the standard integer comparison is that these instructions test for a specific condition (equality or greater than) rather than doing a generic comparison. This is because these instructions, like the other MMX instructions, do not affect any condition code bits in the FLAGS register. This may seem contradictory, after all the whole purpose of the CMP instruction is to set the condition code bits. However, keep in mind that these instructions simultaneously compare two, four, or eight operands; that implies that you would need two, four, or eight sets of condition code bits to hold the results of the comparisons. Since the FLAGS register maintains only one set of condition code bits, it is not possible to reflect the comparison status in the FLAGS. This is why the packed comparison instructions test a specific condition - so they can return true or false to indicate the result of their comparison.

Okay, so where do these instructions return their true or false values? In the destination operand, of course. This is the third big difference between the packed comparisons and the standard integer CMP instruction - the packed comparisons modify their destination operand. Specifically, the PCMPEQB and PCMPGTB instruction compare each pair of bytes in the two operands and write false (\$00) or true (\$FF) to the corresponding byte in the destination operand, depending on the result of the comparison. For example, the instruction “pcmpgtb( MM1, MM0 );” compares the L.O. byte of MM0 (A) with the L.O. byte of MM1 (B) and writes \$00 to the L.O. byte of MM0 if A is not greater than B. It writes \$FF to the L.O. byte of MM0 if A is greater than B (see Figure 11.11).

**Figure 11.11 PCMPEQB and PCMPGTB Instructions**

The PCMPEQW, PCMPGTW, PCMPEQD, and PCMPGTD instructions work in an analogous fashion except, of course, they compare words and double words rather than bytes (see Figure 11.12 and Figure 11.13).

**Figure 11.12 PCMPEQW and PCMPGTW Instructions**

**Figure 11.13 PCMPEQD and PCMPGTD Instructions**

You've probably already noticed that there isn't a set of PCMPPLTx instructions. Intel chose not to provide these instructions because you can simulate them with the PCMPGTD instructions by reversing the operands. That is,  $A > B$  implies  $B < A$ . Therefore, if you want to do a concurrent comparison of multiple operands for less than, you can use the PCMPGTD instructions to do this by simply reversing the operands. The only time this isn't directly possible is if your source operand is a memory operand; since the destination operand of the packed comparison instructions has to be an MMX register, you would have to move the memory operand into an MMX register before comparing them.

In addition to the lack of a packed less than comparison, you're also missing the not equals, less than or equal, and greater than or equal comparisons. You can easily synthesize these comparisons by executing a PXOR or POR instruction after the packed comparison.

To simulate a PCMPNEx instruction, all you've got to do is invert all the bits in the destination operand after executing a PCMPEQx instruction, e.g.,

```
pcmpeqb(mm1, mm0);
pxor(AllOnes, mm0); // Assumption: AllOnes is a qword variable
 // containing $FFFF_FFFF_FFFF_FFFF.
```

Of course, you can save the PXOR instruction by testing for zeros in the destination operand rather than ones (that is, use your program's logic to invert the result rather than actually computing the inverse).

To simulate the PCMPGEx and PCMPLEx instructions, you must do two comparisons, one for equality and one for greater than or less than, and then logically OR the results. Here's an example that computes  $MM0 \leq MM1$ :

```
movq(mm1, mm2); // Need a copy of destination operand.
pcmpgtb(mm0, mm1); // Remember: A<B is equal to B>A, so we're
pcmpeqb(mm0, mm2); // MM0<MM1 and MM0=MM1 here.
por(mm2, mm1); // Leaves boolean results in MM1.
```

If it really bothers you to have to reverse the operands, you can create macros to create your own PCMPPLTx instructions. The following example demonstrates how to create the PCMPPLTB macro:

```
macro pcmpltb(mmOp1, mmOp2);

 pcmptgb(mmOp2, mmOp1);

endmacro;
```

Of course, you must keep in mind that there are two very big differences between this PCMPLTB “instruction” and a true PCMPLTB instruction. First, this form leaves the result in the first operand, not the second operand, hence the semantics of this “instruction” are different than the other packed comparisons. Second, the first operand has to be an MMX register while the second operand can be an MMX register or a quad word variable; again, just the opposite of the other packed instructions. The fact that this instruction’s operands behave differently than the PCMPGTB instruction may create some problems. So you will have to carefully consider whether you really want to use this scheme to create a PCMPLTB “instruction” for use in your programs. If you decide to do this, it would help tremendously if you always commented each invocation of the macro to point out that the first operand is the destination operand, e.g.,

```
pcmpltb(mm0, mm1); // Computes mm0 := mm1<mm0!
```

If the fact that the packed comparison instruction’s operands are reversed bothers you, you can also use macros to swap those operands. The following example demonstrates how to write such macros for the PEQB (PCMPPEQB), PGTB (PCMPGTB), and PLTB (packed less than, byte) instructions.

```
macro peqb(leftOp, rightOp);

 pcmppeqb(rightOp, leftOp);

endmacro;

macro pgtb(leftOp, rightOp);

 pcmpgtb(rightOp, leftOp);

endmacro;

macro pltb(leftOp, rightOp);

 pcmpgtb(leftOp, rightOp);

endmacro;
```

Note that these macros don’t solve the PLTB problem of having the wrong operand as the destination. However, these macros do compare the first operand to the second operand, just like the standard CMP instruction.

Of course, once you obtain a boolean result in an MMX register, you’ll probably want to test the results at one point or another. Unfortunately, the MMX instructions only provide a couple of ways to move comparison information in and out of the MMX processor – you can store an MMX register value into memory or you can copy 32-bits of an MMX register to a general-purpose integer register. Since the comparison instructions produce a 64-bit result, writing the destination of a comparison to memory is the easiest way to gain access to the comparison results in your program. Typically, you’d use an instruction sequence like the following:

```
pcmppeqb(mm1, mm0); // Compare 8 bytes in mm1 to mm0.
movq(mm0, qwordVar); // Write comparison results to memory.
if((type boolean qwordVar)) then

 << do this if byte #0 contained true ($FF, which is non-zero). >>

endif;
if((type boolean qwordVar[1])) then

 << do this if byte #1 contained true. >>

endif;
etc.
```

## 11.7.6 MMX Shift Instructions

```

psllw(mem, mmi);
psllw(mmi, mmi);
psllw(imm8, mmi);

pslld(mem, mmi);
pslld(mmi, mmi);
pslld(imm8, mmi);

psllq(mem, mmi);
psllq(mmi, mmi);
psllq(imm8, mmi);

pslrw(mem, mmi);
pslrw(mmi, mmi);
pslrw(imm8, mmi);

psrld(mem, mmi);
psrld(mmi, mmi);
psrld(imm8, mmi);

pslrq(mem, mmi);
pslrq(mmi, mmi);
pslrq(imm8, mmi);

psraw(mem, mmi);
psraw(mmi, mmi);
psraw(imm8, mmi);

psrad(mem, mmi);
psrad(mmi, mmi);
psrad(imm8, mmi);

```

The MMX shift, like the arithmetic instructions, allow you to simultaneously shift several different values in parallel. The PSSLx instructions perform a packed shift left logical operation, the PSLRx instructions do a packed logical shift right operation, and the PSRAX instruction do a packed arithmetic shift right operation. These instructions operate on word, double word, and quad word operands. Note that Intel does not provide a version of these instructions that operate on bytes.

The first operand to these instructions specifies a shift count. This should be an unsigned integer value in the range 0..15 for word shifts, 0..31 for double word operands, and 0..63 for quadword operands. If the shift count is outside these ranges, then these instructions set their destination operands to all zeros. If the count (first) operand is not an immediate constant, then it must be an MMX register or a *qword* memory location.

The PSSLW instruction simultaneously shifts the four words in the destination MMX register to the left one bit position. The instruction shifts zero into the L.O. bit of each word and the bit shifted out of the H.O. bit of each word is lost. There is no carry from one word to the other (since that would imply a larger shift operation). This instruction, like all the other MMX instructions, does not affect the FLAGS register (including the carry flag).

The PSLLD instruction simultaneously shifts the two double words in the destination MMX register to the left one bit position. Like the PSSLW instruction, this instruction shifts zeros into the L.O. bits and any bits shifted out of the H.O. positions are lost.

The PSSLQ is one of the few MMX instructions that operates on 64-bit quantities. This instruction shifts the entire 64-bit destination register to the left the number of bits specified by the count operand. In addition to allowing you to manipulate 64-bit integer quantities, this instruction is especially useful for moving data around in MMX registers so you can pack or unpack data as needed.

Although there is no PSLLB instruction to shift bits, you can simulate this instruction using a PSLW and a PANDN instruction. After shifting the word values to the left the specified number of bits, all you've got to do is clear the L.O.  $n$  bits of each byte, where  $n$  is the shift count. For example, to shift the bytes in MM0 to the left three positions you could use the following two instructions:

```
static
 ThreeBitsZero: byte; nostorage;
 byte $F8, $F8, $F8, $F8, $F8, $F8, $F8, $F8;
 .
 .
 .
 psllw(3, mm0);
 pandn(ThreeBitsZero, mm0);
```

The PSLRW, PSLRD, and PSLRQ instructions work just like their left shift counterparts except that these instructions shift their operands to the right rather than to the left. They shift zeros into the vacated H.O. positions of the destination values and bits they shift out of the L.O. bits are lost. As with the shift left instructions, there is no PSLRB instruction but you can easily simulate this with a PSLRW and a PANDN instruction.

The PSRAW and PSRAD instructions do an arithmetic shift right operation on the words or double words in the destination MMX register. Note that there isn't a PSRAQ instruction. While shifting data to the right, these instructions replicate the H.O. bit of each word, double word, or quad word rather than shifting in zeros. As for the logical shift right instructions, bits that these instructions shift out of the L.O. bits are lost forever.

The PSLLQ and PSLRQ instructions provide a convenient way to shift a quad word to the left or right. However, the MMX shift instructions are not generally useful for extended precision shifts since all data shifted out of the operands is lost. If you need to do an extended precision shift other than 64 bits, you should stick with the SHLD and SHRD instructions. The MMX shift instructions are mainly useful for shifting several values in parallel or (PSLLQ and PSLRQ) repositioning data in an MMX register.

## 11.8 The EMMS Instruction

```
emms();
```

The EMMS (Empty MMX Machine State) instruction restores the FPU status on the CPU so that it can begin processing FPU instructions again after an MMX instruction sequence. You should always execute the EMMS instruction once you complete some MMX sequence. Failure to do so may cause any following floating point instructions to fail.

When an MMX instruction executes, the floating point tag word is marked valid (00s). Subsequent floating-point instructions that will be executed may produce unexpected results because the floating-point stack seems to contain valid data. The EMMS instruction marks the floating point tag word as empty. This must occur before the execution of any following floating point instructions.

Of course, you don't have to execute the EMMS instruction immediately after an MMX sequence if you're going to execute some additional MMX instructions prior to executing any FPU instructions, but you must take care to execute this instruction if

- You call any library routines or Windows APIs (that might possibly use the FPU).
- You switch tasks in a cooperative fashion (for example, see the chapter on Coroutines in the Volume on Advanced Procedures).
- You execute any FPU instructions.

If the EMMS instruction is not used when trying to execute a floating-point instruction, the following may occur:

- Depending on the exception mask bits of the floating-point control word, a floating point exception event may be generated.

- A “soft exception” may occur. In this case floating-point code continues to execute, but generates incorrect results.

The EMMS instruction is rather slow, so you don't want to unnecessarily execute it, but it is critical that you execute it at the appropriate times. Of course, better safe than sorry; if you're not sure you're going to execute more MMX instructions before any FPU instructions, then go ahead and execute the EMMS instruction to clear the state.

---

## 11.9 The MMX Programming Paradigm

In general, you don't learn scalar (non-MMX) 80x86 assembly language programming and then use that same mindset when writing programs using the MMX instruction set. While it is possible to directly use various MMX instructions the same way you would the general purpose integer instructions, one phrase comes to mind when working with MMX: think parallel. This text has spent many hundreds of pages up to this point attempting to get you to think in assembly language; to think that this small section can teach you how to design optimal MMX sequence would be ludicrous. Nonetheless, a few simple examples are useful to help start you thinking about how to use the MMX instructions to your benefit in your programs. This section will begin by presenting some fairly obvious uses for the MMX instruction set, and then it will attempt to present some examples that exploit the inherent parallelism of the MMX instructions.

Since the MMX registers are 64-bits wide, you can double the speed of certain data movement operations by using MMX registers rather than the 32-bit general purpose registers. For example, consider the following code from the HLA Standard Library that copies one character set object to another:

---

```

procedure cs.cpy(src:cset; var dest:cset); nodisplay;
begin cpy;

 push(eax);
 push(ebx);
 mov(dest, ebx);
 mov((type dword src), eax);
 mov(eax, [ebx]);
 mov((type dword src[4]), eax);
 mov(eax, [ebx+4]);
 mov((type dword src[8]), eax);
 mov(eax, [ebx+8]);
 mov((type dword src[12]), eax);
 mov(eax, [ebx+12]);
 pop(ebx);
 pop(eax);

end cpy;

```

---

### Program 11.2 HLA Standard Library cs.cpy Routine

---

This is a relatively simple code sequence. Indeed, a fair amount of the execution time is spent copying the parameters (20 bytes) onto the stack, calling the routine, and returning from the routine. This entire sequence can be reduced to the following four MMX instructions:

```

movq((type qword src), mm0);
movq((type qword src[8]), mm1);
movq(mm0, (type qword dest));
movq(mm1, (type qword dest[8]));

```

Of course, this sequence assumes two things: (1) it's okay to wipe out the values in MM0 and MM1, and (2) you'll execute the EMMS instruction a little later on after the execution of some other MMX instructions. If either, or both, of these assumptions is incorrect, the performance of this sequence won't be quite as good (though probably still better than the *cs.cpy* routine). However, if these two assumptions do hold, then it's relatively easy to implement the *cs.cpy* routine as an in-line function (i.e., a macro) and have it run much faster. If you really need this operation to occur inside a procedure and you need to preserve the MMX registers, and you don't know if any MMX instructions will execute shortly thereafter (i.e., you'll need to execute EMMS), then it's doubtful that using the MMX instructions will help here. However, in those cases when you can put the code in-line, using the MMX instructions will be faster.

Warning: don't get too carried away with the MMX MOVQ instruction. Several programmers have gone to great extremes to use this instruction as part of a high performance MOVSD replacement. However, except in very special cases on very well designed systems, the limiting factor for a block move is the speed of memory. Since Intel has optimized the operation of the MOVSD instruction, you're best off using the MOVSD instructions when moving blocks of memory around.

Earlier, this chapter used the *cs.difference* function as an example when discussing the PANDN instruction. Here's the HLA Standard Library implementation of this function:

---

---

```

procedure cs.difference(src:cset; var dest:cset); nodisplay;
begin difference;

 push(eax);
 push(ebx);
 mov(dest, ebx);
 mov((type dword src), eax);
 not(eax);
 and(eax, [ebx]);
 mov((type dword src[4]), eax);
 not(eax);
 and(eax, [ebx+4]);
 mov((type dword src[8]), eax);
 not(eax);
 and(eax, [ebx+8]);
 mov((type dword src[12]), eax);
 not(eax);
 and(eax, [ebx+12]);
 pop(ebx);
 pop(eax);

end difference;

```

---

---

### Program 11.3 HLA Standard Library *cs.difference* Routine

---

---

Once again, the high-level nature of HLA is hiding the fact that calling this function is somewhat expensive. A typical call to *cs.difference* emits five or more instructions just to push the parameters (it takes four 32-bit PUSH instructions to pass the *src* character set because it is a value parameter). If you're willing to wipe out the values in MM0 and MM1, and you don't need to execute an EMMS instruction right away, it's possible to compute the set difference with only six instructions – that's about the same number of instructions (and often fewer) than are needed to call this routine, much less do the actual work. Here are those six instructions:

```

movq(dest, mm0);
movq(dest[8], mm1);
pandn(src, mm0);
pandn(src[8], mm1);

```

```
movq(mm0, dest);
movq(mm1, dest[8]);
```

These six instructions replace 12 of the instructions in the body of the function. The sequence is sufficiently short that it's reasonable to code it in-line rather than in a function. However, were you to bury this code in the `cs.difference` routine, you needed to preserve MM0 and MM1<sup>4</sup>, and you needed to execute EMMS afterwards, this would cost more than it's worth. As an in-line macro, however, it is going to be significantly faster since it avoids passing parameters and the call/return sequence.

If you want to compute the intersection of two character sets, the instruction sequence is identical to the above except you substitute PAND for PANDN. Similarly, if you want to compute the union of two character sets, use the code sequence above substituting POR for PANDN. Again, both approaches pay off handsomely if you insert the code in-line rather than burying it in a procedure and you don't need to preserve MMX registers or execute EMMS afterwards.

We can continue with this exercise of working our way through the HLA Standard Library character set (and other) routines substituting MMX instructions in place of standard integer instructions. As long as we don't need to preserve the MMX machine state (i.e., registers) and we don't have to execute EMMS, most of the character set operations will be short enough to code in-line. Unfortunately, we're not buying that much over code the standard implementations of these functions in-line from a performance point of view (though the code would be quite a bit shorter). The problem here is that we're not "thinking in MMX." We're still thinking in scalar (non-parallel mode) and the fact that the MMX instruction set requires a lot of set-up (well, "tear-down" actually) negates many of the advantages of using MMX instructions in our programs.

The MMX instructions truly shine when you compute multiple results in parallel. The problem with the character set examples above is that we're not even processing a whole data object with a single instruction; we're actually only processing a half of a character set with a sequence of three MMX instructions (i.e., it requires six instructions to compute the intersection, union, or difference of two character sets). At best, we can only expect the code to run about twice as fast since we're processing 64 bits at a time instead of 32 bits. Executing EMMS (and, God help us, having to preserve MMX registers) negates much of what we might gain by using the MMX instructions. Again, we're only going to see a speed improvement if we process multiple objects with a single MMX instruction. We're not going to do that manipulating large objects like character sets.

One data type that will let us easily manipulate up to eight objects at one time is a character string. We can speed up many character string operations by operating on eight characters in the string at one time. Consider the HLA Standard Library `str.uppercase` procedure. This function steps through each character of a string, tests to see if it's a lower case character, and if so, converts the lower case character to upper case. A good question to ask is "can we process eight characters at a time using the MMX instructions?" The answer turns out to be yes and the MMX implementation of this function provides an interesting perspective on writing MMX code.

At first glance it might seem impractical to use the MMX instructions to test for lower case characters and convert them to upper case. Consider the typical scalar approach that tests and converts a single character at a time:

```
<< Get character to convert into the AL register >>

 cmp(al, 'a');
 jb noConversion;
 cmp(al, 'z');
 ja noConversion;
 sub($20, al); // Could also use AND($5f, al); here.
noConversion:
```

This code first checks the value in AL to see if it's actually a lower case character (that's the CMP and Jcc instructions in the code above). If the character is outside the range 'a'..'z' then this code skips over the conversion (the SUB instruction); however, if the code is in the specified range, then the sequence above drops through to the SUB instruction and converts the lower case character to upper case by subtracting \$20 from

---

4. Actually, the code could be rewritten easily enough to use only one MMX register.

the lower case character's ASCII code (since lower case characters always have bit #5 set, subtracting \$20 always clears this bit).

Any attempt to convert this code directly to an MMX sequence is going to fail. Comparing and branching around the conversion instruction only works if you're converting one value at a time. When operating on eight character simultaneously, any mixture of the eight characters may or may not require conversion from lower case to upper case. Hence, we need to be able to perform some calculation that is benign if the character is not lower case (i.e., doesn't affect the character's value) while converting the character to upper case if it was lower case to begin with. Worse, we have to do this with pure computation since flow of control isn't going to be particularly effective here (if we test each individual result in our MMX register we won't really save anything over the scalar approach). To save you some suspense, yes, such a calculation does exist.

Consider the following algorithm that converts lower case characters to upper case:

```
<< Get character to test into AL >>
cmp(al, 'a');
setae(bl); // bl := al >= 'a'
cmp(al, 'z');
setbe(bh); // bh := al <= 'z'
and(bh, bl); // bl := (al >= 'a') && (al <= 'z');
dec(bl); // bl := $FF/$00 if false/true.
not(bl); // bl := $FF/$00 if true/false.
and($20, bl); // bl := $20/$00 if true/false.
sub(bl, al); // subtract $20 if al was lowercase.
```

This code sequence is fairly straight-forward up until the DEC instruction above. It computes true/false in BL depending on whether AL is in the range 'a'..'z'. At the point of the DEC instruction, BL contains one if AL is a lower case character, it contains zero if AL's value is not lower case. After the DEC instruction, BL contains \$FF for false (AL is not lower case) and \$00 for true (AL is lowercase). The code is going to use this as a mask a little later, but it really needs true to be \$FF and false \$00, hence the NOT instruction that follows. The (second) AND instruction above converts true to \$20 and false to \$00 and the final SUB instruction subtracts \$20 if AL contained lower case, it subtracts \$00 from AL if AL did not contain a lower case character (subtracting \$20 from a lower case character will convert it to upper case).

Whew! This sequence probably isn't very efficient when compared to the simpler code given previously. Certainly there are more instructions in this version (nearly twice as many). Whether this code without any branches runs faster or slower than the earlier code with two branches is a good question. The important thing to note here, though, is that we converted the lower case characters to upper case (leaving other characters unchanged) using only a calculation; no program flow logic is necessary. This means that the code sequence above is a good candidate for conversion to MMX. Even if the code sequence above is slower than the previous algorithm when converting one character at a time to upper case, it's positively going to scream when it converts eight characters at a shot (since you'll only need to execute the sequence one-eighth as many times).

The following is the code sequence that will convert the eight characters starting at location [EDI] in memory to upper case:

```
data
A:qword;
 byte $60, $60, $60, $60, $60, $60, $60, $60; // Note: $60 = 'a'-1.
Z:qword;
 byte $7B, $7B, $7B, $7B, $7B, $7B, $7B, $7B; // Note: $7B = 'z' + 1.
ConvFactor:qword;
 byte $20, $20, $20, $20, $20, $20, $20, $20; // Magic value for lc->UC.
 .
 .
 .
 movq(ConvFactor, mm4); // Eight copies of conversion value.
 movq(A, mm2); // Put eight "a" characters in mm2.
 movq(Z, mm3); // Put eight "z" characters in mm3.
 movq([edi], mm0); // Get next eight characters of our string.
```

```

movq(mm0, mm1); // We need two copies.
pcmpgtb(mm2, mm1); // Generate 1's in MM1 everywhere chars >= 'a'
pcmpgtb(mm0, mm3); // Generate 1's in MM3 everywhere chars <= 'z'
pand(mm3, mm1); // Generate 1's in MM1 when 'a'<=chars<='z'
pand(mm4, mm1); // Generates $20 in each spot we have a l.c. char
psubb(mm1, mm0); // Convert l.c. chars to U.C. by adding $20.
movq(mm0, [edi]);

```

Note that this code compares the characters that [EDI] points at to 'a'-1 and 'z'+1 because we only have a greater than comparison rather than a greater or equal comparison (this saves a few extra instructions). Other than setting up the MMX registers and taking advantage of the fact that the PCMPGTB instructions automatically produce \$FF for true and \$00 for false, this is a faithful reproduction of the previous algorithm except it operates on eight bytes simultaneously. So if we put this code in a loop and execute it once for each eight characters in the string, there will be one-eighth the iterations of a similar loop using the scalar instructions.

Of course, there is one problem with this code. Not all strings have lengths that are an even multiple of eight bytes. Therefore, we've got to put some special case code into our algorithm to handle strings that are less than eight characters long and handle strings whose length is not an even multiple of eight characters. In the following program, the `mmxupper` function simply borrows the scalar code from the HLA Standard Library's `str.upper` procedure to handle the leftover characters. The following example program provides both an MMX and a scalar solution with a main program that compares the running time of both. If you're wondering, the MMX version is about three times faster (on a Pentium III) for strings around 35 characters long, containing mostly lower case (mostly lower case favors the scalar algorithm since fewer branches are taken with lower case characters; longer strings favor the MMX algorithm since it spends more time in the MMX code compared to the scalar code at the end).

```

program UpperCase;
#include("stdlib.hhf")

// The following code was stolen from the
// HLA Standard Library's str.upper function.
// It is not optimized, but then none of this
// code is optimized other than to use the MMX
// instruction set (later).

procedure strupper(dest: string); nodisplay;
begin strupper;

 push(edi);
 push(eax);

 mov(dest, edi);
 if(edi = 0) then

 raise(ex.AttemptToDerefNULL);

 endif;

 // Until we encounter a zero byte, convert any lower
 // case characters to upper case.

 forever

 mov([edi], al);
 breakif(al = 0); // Quit when we find a zero byte.

 // If a lower case character, convert it to upper case

```

```

 // and store the result back into the destination string.

 if
 (#{
 cmp(al, 'a');
 jb false;
 cmp(al, 'z');
 ja false;
 }#) then

 and($5f, al); // Magic lc->UC translation.
 mov(al, [edi]); // Save result.

 endif;

 // Move on to the next character.

 inc(edi);

endfor;

pop(edi);
pop(eax);

end strupper;

```

```

procedure mmxupper(dest: string); nodisplay;
const
 zCh:char := char(uns8('z') + 1);
 aCh:char := char(uns8('a') - 1);

static

 // Create eight copies of the A-1 and Z+1 characters
 // so we can compare eight characters at once:

 A:qword; nostorage;
 byte aCh, aCh, aCh, aCh, aCh, aCh, aCh, aCh;

 Z:qword; nostorage;
 byte zCh, zCh, zCh, zCh, zCh, zCh, zCh, zCh;

 // Conversion factor: UC := LC - $20.

 ConvFactor: qword; nostorage;
 byte $20, $20, $20, $20, $20, $20, $20, $20;

begin mmxupper;

 push(edi);
 push(eax);

 mov(dest, edi);
 if(edi = 0) then

 raise(ex.AttemptToDerefNULL);

 endif;

```

```

// Some invariant operations (things that don't
// change on each iteration of the loop):

movq(A, mm2);
movq(ConvFactor, mm4);

// Get the string length from the length field:

mov((type str.strRec [edi]).length, eax);

// Process the string in blocks of eight characters:

while((type int32 eax) >= 8) do

 movq([edi], mm0); // Get next eight characters of our string.
 movq(mm0, mm1); // We need two copies.
 movq(Z, mm3); // Need to refresh on each loop.
 pcmptgb(mm2, mm1); // Generate 1's in MM1 everywhere chars >= 'a'
 pcmptgb(mm0, mm3); // Generate 1's in MM3 everywhere chars <= 'z'
 pand(mm3, mm1); // Generate 1's in MM1 when 'a'<=chars<='z'
 pand(mm4, mm1); // Generates $20 in each spot we have a l.c. char
 psubb(mm1, mm0); // Convert l.c. chars to U.C. by adding $20.
 movq(mm0, (type qword [edi]));

 // Move on to the next eight characters in the string.

 sub(8, eax);
 add(8, edi);

endwhile;

// If we're processing less than eight characters, do it the old-fashioned
// way (one character at a time). This also handles the last 1..7 chars
// if the number of characters is not an even multiple of eight. This
// code was swiped directly from the HLA str.upper function (above).

if(eax != 0) then

 forever

 mov([edi], al);
 breakif(al = 0); // Quit when we find a zero byte.

 // If a lower case character, convert it to upper case
 // and store the result back into the destination string.

 if

mov(edx, (type dword strCycles[4]));

stdout.put("Dest String(2) = '", destStr, "'", nl);

stdout.put("MMX cycles:");
stdout.puti64(mmxCycles);
stdout.put(nl "HLA cycles: ");
stdout.puti64(strCycles);
stdout.newln();

end UpperCase;

```

---

#### Program 11.4 MMX Implementation of the HLA Standard Library str.upper Procedure

---

Other string functions, like a case insensitive string comparison, can greatly benefit from the use of parallel computation via the MMX instruction set. Implementation of other string functions is left as an exercise to the reader; interested readers should consider converting string functions that involve calculations and tests on each individual characters in a string as candidates for optimization via MMX.

---

## 11.10 Putting It All Together

Intel's MMX enhancements to the basic Pentium instruction set allow the acceleration of certain algorithms. Unfortunately, the MMX instruction set isn't generally applicable to a wide range of problems. The MMX instructions, with their SIMD orientation, are generally useful for manipulating a large amount of data organized as byte, word, or double word arrays where the MMX instructions can calculate several values in parallel. Learning to effectively use the MMX instruction set requires a paradigm shift on the part of the programmer. You don't apply the same rules for scalar 80x86 instructions to the MMX instructions. However, if you take the time to master parallel programming techniques with the MMX instructions, then you will be able to accelerate many of your applications.

---

# Mixed Language Programming

# Chapter Twelve

---

## 12.1 Chapter Overview

Most assembly language code doesn't appear in a stand-alone assembly language program. Instead, most assembly code is actually part of a library package that programs written in a high level language wind up calling. Although HLA makes it really easy to write standalone assembly applications, at one point or another you'll probably want to call an HLA procedure from some code written in another language or you may want to call code written in another language from HLA. This chapter discusses the mechanisms for doing this in three languages: MASM (low-level assembly), C/C++, and Delphi. The mechanisms for other languages are usually similar to one of these three, so the material in this chapter will still apply even if you're using some other high level language.

---

## 12.2 Mixing HLA and MASM Code in the Same Program

It may seem kind of weird to mix MASM and HLA code in the same program. After all, they're both assembly languages and almost anything you can do with MASM can be done in HLA. So why bother trying to mix the two in the same program? Well, there are three reasons:

- You've already got a lot of code written in MASM and you don't want to convert it to HLA's syntax.
- There are a few things MASM does that HLA cannot, and you happen to need to do one of those things.
- Someone else has written some MASM code and they want to be able to call code you've written using HLA.

In this section, we'll discuss two ways to merge MASM and HLA code in the same program: via in-line assembly code and through linking OBJ files.

---

### 12.2.1 In-Line (MASM) Assembly Code in Your HLA Programs

As you're probably aware, the HLA compiler doesn't actually produce machine code directly from your HLA source files. Instead, it first compiles the code to a MASM-compatible assembly language source file and then it calls MASM to assemble this code to object code. If you're interested in seeing the MASM output HLA produces, just edit the *filename.ASM* file that HLA creates after compiling your *filename.HLA* source file. The output assembly file isn't amazingly readable, but it is fairly easy to correlate the assembly output with the HLA source file.

HLA provides two mechanisms that let you inject raw MASM code directly into the output file it produces: the `#ASM..#ENDASM` sequence and the `#EMIT` statement. The `#ASM..#ENDASM` sequence copies all text between these two clauses directly to the MASM output file, e.g.,

```
#asm
 mov eax, 0 ;MASM syntax for MOV(0, EAX);
 add eax, ebx ; " " " ADD(ebx, eax);
#endasm
```

The `#ASM..#ENDASM` sequence is how you inject in-line (MASM) assembly code into your HLA programs. For the most part there is very little need to use this feature, but in a few instances it is valuable. For example, if you're writing structured exception handling code under Windows, you'll need to access the double word at address `FS:[0]` (offset zero in the segment pointed at by the 80x86's FS segment register).

Unfortunately, HLA does not support segmentation and the use of segment registers. However, you can drop into MASM for a statement or two in order to access this value:

```
#asm
 mov ebx, fs:[0] ; Loads process pointer into EBX
#endasm
```

At the end of this instruction sequence, EBX will contain the pointer to the process information structure that Windows maintains.

HLA blindly copies all text between the #ASM and #ENDASM clauses directly to the MASM output file. HLA does not check the syntax of this code or otherwise verify its correctness. If you introduce an error within this section of your program, MASM will report the error when HLA assembles your code by calling MASM.

The #EMIT statement also writes text directly to the assembly output file. However, this statement does not simply copy the text from your source file to the output file; instead, this statement copies the value of a string (constant) expression to the output file. The syntax for this statement is as follows:

```
#emit(string_expression);
```

This statement evaluates the expression and verifies that it's a string expression. Then it copies the string data to the output file. Like the #ASM/#ENDASM statement, the #EMIT statement does not check the syntax of the MASM statement it writes to the assembly file. If there is a syntax error, MASM will catch it later on when HLA assembles the output file.

When HLA compiles your programs into assembly language, it does not use the same symbols in the assembly language output file that you use in the HLA source files. There are several technical reasons for this, but the bottom line is this: you cannot easily reference your HLA identifiers in your in-line assembly code. The only exception to this rule are external identifiers. HLA external identifiers use the same name in the MASM file as in the HLA source file. Therefore, you can refer to external objects within your in-line assembly sequences or in the strings you output via #EMIT.

One advantage of the #EMIT statement is that it lets you construct MASM statements under (compile-time) program control. You can write an HLA compile-time program that generates a sequence of strings and emits them to the MASM file via the #EMIT statement. The compile-time program has access to the HLA symbol table; this means that you can extract the identifiers that HLA emits to the assembly file and use these directly, even if they aren't external objects.

The @StaticName compile-time function returns the name that HLA uses to refer to most static objects in your program. The following program demonstrates a simple use of this compile-time function to obtain the MASM name of an HLA procedure:

```
program emitDemo;
#include("stdlib.hhf")

 procedure myProc;
 begin myProc;

 stdout.put("Inside MyProc" nl);

 end myProc;

begin emitDemo;

 ?stmt:string := "call " + @StaticName(myProc);
 #emit(stmt);

end emitDemo;
```

---

---

### Program 12.1 Using the @StaticName Function

---

---

This example creates a string value (*stmt*) that contains something like “call ?741\_myProc” and emits this MASM instruction directly to the source file (“?741\_myProc” is typical of the type of name mangling that HLA does to static names it writes to the output file). If you compile and run this program, it should display “Inside MyProc” and then quit. If you look at the MASM file that HLA emits, you will see that it has given the *myProc* procedure the same name it appends to the CALL instruction<sup>1</sup>.

The @StaticName function is only valid for static symbols. This includes STATIC, READONLY, and STORAGE variables, procedures, and iterators. It does not include VAR objects, constants, macros, class iterators, or methods.

You can access VAR variables by using the [EBP+offset] addressing mode, specifying the offset of the desired local variable. You can use the @offset compile-time function to obtain the offset of a VAR object or a parameter. The following program demonstrates how to do this:

---

---

```

program offsetDemo;
#include("stdlib.hhf")

var
 i:int32;

begin offsetDemo;

 mov(-255, i);
 ?stmt := "mov eax, [ebp+(" + string(@offset(i)) + ")]";
 #print("Emitting '", stmt, "'");
 #emit(stmt);
 stdout.put("eax = ", (type int32 eax), nl);

end offsetDemo;

```

---

---

### Program 12.2 Using the @Offset Compile-Time Function

---

---

This example emits the statement “mov eax, [ebp+(-8)]” to the assembly language source file. It turns out that -8 is the offset of the *i* variable in the offsetDemo program’s activation record.

Of course, the examples of #EMIT up to this point have been somewhat ridiculous since you can achieve the same results by using HLA statements. One very useful purpose for the #emit statement, however, is to create some instructions that HLA does not support. For example, as of this writing HLA does not support the LES instruction because you can’t really use it under Win32. However, if you found a need for this instruction, you could easily write a macro to emit this instruction and appropriate operands to the MASM source file. Using the #EMIT statement gives you the ability to reference HLA objects, something you cannot do with the #ASM.#ENDASM sequence.

---

1. HLA may assign a different name than “?741\_myProc” when you compile the program. The exact symbol HLA chooses varies from version to version of the assembler (it depends on the number of symbols defined prior to the definition of *myProc*). In this example, there were 741 static symbols defined in the HLA Standard Library before the definition of *myProc*.

## 12.2.2 Linking MASM-Assembled Modules with HLA Modules

Although you can do some interesting things with HLA's in-line assembly statements, you'll probably never use them. Further, future versions of HLA may not even support these statements, so you should avoid them as much as possible even if you see a need for them. Of course, HLA does most of the stuff you'd want to do with the #ASM/#ENDASM and #EMIT statements anyway, so there is very little reason to use them at all. If you're going to combine MASM (or other assembler) code and HLA code together in a program, most of the time this will occur because you've got a module or library routine written in some other assembly language and you would like to take advantage of that code in your HLA programs. Rather than convert the other assembler's code to HLA, the easy solution is to simply compile that other code to an OBJ file and link it with your HLA programs.

Once you've compiled or assembled a source file to an OBJ file, the routines in that module are callable from almost any machine code that can handle the routines' calling sequences. If you have an OBJ file that contains a SQRT function, for example, it doesn't matter whether you compiled that function with HLA, MASM, TASM, NASM, Gas, or even a high level language; if it's object code and it exports the proper symbols, you can call it from your HLA program.

Compiling a module in MASM and linking that with your HLA program is little different than linking other HLA modules with your main HLA program. In the MASM source file you will have to export some symbols (using the PUBLIC directive) and in your HLA program you've got to tell HLA that those symbols appear in a separate module (using the EXTERNAL option).

Since the two modules are written in assembly language, there is very little language imposed structure on the calling sequence and parameter passing mechanisms. If you're calling a function written in MASM from your HLA program, then all you've got to do is to make sure that your HLA program passes parameters in the same locations where the MASM function is expecting them.

About the only issue you've got to deal with is the case of identifiers in the two programs. By default, MASM is case insensitive. HLA, on the other hand, enforces case neutrality (which, essentially, means that it is case sensitive). Fortunately, there is a MASM command line option ("/Cp") that tells MASM to preserve case in all public symbols. It's a real good idea to use this option when assembling modules you're going to link with HLA so that MASM doesn't mess with the case of your identifiers during assembly.

Of course, once MASM starts processing symbols in a case sensitive manner, it's possible to create two separate identifiers that are the same except for alphabetic case. HLA enforces case neutrality so it won't let you (directly) create two different identifiers that differ only in case. In general, this is such a bad programming practice that one would hope you never encounter it (and God forbid you actually do this yourself). However, if you inherit some MASM code written by a C hacker, it's quite possible the code uses this technique. The way around this problem is to use two separate identifiers in your HLA program and use the extended form of the EXTERNAL directive to provide the external names. For example, suppose that in MASM you have the following declarations:

```

 public AVariable
 public avariable
 .
 .
 .
 .data
AVariable dword ?
avariable byte ?

```

If you assemble this code with the "/Cp" or "/Cx" (total case sensitivity) command line options, MASM will emit these two external symbols for use by other modules. Of course, were you to attempt to define variables by these two names in an HLA program, HLA would complain about a duplicate symbol definition. However, you can connect two different HLA variables to these two identifiers using code like the following:

```

static
 AVariable: dword; external("AVariable");
 AnotherVar: byte; external("avariable");

```

HLA does not check the strings you supply as parameters to the EXTERNAL clause. Therefore, you can supply two names that are the same except for case and HLA will not complain. Note that when HLA calls MASM to assemble its output file, HLA specifies the "/Cp" option that tells MASM to preserve case in public and global symbols.

The following program demonstrates how to call a MASM subroutine from an HLA main program:

---

---

```
// To compile this module and the attendant MASM file, use the following
// command line:
//
// hla masmdemo1.hla masmupper.asm
//
// Sorry about no make file for this code, but these two files are in
// the HLA Vol4/Ch12 subdirectory that has its own makefile for building
// all the source files in the directory and I wanted to avoid confusion.

program MasmDemo1;
#include("stdlib.hhf")

 // The following external declaration defines a function that
 // is written in MASM to convert the character in AL from
 // lower case to upper case.

 procedure masmUpperCase(c:char in al); external("masmUpperCase");

static
 s: string := "Hello World!";

begin MasmDemo1;

 stdout.put("String converted to uppercase: ``");
 mov(s, edi);
 while(mov([edi], al) <> #0) do

 masmUpperCase(al);
 stdout.putc(al);
 inc(edi);

 endwhile;
 stdout.put(``" nl);

end MasmDemo1;
```

---

---

### Program 12.3 Main HLA Program to Link with a MASM Program

---

---

```
; MASM source file to accompany the MasmDemo1.HLA source
; file. This code compiles to an object module that
; gets linked with an HLA main program. The function
; below converts the character in AL to upper case if it
; is a lower case character.
```

```

.586
.model flat, pascal

.code
public masmUpperCase
masmUpperCase proc near32
.if al >= 'a' && al <= 'z'
and al, 5fh
.endif
ret
masmUpperCase endp
end

```

---

---

#### Program 12.4 Calling a MASM Procedure from an HLA Program: MASM Module

---

---

It is also possible to call an HLA procedure from a MASM program (this should be obvious since HLA compiles its source code to a MASM source file and that MASM source file can call HLA procedures such as those found in the HLA Standard Library). There are a few restrictions when calling HLA code from some other language. First of all, you can't easily use HLA's exception handling facilities in the modules you call from other languages (including MASM). The HLA main program initializes the exception handling system; this initialization is probably not done by your MASM programs. Further, the HLA main program exports a couple of important symbols needed by the exception handling subsystem; again, it's unlikely your main MASM program provides these public symbols. In the Volume on Advanced Procedures this text will discuss how to deal with Window's Structured Exception Handling subsystem and HLA's layer on top of this. However, that topic is a little too advanced for this chapter. Until you get to the point you can write code in MASM to properly set up the HLA exception handling system, you should not execute any code that uses the TRY..ENDTRY, RAISE, or any other exception handling statements.

**Warning:** a large percentage of the HLA Standard Library routines include exception handling statements or call other routines that use exception handling statements. Unless you've set up the HLA exception handling subsystem properly, you should not call any HLA Standard Library routines from non-HLA programs.

Other than the issue of exception handling, calling HLA procedures from MASM code is really easy. All you've got to do is put an EXTERNAL prototype in the HLA code to make the symbol you wish to access public and then include an EXTERN (or EXTERNDEF) statement in the MASM source file to provide the linkage. Then just compile the two source files and link them together.

About the only issue you need concern yourself with when calling HLA procedures from MASM is the parameter passing mechanism. Of course, if you pass all your parameters in registers (the best place), then communication between the two languages is trivial. Just load the registers with the appropriate parameters in your MASM code and call the HLA procedure. Inside the HLA procedure, the parameter values will be sitting in the appropriate registers (sort of the converse of what happened in Program 12.4).

If you decide to pass parameters on the stack, note that HLA uses the PASCAL language calling model. Therefore, you push parameters on the stack in the order they appear in a parameter list (from left to right) and it is the called procedure's responsibility to remove the parameters from the stack. Note that you can specify the PASCAL calling convention for use with MASM's INVOKE statement using the ".model" directive, e.g.,

```

.586
.model flat, pascal
.
.
.

```

Of course, if you manually push the parameters on the stack yourself, then the specific language model doesn't really matter.

This section is not going to attempt to go into gory details about MASM syntax. There is an appendix in this text that contrasts the HLA language with MASM; you should be able to get a rough idea of MASM syntax from that appendix if you're completely unfamiliar with MASM. Another alternative is to read a copy of the DOS/16-bit edition of this text that uses the MASM assembler. That text describes MASM syntax in much greater detail, albeit from a 16-bit perspective. Finally, this section isn't going to go into any further detail because, quite frankly, the need to call MASM code from HLA (or vice versa) just isn't that great. After all, most of the stuff you can do with MASM can be done directly in HLA so there really is little need to spend much more time on this subject. Better to move on to more important questions, like how do you call HLA routines from C or Pascal...

---

## 12.3 Programming in Delphi and HLA

Delphi is a marvelous language for writing Win32 GUI-based applications. Its support for Rapid Application Design (RAD) and visual programming is superior to almost every other Win32 programming approach available. However, being Pascal-based, there are some things that just cannot be done in Delphi and many things that cannot be done as efficiently in Delphi as in assembly language. Fortunately, Delphi lets you call assembly language procedures and functions so you can overcome Delphi's limitations.

Delphi provides two ways to use assembly language in the Pascal code: via a built-in assembler (BASM) or by linking in separately compiled assembly language modules. The built-in "Borland Assembler" (BASM) is a very weak Intel-syntax assembler. It is suitable for injecting a few instructions into your Pascal source code or perhaps writing a very short assembly language function or procedure. It is not suitable for serious assembly language programming. If you know Intel syntax and you only need to execute a few machine instructions, then BASM is perfect. However, since this is a text on assembly language programming, the assumption here is that you want to write some serious assembly code to link with your Pascal/Delphi code. To do that, you will need to write the assembly code and compile it with a different assembler (e.g., HLA) and link the code into your Delphi application. That is the approach this section will concentrate on. For more information about BASM, check out the Delphi documentation.

Before we get started discussing how to write HLA modules for your Delphi programs, you must understand two very important facts:

HLA's exception handling facilities are not directly compatible with Delphi's. This means that you cannot use the TRY..ENDTRY and RAISE statements in the HLA code you intend to link to a Delphi program. This also means that you cannot call library functions that contain such statements. Since the HLA Standard Library modules use exception handling statements all over the place, this effectively prevents you from calling HLA Standard Library routines from the code you intend to link with Delphi<sup>2</sup>.

Although you can write console applications with Delphi, 99% of Delphi applications are Windows/GUI applications. You cannot call console-related functions (e.g., stdin.xxxx or stdout.xxxx) from a GUI application. Even if HLA's console and standard input/output routines didn't use exception handling, you wouldn't be able to call them from a standard Delphi application.

Given the rich set of language features that Delphi supports, it should come as no surprise that the interface between Delphi's Object Pascal language and assembly language is somewhat complex. Fortunately there are two facts that reduce this problem. First, HLA uses many of the same calling conventions as Pascal; so much of the complexity is hidden from sight by HLA. Second, the other complex stuff you won't use very often, so you may not have to bother with it.

**Note:** the following sections assume you are already familiar with Delphi programming. They make no attempt to explain Delphi syntax or features other than as needed to explain the Delphi assembly language interface. If you're not familiar with Delphi, you will probably want to skip this section.

---

2. Note that the HLA Standard Library source code is available; feel free to modify the routines you want to use and remove any exception handling statements contained therein.

### 12.3.1 Linking HLA Modules With Delphi Programs

The basic unit of interface between a Delphi program and assembly code is the procedure or function. That is, to combine code between the two languages you will write procedures in HLA (that correspond to procedures or functions in Delphi) and call these procedures from the Delphi program. Of course, there are a few mechanical details you've got to worry about, this section will cover those.

To begin with, when writing HLA code to link with a Delphi program you've got to place your HLA code in an HLA UNIT. An HLA PROGRAM module contains start up code and other information that Windows uses to determine where to begin program execution when it loads an EXE file from disk. However, the Delphi program also supplies this information and specifying two starting addresses confuses the linker, therefore, you must place all your HLA code in a UNIT rather than a PROGRAM module.

Within the HLA UNIT you must create EXTERNAL procedure prototypes for each procedure you wish to call from Delphi. If you prefer, you can put these prototype declarations in a header file and #INCLUDE them in the HLA code, but since you'll probably only reference these declarations from this single file, it's okay to put the EXTERNAL prototype declarations directly in the HLA UNIT module. These EXTERNAL prototype declarations tell HLA that the associated functions will be public so that Delphi can access their names during the link process. Here's a typical example:

```
unit LinkWithDelphi;

 procedure prototype; external;

 procedure prototype;
 begin prototype;

 << Code to implement prototype's functionality >>

 end prototype;

end LinkWithDelphi;
```

After creating the module above, you'd compile it using HLA's "-s" (compile to assembly only) command line option. This will produce an ASM file. Were this just about any other language, you'd then assemble the ASM file with MASM. Unfortunately, Delphi doesn't like OBJ files that MASM produces. For all but the most trivial of assembly modules, Delphi will reject the MASM's output. Borland Delphi expects external assembly modules to be written with Borland's assembler, TASM32.EXE (the 32-bit Turbo Assembler). Fortunately, as of HLA v1.26, HLA provides an option to produce TASM output that is compatible with TASM v5.3 and later. Unfortunately, Borland doesn't really sell TASM anymore; the only way to get a copy of TASM v5.3 is to obtain a copy of Borland's C++ Builder Professional system which includes TASM32 v5.3. If you don't own Borland C++ and really have no interest in using C++ Builder, Borland has produced an evaluation disk for C++ Builder that includes TASM 5.3. Note that earlier versions of TASM32 (e.g., v5.0) do not support MMX and various Pentium-only instructions, you really need TASM v5.3 if you want to use the MASM output.

Here are all the commands to compile and assemble the module given earlier:

```
hla -c -tasm -omf LinkWithDelphi.hla
```

Of course, if you don't like typing this long command to compile and assemble your HLA code, you can always create a make file or a batch file that will let you do both operations with a single command. See the chapter on Managing Large Programs for more details (see "Make Files" on page 557).

Once you've created the HLA code and compiled it to an OBJ file, the next step is to tell Delphi that it needs to call the HLA/assembly code. There are two steps needed to achieve this: You've got to inform Delphi that a procedure (or function) is written in assembly language (rather than Pascal) and you've got to tell Delphi to link in the OBJ file you've created when compiling the Delphi code.

The second step above, telling Delphi to include the HLA object module, is the easiest task to achieve. All you've got to do is insert a compiler directive of the form "{ \$L *objectFileName.obj* }" in the Delphi pro-

gram before declaring and calling your object module. A good place to put this is after the **implementation** reserved word in the module that calls your assembly procedure. The code examples a little later in this section will demonstrate this.

The next step is to tell Delphi that you're supplying an external procedure or function. This is done using the Delphi `EXTERNAL` directive on a procedure or function prototype. For example, a typical external declaration for the *prototype* procedure appearing earlier is

```
procedure prototype; external; // This may look like HLA code, but it's
 // really Delphi code!
```

As you can see here, Delphi's syntax for declaring external procedures is nearly identical to HLA's (in fact, in this particular example the syntax is identical). This is not an accident, much of HLA's syntax was borrowed directly from Pascal.

The next step is to call the assembly procedure from the Delphi code. This is easily accomplished using standard Pascal procedure calling syntax. The following two listings provide a complete, working, example of an HLA procedure that a Delphi program can call. This program doesn't accomplish very much other than to demonstrate how to link in an assembly procedure. The Delphi program contains a form with a single button on it. Pushing the button calls the HLA procedure, whose body is empty and therefore returns immediately to the Delphi code without any visible indication that it was ever called. Nevertheless, this code does provide all the syntactical elements necessary to create and call an assembly language routine from a Delphi program.

```
unit LinkWithDelphi;

 procedure CalledFromDelphi; external;

 procedure CalledFromDelphi;
 begin CalledFromDelphi;
 end CalledFromDelphi;

end LinkWithDelphi;
```

### Program 12.5 CalledFromDelphi.HLA Module Containing the Assembly Code

```
unit DelphiEx1;

interface

uses
 Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
 StdCtrls;

type
 TDelphiEx1Form = class(TForm)
 Button1: TButton;
 procedure Button1Click(Sender: TObject);
 private
 { Private declarations }
 public
 { Public declarations }
 end;
```

```

var
 DelphiEx1Form: TDelphiEx1Form;

implementation

{$R *.DFM}
{$L CalledFromDelphi.obj }

procedure CalledFromDelphi; external;

procedure TDelphiEx1Form.Button1Click(Sender: TObject);
begin
 CalledFromDelphi();
end;

end.

```

---

---

### Program 12.6 DelphiEx1– Delphi Source Code that Calls an Assembly Procedure

---

---

The full Delphi and HLA source code for the programs appearing in Program 12.5 and Program 12.6 accompanies the HLA software distribution in the appropriate subdirectory for this chapter in the Example code module. If you've got a copy of Delphi 5 or later, you might want to load this module and try compiling it. To compile the HLA code for this example, you would use the following commands from the command prompt:

```
hla -tasm -c -omf CalledFromDelphi.hla
```

After producing the CalledFromDelphi object module with the two commands above, you'd enter the Delphi Integrated Development Environment and tell it to compile the DelphiEx1 code (i.e., you'd load the DelphiEx1Project file into Delphi and compile the code). This process automatically links in the HLA code and when you run the program you can call the assembly code by simply pressing the single button on the Delphi form.

---

## 12.3.2 Register Preservation

Delphi code expects all procedures to preserve the EBX, ESI, EDI, and EBP registers. Routines written in assembly language may freely modify the contents of EAX, ECX, and EDX without preserving their values. The HLA code will have to modify the ESP register to remove the activation record (and, possibly, some parameters). Of course, HLA procedures (unless you specify the NOFRAME option) automatically preserve and set up EBP for you, so you don't have to worry about preserving this register's value; of course, you will not usually manipulate EBP's value since it points at your procedure's parameters and local variables.

Although you can modify EAX, ECX, and EDX to your heart's content and not have to worry about preserving their values, don't get the idea that these registers are available for your procedure's exclusive use. In particular, Delphi may pass parameters into a procedure within these registers and you may need to return function results in some of these registers. Details on the further use of these registers appears in later sections of this chapter.

Whenever Delphi calls a procedure, that procedure can assume that the direction flag is clear. On return, all procedures must ensure that the direction flag is still clear. So if you manipulate the direction flag in your assembly code (or call a routine that might set the direction flag), be sure to clear the direction flag before returning to the Delphi code.

If you use any MMX instructions within your assembly code, be sure to execute the EMMS instruction before returning. Delphi code assumes that it can manipulate the floating point stack without running into problems.

Although the Delphi documentation doesn't explicitly state this, experiments with Delphi code seem to suggest that you don't have to preserve the FPU (or MMX) registers across a procedure call other than to ensure that you're in FPU mode (versus MMX mode) upon return to Delphi.

### 12.3.3 Function Results

Delphi generally expects functions to return their results in a register. For ordinal return results, a function should return a byte value in AL, a word value in AX, or a double word value in EAX. Functions return pointer values in EAX. Functions return real values in ST0 on the FPU stack. The code example in this section demonstrates each of these parameter return locations.

For other return types (e.g., arrays, sets, records, etc.), Delphi generally passes an extra VAR parameter containing the address of the location where the function should store the return result. We will not consider such return results in this text, see the Delphi documentation for more details.

The following Delphi/HLA program demonstrates how to return different types of scalar (ordinal and real) parameters to a Delphi program from an assembly language function. The HLA functions return boolean (one byte) results, word results, double word results, a pointer (PChar) result, and a floating point result when you press an appropriate button on the form. See the DelphiEx2 example code in the HLA/Art of Assembly examples code for the full project. Note that the following code doesn't really do anything useful other than demonstrate how to return Function results in EAX and ST0.

```

unit DelphiEx2;

interface

uses
 Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
 StdCtrls;

type
 TDelphiEx2Form = class(TForm)

 fld(realData);
 ret();

end ReturnReal;

end ReturnRealUnit;

```

---

### Program 12.12 ReturnReal: Demonstrates Returning a Real Value in ST0

---

The second thing to note is the `#code`, `#static`, etc., directives at the beginning of each file to change the segment name declarations. You'll learn the reason for these segment renaming directives a little later in this chapter.

---

## 12.3.4 Calling Conventions

Delphi supports five different calling mechanisms for procedures and functions: **register**, **pascal**, **cdecl**, **stdcall**, and **safecall**. The **register** and **pascal** calling methods are very similar except that the **pascal** parameter passing scheme always passes all parameters on the stack while the **register** calling mechanism passes the first three parameters in CPU registers. We'll return to these two mechanisms shortly since they are the primary mechanisms we'll use. The **cdecl** calling convention uses the C/C++ programming language calling convention. We'll study this scheme more in the section on interfacing C/C++ with HLA. There is no need to use this scheme when calling HLA procedures from Delphi. If you must use this scheme, then see the section on the C/C++ languages for details. The **stdcall** convention is used to call Windows API functions. Again, there really is no need to use this calling convention, so we will ignore it here. See the Delphi documentation for more details. **Safecall** is another specialized calling convention that we will not use. See, we've already reduced the complexity from five mechanisms to two! Seriously, though, when calling assembly language routines from Delphi code that you're writing, you only need to use the **pascal** and **register** conventions.

The calling convention options specify how Delphi passes parameters between procedures and functions as well as who is responsible for cleaning up the parameters when a function or procedure returns to its caller. The **pascal** calling convention passes all parameters on the stack and makes it the procedure or function's responsibility to remove those parameters from the stack. The pascal calling convention mandates that the caller push parameters in the order the compiler encounters them in the parameter list (i.e., left to right). This is exactly the calling convention that HLA uses (assuming you don't use the "IN register" parameter option). Here's an example of a Delphi external procedure declaration that uses the **pascal** calling convention:

```
procedure UsesPascal(parm1:integer; parm2:integer; parm3:integer);
```

The following program provides a quick example of a Delphi program that calls an HLA procedure (function) using the **pascal** calling convention.

---

```

unit DelphiEx3;

interface

uses
 Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,

```

```

 StdCtrls;

type
 TForm1 = class(TForm)
 callUsesPascalBtn: TButton;
 UsesPascalLabel: TLabel;
 procedure callUsesPascalBtnClick(Sender: TObject);
 private
 { Private declarations }
 public
 { Public declarations }
 end;

var
 Form1: TForm1;

implementation

{$R *.DFM}
{$L usespascal.obj}

function UsesPascal
(
 parm1:integer;
 parm2:integer;
 parm3:integer
):integer; pascal; external;

procedure TForm1.callUsesPascalBtnClick(Sender: TObject);
var
 i: integer;
 strVal: string;
begin

 i := UsesPascal(5, 6, 7);
 str(i, strVal);
 UsesPascalLabel.caption := 'Uses Pascal = ' + strVal;

end;

end.

```

---

---

### Program 12.13 DelphiEx3 – Sample Program that Demonstrates the **pascal** Calling Convention

---

---

```

// UsesPascalUnit-
//
// Provides the UsesPascal function for the DelphiEx3 program.

unit UsesPascalUnit;

// Tell HLA that UsesPascal is a public symbol:

procedure UsesPascal(parm1:int32; parm2:int32; parm3:int32); external;

// Demonstration of a function that uses the PASCAL calling convention.

```

```

// This function simply computes parm1+parm2-parm3 and returns the
// result in EAX. Note that this function does not have the
// "NOFRAME" option because it needs to build the activation record
// (stack frame) in order to access the parameters. Furthermore, this
// code must clean up the parameters upon return (another chore handled
// automatically by HLA if the "NOFRAME" option is not present).

procedure UsesPascal(parm1:int32; parm2:int32; parm3:int32);
 nodisplay; noalignstk;

begin UsesPascal;

 mov(parm1, eax);
 add(parm2, eax);
 sub(parm3, eax);

end UsesPascal;

end UsesPascalUnit;

```

---

### Program 12.14 UsesPascal – HLA Function the Previous Delphi Code Will Call

---

To compile the HLA code, you would use the following two commands in a command window:

```
hla -c -tasm -omf UsesPascal.hla
```

Once you produce the OBJ file with the above two commands, you can get into Delphi and compile the Pascal code.

The **register** calling convention also processes parameters from left to right and requires the procedure/function to clean up the parameters upon return; the difference is that procedures and functions that use the **register** calling convention will pass their first three (ordinal) parameters in the EAX, EDX, and ECX registers (in that order) rather than on the stack. You can use HLA's "IN *register*" syntax to specify that you want the first three parameters passed in this registers, e.g.,

```

procedure UsesRegisters
(
 parm1:int32 in EAX;
 parm2:int32 in EDX;
 parm3:int32 in ECX
);

```

If your procedure had four or more parameters, you would not specify registers as their locations. Instead, you'd access those parameters on the stack. Since most procedures have three or fewer parameters, the **register** calling convention will typically pass all of a procedure's parameters in a register.

Although you can use the **register** keyword just like **pascal** to force the use of the **register** calling convention, the register calling convention is the default mechanism in Delphi. Therefore, a Delphi declaration like the following will automatically use the **register** calling convention:

```

procedure UsesRegisters
(
 parm1:integer;
 parm2:integer;
 parm3:integer
); external;

```

The following program is a modification of the previous program in this section that uses the **register** calling convention rather than the **pascal** calling convention.

---

---

```

unit DelphiEx4;

interface

uses
 Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
 StdCtrls;

type
 TForm1 = class(TForm)
 callUsesRegisterBtn: TButton;
 UsesRegisterLabel: TLabel;
 procedure callUsesRegisterBtnClick(Sender: TObject);
 private
 { Private declarations }
 public
 { Public declarations }
 end;

var
 Form1: TForm1;

implementation

{$R *.DFM}
{$L usesregister.obj}

function UsesRegister
(
 parm1:integer;
 parm2:integer;
 parm3:integer;
 parm4:integer
):integer; external;

procedure TForm1.callUsesRegisterBtnClick(Sender: TObject);
var
 i: integer;
 strVal: string;
begin
 i := UsesRegister(5, 6, 7, 3);
 str(i, strVal);
 UsesRegisterLabel.caption := 'Uses Register = ' + strVal;

end;

end.

```

---

---

### Program 12.15 DelphiEx4 – Using the **register** Calling Convention

---

---

```

// UsesRegisterUnit-
//

```

```

// Provides the UsesRegister function for the DelphiEx4 program.

unit UsesRegisterUnit;

// Tell HLA that UsesRegister is a public symbol:

procedure UsesRegister
(
 parm1:int32 in eax;
 parm2:int32 in edx;
 parm3:int32 in ecx;
 parm4:int32
); external;

// Demonstration of a function that uses the REGISTER calling convention.
// This function simply computes (parm1+parm2-parm3)*parm4 and returns the
// result in EAX. Note that this function does not have the
// "NOFRAME" option because it needs to build the activation record
// (stack frame) in order to access the fourth parameter. Furthermore, this
// code must clean up the fourth parameter upon return (another chore handled
// automatically by HLA if the "NOFRAME" option is not present).

procedure UsesRegister
(
 parm1:int32 in eax;
 parm2:int32 in edx;
 parm3:int32 in ecx;
 parm4:int32
); nodisplay; noalignstk;

begin UsesRegister;

 mov(parm1, eax);
 add(parm2, eax);
 sub(parm3, eax);
 intmul(parm4, eax);

end UsesRegister;

end UsesRegisterUnit;

```

---

### Program 12.16 HLA Code to support the DelphiEx4 Program

---

To compile the HLA code, you would use the following two commands in a command window:

```
hla -tasm -c -omf UsesRegister.hla
```

Once you produce the OBJ file with the above command, you can get into Delphi and compile the Pascal code.

---

## 12.3.5 Pass by Value, Reference, CONST, and OUT in Delphi

A Delphi program can pass parameters to a procedure or function using one of four different mechanisms: pass by value, pass by reference, CONST parameters, and OUT parameters. The examples up to this point in this chapter have all used Delphi's (and HLA's) default pass by value mechanism. In this section we'll look at the other parameter passing mechanisms.

HLA and Delphi also share a (mostly) common syntax for pass by reference parameters. The following two lines provide an external declaration in Delphi and the corresponding external (public) declaration in HLA for a pass by reference parameter using the **pascal** calling convention:

```
procedure HasRefParm(var refparm: integer); pascal; external; // Delphi
procedure HasRefParm(var refparm: int32); external; // HLA
```

Like HLA, Delphi will pass the 32-bit address of whatever actual parameter you specify when calling the *HasRefParm* procedure. Don't forget, inside the HLA code, that you must dereference this pointer to access the actual parameter data. See the chapter on Intermediate Procedures for more details (see "Pass by Reference" on page 793).

The CONST and OUT parameter passing mechanisms are virtually identical to pass by reference. Like pass by reference these two schemes pass a 32-bit address of their actual parameter. The difference is that the called procedure is not supposed to write to CONST objects since they're, presumably, constant. Conversely, the called procedure is supposed to write to an OUT parameter (and not assume that it contains any initial value of consequence) since the whole purpose of an OUT parameter is to return data from a procedure or function. Other than the fact that the Delphi compiler will check procedures and functions (written in Delphi) for compliance with this rules, there is no difference between CONST, OUT, and reference parameters. Delphi passes all such parameters by reference to the procedure or function. Note that in HLA you would declare all CONST and OUT parameters as pass by reference parameters. HLA does not enforce the readonly attribute of the CONST object nor does it check for an attempt to access an uninitialized OUT parameter; those checks are the responsibility of the assembly language programmer.

As you learned in the previous section, by default Delphi uses the **register** calling convention. If you pass one of the first three parameters by reference to a procedure or function, Delphi will pass the address of that parameter in the EAX, EDX, or ECX register. This is very convenient as you can immediately apply the register indirect addressing mode without first loading the parameter into a 32-bit register.

Like HLA, Delphi lets you pass untyped parameters by reference (or by CONST or OUT). The syntax to achieve this in Delphi is the following:

```
procedure UntypedRefParm(var parm1; const parm2; out parm3); external;
```

Note that you do not supply a type specification to these parameters. Delphi will compute the 32-bit address of these objects and pass them on to the *UntypedRefParm* procedure without any further type checking. In HLA, you can use the VAR keyword as the data type to specify that you want an untyped reference parameter. Here's the corresponding prototype for the *UntypedRefParm* procedure in HLA:

```
procedure UntypedRefParm(var parm1:var; var parm2:var; var parm3:var);
external;
```

As noted above, you use the VAR keyword (pass by reference) when passing CONST and OUT parameters. Inside the HLA procedure it's your responsibility to use these pointers in a manner that is reasonable given the expectations of the Delphi code.

---

### 12.3.6 Scalar Data Type Correspondence Between Delphi and HLA

When passing parameters between Delphi and HLA procedures and functions, it's very important that the calling code and the called code agree on the basic data types for the parameters. In this section we will draw a correspondence between the Delphi (v5.0) scalar data types and the HLA (v1.x) data types<sup>3</sup>.

Assembly language supports any possible data format, so HLA's data type capabilities will always be a superset of Delphi's. Therefore, there may be some objects you can create in HLA that have no counterpart in Delphi, but the reverse is not true. Since the assembly functions and procedures you write are generally manipulating data that Delphi provides, you don't have to worry too much about not being able to process some data passed to an HLA procedure by Delphi<sup>4</sup>.

---

3. Scalar data types are the ordinal, pointer, and real types. It does not include strings or other composite data types.

Delphi 5.0 provides a wide range of different integer data types. The following table lists the Delphi types and the HLA equivalents:

**Table 1: Delphi and HLA Integer Types**

| Delphi         | HLA Equivalent     | Range               |                      |
|----------------|--------------------|---------------------|----------------------|
|                |                    | Minimum             | Maximum              |
| integer        | int32 <sup>a</sup> | -2147483648         | 2147483647           |
| cardinal       | uns32 <sup>b</sup> | 0                   | 4294967295           |
| shortint       | int8               | -128                | 127                  |
| smallint       | int16              | -32768              | 32767                |
| longint        | int32              | -2147483648         | 2147483647           |
| int64          | qword              | -2 <sup>63</sup>    | (2 <sup>63</sup> -1) |
| byte           | uns8               | 0                   | 255                  |
| word           | uns16              | 0                   | 65535                |
| longword       | uns32              | 0                   | 4294967295           |
| subrange types | Depends on range   | minimum range value | maximum range value  |

a. Int32 is the implementation of integer in Delphi 5. This may change in later releases.

b. Uns32 is the implementation of cardinal in Delphi 5. This may change in later releases.

In addition to the integer values, Delphi supports several non-integer ordinal types. The following table provides their HLA equivalents:

**Table 2: Non-integer Ordinal Types in Delphi and HLA**

| Delphi   | HLA     | Range      |                               |
|----------|---------|------------|-------------------------------|
|          |         | Minimum    | Maximum                       |
| char     | char    | #0         | #255                          |
| widechar | word    | chr( 0 )   | chr( 65535 )                  |
| boolean  | boolean | false (0)  | true( 1 )                     |
| bytebool | byte    | 0( false ) | 255 (non-zero is true)        |
| wordbool | word    | 0 (false ) | 65535 (non-zero is true)      |
| longbool | dword   | 0 (false)  | 4294967295 (non-zero is true) |

4. Delphi string objects are an exception. For reasons that have nothing to do with data representation, you should not manipulate string parameters passed in from Delphi to an HLA routine. This section will explain the problems more fully a little later.

**Table 2: Non-integer Ordinal Types in Delphi and HLA**

| Delphi           | HLA                 | Range   |                                                                                            |
|------------------|---------------------|---------|--------------------------------------------------------------------------------------------|
|                  |                     | Minimum | Maximum                                                                                    |
| enumerated types | enum, byte, or word | 0       | Depends on number of items in the enumeration list. Usually the upper limit is 256 symbols |

Like the integer types, Delphi supports a wide range of real numeric formats. The following table presents these types and their HLA equivalents.

**Table 3: Real Types in Delphi and HLA**

| Delphi              | HLA     | Range                 |                      |
|---------------------|---------|-----------------------|----------------------|
|                     |         | Minimum               | Maximum              |
| real                | real64  | 5.0 E-324             | 1.7 E+308            |
| single              | real32  | 1.5 E-45              | 3.4 E+38             |
| double              | real64  | 5.0 E-324             | 1.7 E+308            |
| extended            | real80  | 3.6 E-4951            | 1.1 E+4932           |
| comp                | real80  | $-2^{63}+1$           | $2^{63}-1$           |
| currency            | real80  | -922337203685477.5808 | 922337203685477.5807 |
| real48 <sup>a</sup> | byte[6] | 2.9 E-39              | 1.7 E+38             |

a. real48 is an obsolete type that depends upon a software floating point library. You should never use this type in assembly code. If you do, you are responsible for writing the necessary floating point sub-routines to manipulate the data.

The last scalar type of interest is the pointer type. Both HLA and Delphi use a 32-bit address to represent pointers, so these data types are completely equivalent in both languages.

---

### 12.3.7 Passing String Data Between Delphi and HLA Code

Delphi supports a couple of different string formats. The native string format is actually very similar to HLA's string format. A string object is a pointer that points at a zero terminated sequence of characters. In the four bytes preceding the first character of the string, Delphi stores the current dynamic length of the string (just like HLA). In the four bytes before the length, Delphi stores a reference count (unlike HLA, which stores a maximum length value in this location). Delphi uses the reference count to keep track of how many different pointers contain the address of this particular string object. Delphi will automatically free the storage associated with a string object when the reference count drops to zero (this is known as garbage collection).

The Delphi string format is just close enough to HLA's to tempt you to use some HLA string functions in the HLA Standard Library. This will fail for two reasons: (1) many of the HLA Standard Library string functions check the maximum length field, so they will not work properly when they access Delphi's refer-

ence count field; (2) HLA Standard Library string functions have a habit of raising string overflow (and other) exceptions if they detect a problem (such as exceeding the maximum string length value). Remember, the HLA exception handling facility is not directly compatible with Delphi's, so you should never call any HLA code that might raise an exception.

Of course, you can always grab the source code to some HLA Standard Library string function and strip out the code that raises exceptions and checks the maximum length field (this is usually the same code that raises exceptions). However, you could still run into problems if you attempt to manipulate some Delphi string. In general, it's okay to read the data from a string parameter that Delphi passes to your assembly code, but you should never change the value of such a string. To understand the problem, consider the following HLA code sequence:

```
static
 s:string := "Hello World";
 sref:string;
 scopy:string;
 .
 .
 .
 str.a_cpy(s, scopy); // scopy has its own copy of "Hello World"

 mov(s, eax); // After this sequence, s and sref point at
 mov(eax, sref); // the same character string in memory.
```

After the code sequence above, any change you would make to the *scopy* string would affect only *scopy* because it has its own copy of the "Hello World" string. On the other hand, if you make any changes to the characters that *s* points at, you'll also be changing the string that *sref* points at because *sref* contains the same pointer value as *s*; in other words, *s* and *sref* are aliases of the same data. Although this aliasing process can lead to the creation of some killer defects in your code, there is a big advantage to using copy by reference rather than copy by value: copy by reference is much quicker since it only involves copying a single four-byte pointer. If you rarely change a string variable after you assign one string to that variable, copy by reference can be very efficient.

Of course, what happens if you use copy by reference to copy *s* to *sref* and then you want to modify the string that *sref* points at without changing the string that *s* points at? One way to do this is to make a copy of the string at the time you want to change *sref* and then modify the copy. This is known as *copy on write semantics*. In the average program, copy on write tends to produce faster running programs because the typical program tends to assign one string to another without modification more often than it assigns a string value and then modifies it later. Of course, the real problem is "how do you know whether multiple string variables are pointing at the same string in memory?" After all, if only one string variable is pointing at the string data, you don't have to make a copy of the data, you can manipulate the string data directly. The *reference counter field* that Delphi attaches to the string data solves this problem. Each time a Delphi program assigns one string variable to another, the Delphi code simply copies a pointer and then increments the reference counter. Similarly, if you assign a string address to some Delphi string variable and that variable was previously pointing at some other string data, Delphi decrements the reference counter field of that previous string value. When the reference count hits zero, Delphi automatically deallocates storage for the string (this is the garbage collection operation).

Note that Delphi strings don't need a maximum length field because Delphi dynamically allocates (standard) strings whenever you create a new string. Hence, string overflow doesn't occur and there is no need to check for string overflow (and, therefore, no need for the maximum length field). For literal string constants (which the compiler allocates statically, not dynamically on the heap), Delphi uses a reference count field of -1 so that the compiler will not attempt to deallocate the static object.

It wouldn't be that hard to take the HLA Standard Library strings module and modify it to use Delphi's dynamically allocated string format. There is, however, one problem with this approach: Borland has not published the internal string format for Delphi strings (the information appearing above is the result of sleuthing through memory with a debugger). They have probably withheld this information because they want the ability to change the internal representation of their string data type without breaking existing Delphi programs. So if you poke around in memory and modify Delphi string data (or allocate or deallocate

these strings on your own), don't be surprised if your program malfunctions when a later version of Delphi appears. By the way, the discussion above is current as of Delphi v5.0. Who knows if this explanation will still apply in Kylix (the Linux version of Delphi), Delphi 6.0, or any later versions.

Like HLA strings, a Delphi string is a pointer that happens to contain the address of the first character of a zero terminated string in memory. As long as you don't modify this pointer, you don't modify any of the characters in that string, and you don't attempt to access any bytes before the first character of the string or after the zero terminating byte, you can safely access the string data in your HLA programs. Just remember that you cannot use any Standard Library routines that check the maximum string length or raise any exceptions. If you need the length of a Delphi string that you pass as a parameter to an HLA procedure, it would be wise to use the Delphi *Length* function to compute the length and pass this value as an additional parameter to your procedure. This will keep your code working should Borland ever decide to change their internal string representation.

Delphi also supports a *ShortString* data type. This data type provides backwards compatibility with older versions of Borland's Turbo Pascal (Borland Object Pascal) product. *ShortString* objects are traditional length-prefixed strings (see "Character Strings" on page 401). A short string variable is a sequence of one to 256 bytes where the first byte contains the current dynamic string length (a value in the range 0..255) and the following *n* bytes hold the actual characters in the string (*n* being the value found in the first byte of the string data). If you need to manipulate the value of a string variable within an assembly language module, you should pass that parameter as a *ShortString* variable (assuming, of course, that you don't need to handle strings longer than 256 characters). For efficiency reasons, you should always pass *ShortString* variables by reference (or CONST or OUT) rather than by value. If you pass a short string by value, Delphi must copy all the characters allocated for that string (even if the current length is shorter) into the procedure's activation record. This can be very slow. If you pass a *ShortString* by reference, then Delphi will only need to pass a pointer to the string's data; this is very efficient.

Note that *ShortString* objects do not have a zero terminating byte following the string data. Therefore, your assembly code should use the length prefix byte to determine the end of the string, it should not search for a zero byte in the string.

If you need the maximum length of a *ShortString* object, you can use the Delphi *high* function to obtain this information and pass it to your HLA code as another parameter. Note that the high function is a compiler intrinsic much like HLA's @size function. Delphi simply replaces this "function" with the equivalent constant at compile-time; this isn't a true function you can call. This maximum size information is not available at run-time (unless you've used the Delphi *high* function) and you cannot compute this information within your HLA code.

### 12.3.8 Passing Record Data Between HLA and Delphi

Records in HLA are (mostly) compatible with Delphi records. Syntactically their declarations are very similar and if you've specified the correct Delphi compiler options you can easily translate a Delphi record to an HLA record. In this section we'll explore how to do this and learn about the incompatibilities that exist between HLA records and Delphi records.

For the most part, translating Delphi records to HLA is a no brainer. The two record declarations are so similar syntactically that conversion is trivial. The only time you really run into a problem in the conversion process is when you encounter case variant records in Delphi; fortunately, these don't occur very often and when they do, HLA's anonymous unions within a record come to the rescue.

Consider the following Pascal record type declaration:

```
type
 recType =
 record

 day: byte;
 month:byte;
 year:integer;
 dayOfWeek:byte;
```

```
end;
```

The translation to an HLA record is, for the most part, very straight-forward. Just translate the field types accordingly and use the HLA record syntax (see “Records” on page 465) and you’re in business. The translation is the following:

```
type
 recType:
 record

 day: byte;
 month: byte;
 year: int32;
 dayOfWeek: byte;

 endrecord;
```

There is one minor problem with this example: data alignment. By default Delphi aligns each field of a record on the size of that object and pads the entire record so its size is an even multiple of the largest (scalar) object in the record. This means that the Delphi declaration above is really equivalent to the following HLA declaration:

```
type
 recType:
 record

 day: byte;
 month: byte;
 padding: byte[2]; // Align year on a four-byte boundary.
 year: int32;
 dayOfWeek: byte;
 morePadding: byte[3]; // Make record an even multiple of four bytes.

 endrecord;
```

Of course, a better solution is to use HLA’s ALIGN directive to automatically align the fields in the record:

```
type
 recType:
 record

 day: byte;
 month: byte;
 align(4); // Align year on a four-byte boundary.
 year: int32;
 dayOfWeek: byte;
 align(4); // Make record an even multiple of four bytes.

 endrecord;
```

Alignment of the fields is good insofar as access to the fields is faster if they are aligned appropriately. However, aligning records in this fashion does consume extra space (five bytes in the examples above) and that can be expensive if you have a large array of records whose fields need padding for alignment.

The alignment parameters for an HLA record should be the following:

**Table 4: Alignment of Record Fields**

| Data Type       | Alignment                                                        |
|-----------------|------------------------------------------------------------------|
| Ordinal Types   | Size of the type: 1, 2, or 4 bytes.                              |
| Real Types      | 2 for real48 and extended, 4 bytes for other real types          |
| ShortString     | 1                                                                |
| Arrays          | Same as the element size                                         |
| Records         | Same as the largest alignment of all the fields.                 |
| Sets            | 1 or two if the set has fewer than 8 or 16 elements, 4 otherwise |
| All other types | 4                                                                |

Another possibility is to tell Delphi not to align the fields in the record. There are two ways to do this: use the **packed** reserved word or use the `{$A-}` compiler directive.

The packed keyword tells Delphi not to add padding to a specific record. For example, you could declare the original Delphi record as follows:

```
type
 recType =
 packed record

 day: byte;
 month:byte;
 year:integer;
 dayOfWeek:byte;

 end;
```

With the **packed** reserved word present, Delphi does not add any padding to the fields in the record. The corresponding HLA code would be the original record declaration above, e.g.,

```
type
 recType:
 record

 day: byte;
 month: byte;
 year:int32;
 dayOfWeek:byte;

 endrecord;
```

The nice thing about the **packed** keyword is that it lets you explicitly state whether you want data alignment/padding in a record. On the other hand, if you've got a lot of records and you don't want field alignment on any of them, you'll probably want to use the `"{$A-}"` (turn data alignment off) option rather than add the **packed** reserved word to each record definition. Note that you can turn data alignment back on with the `"{$A+}"` directive if you want a sequence of records to be packed and the rest of them to be aligned.

While it's far easier (and syntactically safer) to use packed records when passing record data between assembly language and Delphi, you will have to determine on a case-by-case basis whether you're willing to give up the performance gain in exchange for using less memory (and a simpler interface). It is certainly the

case that packed records are easier to maintain in HLA than aligned records (since you don't have to carefully place ALIGN directives throughout the record in the HLA code). Furthermore, on new processors most mis-aligned data accesses aren't particularly expensive. However, if performance really matters you will have to measure the performance of your program and determine the cost of using packed records.

Case variant records in Delphi let you add mutually exclusive fields to a record with an optional tag field. Here are two examples:

```

type
 r1=
 record

 stdField: integer;
 case choice:boolean of
 true:(i:integer);
 false:(r:real);
 end;

 r2=
 record
 s2:real;
 case boolean of // Notice no tag object here.
 true:(s:string);
 false:(c:char);
 end;

```

HLA does not support the case variant syntax, but it does support anonymous unions in a record that let you achieve the same semantics. The two examples above, converted to HLA (assuming "{A-}") are

```

type
 r1:
 record

 stdField: int32;
 choice: boolean; // Notice that the tag field is just another field
 union

 i:int32;
 r:real64;

 endunion;

 endrecord;

 r2:
 record

 s2:real64;
 union

 s: string;
 c: char;

 endunion;

 endrecord;

```

Again, you should insert appropriate ALIGN directives if you're not creating a packed record. Note that you shouldn't place any ALIGN directives inside the anonymous union section; instead, place a single ALIGN directive before the UNION reserved word that specifies the size of the largest (scalar) object in the union as given by the table "Alignment of Record Fields" on page 1146.

In general, if the size of a record exceeds about 16 bytes, you should pass the record by reference rather than by value.

---

### 12.3.9 Passing Set Data Between Delphi and HLA

Sets in Delphi can have between 1 and 256 elements. Delphi implements sets using an array of bits, exactly as HLA implements character sets (see “Character Sets” on page 423). Delphi reserves one to 32 bytes for each set; the size of the set (in bytes) is  $(\text{Number\_of\_elements} + 7) \text{ div } 8$ . Like HLA’s character sets, Delphi uses a set bit to indicate that a particular object is a member of the set and a zero bit indicates absence from the set. You can use the bit test (and set/complement/reset) instructions and all the other bit manipulation operations to manipulate character sets. Furthermore, the MMX instructions might provide a little added performance boost to your set operations (see “The MMX Instruction Set” on page 1083). For more details on the possibilities, consult the Delphi documentation and the chapters on character sets and the MMX instructions in this text.

Generally, sets are sufficiently short (maximum of 32 bytes) that passing the by value isn’t totally horrible. However, you will get slightly better performance if you pass larger sets by reference. Note that HLA often passes character sets by value (16 bytes per set) to various Standard Library routines, so don’t be totally afraid of passing sets by value.

---

### 12.3.10 Passing Array Data Between HLA and Delphi

Passing array data between some procedures written in Delphi and HLA is little different than passing array data between two HLA procedures. Generally, if the arrays are large, you’ll want to pass the arrays by reference rather than value. Other than that, you should declare an appropriate array type in HLA to match the type you’re passing in from Delphi and have at it. The following code fragments provide a simple example:

```
type
 PascalArray = array[0..127, 0..3] of integer;

procedure PassedArray(var ary: PascalArray); external;
```

Corresponding HLA code:

```
type
 PascalArray: int32[128, 4];

procedure PassedArray(var ary: PascalArray); external;
```

As the above examples demonstrate, Delphi’s array declarations specify the starting and ending indices while HLA’s array bounds specify the number of elements for each dimension. Other than this difference, however, you can see that the two declarations are very similar.

Delphi uses row-major ordering for arrays. So if you’re accessing elements of a Delphi multi-dimensional array in HLA code, be sure to use the row-major order computation (see “Row Major Ordering” on page 451).

---

### 12.3.11 Delphi Limitations When Linking with (Non-TASM) Assembly Code

Delphi places a couple of restrictions on OBJ files that it links with the Pascal code. Some of these restrictions appears to be defects in the implementation of the linker, but only Borland can say for sure if these are defects or they are design deficiencies. The bottom line is that Delphi seems to work okay with the OBJ files that TASM produces, but fails miserably with OBJ files that other assemblers (including MASM) produce. While there are workarounds for those who insist on using the other assemblers, the only reasonable solution is to use the TASM assembler when assembling HLA output.

Note that TASM v5.0 does not support Pentium+ instructions. Further, the latest (and probably last) version of TASM (v5.3) does not support many of the newer SSE instructions. Therefore, you should avoid using these instructions in your HLA programs when linking with Delphi code.

---

### 12.3.12 Referencing Delphi Objects from HLA Code

Symbols you declare in the INTERFACE section of a Delphi program are public. Therefore, you can access these objects from HLA code if you declare those objects as external in the HLA program. The following sample program demonstrates this fact by declaring a structured constant (*y*) and a function (*callme*) that the HLA code uses when you press the button on a form. The HLA code calls the *callme* function (which returns the value 10) and then the HLA code stores the function return result into the *y* structured constant (which is really just a static variable).

---

```

unit DelphiEx5;

interface

uses
 Windows, Messages, SysUtils, Classes, Graphics, Controls, Forms, Dialogs,
 StdCtrls;

type
 TDataTable = class(TForm)
 GetDataBtn: TButton;
 DataLabel: TLabel;
 procedure GetDataBtnClick(Sender: TObject);
 private
 { Private declarations }
 public
 { Public declarations }
 end;

 // Here's a static variable that we will export to
 // the HLA source code (in Delphi, structured constants
 // are initialized static variables).

const
 y:integer = 12345;

var
 DataTable: TDataTable;

 // Here's the function we will export to the HLA code:

 function callme:integer;

implementation

{$R *.DFM}
{$L TableData.obj }

function TableData:integer; external;

// This function will simply return 10 as the function
// result (remember, function results come back in EAX).

function callme;

```

```

begin
 callme := 10;
end;

procedure TDataTable.GetDataBtnClick(Sender: TObject);
var
 strVal: string;
 yVal: string;
begin
 // Display the value that TableData returns.
 // Also display the value of y, which TableValue modifies

 str(TableData(), strVal);
 str(y, yVal);
 DataLabel.caption := 'Data = ' + strVal + ' y=' + yVal;
end;

end.

```

---

---

### Program 12.17 DelphiEx5 – Static Data and Delphi Public Symbols Demonstration

---

---

```

#code("_TEXT", "para", "CODE")
#static("_DATA", "para", "DATA")
#readonly("_DATA", "para", "DATA")
#storage("_DATA", "para", "DATA")
#const("_INITDATA_", "para", "INITDATA")

unit TableDataUnit;

// In order to reference more than a single static object
// in this code, we'll bury all the static variables in the
// following record.

type
 dataseg:
 record
 index: uns32;
 TheTable: int32;
 endrecord;

// Here's the actual variable declarations for this code:

static
 y: int32; external; // Static object from Delphi code

 d: dataseg; nostorage; // All of our static variables are here.

```

```

dword -1; // index initial value;
dword -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5, 6; // TheTable values.

// Interface to "callme" procedure found in the Delphi code:

procedure callme; external;

// Declare the procedure we're supplying to the Delphi code:

procedure TableData; external;
procedure TableData; nodisplay; noalignstk; noframe;
begin TableData;

 callme(); // Call Delphi code.
 mov(eax, y); // Store return result in Y.

 // Okay, on each successive call to this function, return
 // the next element (or wraparound to the first element) from
 // the "TheTable" array:

 inc(d.index);
 mov(d.index, eax);
 if(eax > 11) then

 xor(eax, eax);
 mov(eax, d.index);

 endif;
 mov(d.TheTable[eax*4], eax);
 ret();

end TableData;

end TableDataUnit;

```

Program 12.18 HLA Code for DelphiEx5 Example

---

---

## 12.4 Programming in C/C++ and HLA

Without question, the most popular language used to develop Win32 applications is, uh, Visual Basic. We're not going to worry about interfacing Visual Basic to assembly in this text for two reasons: (1) Visual Basic programmers will get better control and performance from their code if they learn Delphi, and (2) Visual Basic's interface to assembly is very similar to Pascal's (Delphi's) so teaching the interface to Visual Basic would repeat a lot of the material from the previous section. Coming in second as the Win32 development language of choice is C/C++. The C/C++ interface to assembly language is a bit different than Pascal/Delphi. That's why this section appears in this text.

Unlike Delphi, that has only a single vendor, there are many different C/C++ compilers available on the market. Each vendor (Microsoft, Borland, Watcom, GNU, etc.) has their own ideas about how C/C++ should interface to external code. Many vendors have their own extensions to the C/C++ language to aid in the interface to assembly and other languages. For example, Borland provides a special keyword to let Bor-

land C++ (and C++ Builder) programmers call Pascal code (or, conversely, allow Pascal code to call the C/C++ code). Microsoft, who stopped making Pascal compilers years ago, no longer supports this option. This is unfortunate since HLA uses the Pascal calling conventions. Fortunately, HLA provides a special interface to code that C/C++ systems generate.

Before we get started discussing how to write HLA modules for your C/C++ programs, you must understand two very important facts:

HLA's exception handling facilities are not directly compatible with C/C++'s exception handling facilities. This means that you cannot use the TRY..ENDTRY and RAISE statements in the HLA code you intend to link to a C/C++ program. This also means that you cannot call library functions that contain such statements. Since the HLA Standard Library modules use exception handling statements all over the place, this effectively prevents you from calling HLA Standard Library routines from the code you intend to link with C/C++<sup>5</sup>.

Although you can write console applications with C/C++, a good percentage of C/C++ (and nearly all C++ Builder) applications are Windows/GUI applications. You cannot call console-related functions (e.g., `stdin.xxxx` or `stdout.xxxx`) from a GUI application. Even if HLA's console and standard input/output routines didn't use exception handling, you wouldn't be able to call them from a standard C/C++ application. Even if you are writing a console application in C/C++, you still shouldn't call the `stdin.xxxx` or `stdout.xxx` routines because they use the RAISE statement.

Given the rich set of language features that C/C++ supports, it should come as no surprise that the interface between the C/C++ language and assembly language is somewhat complex. Fortunately there are two facts that reduce this problem. First, HLA (v1.26 and later) supports C/C++'s calling conventions. Second, the other complex stuff you won't use very often, so you may not have to bother with it.

**Note:** the following sections assume you are already familiar with C/C++ programming. They make no attempt to explain C/C++ syntax or features other than as needed to explain the C/C++ assembly language interface. If you're not familiar with C/C++, you will probably want to skip this section.

**Also note:** although this text uses the generic term "C/C++" when describing the interface between HLA and various C/C++ compilers, the truth is that you're really interfacing HLA with the C language. There is a fairly standardized interface between C and assembly language that most vendors follow. No such standard exists for the C++ language and every vendor, if they even support an interface between C++ and assembly, uses a different scheme. In this text we will stick to interfacing HLA with the C language. Fortunately, all popular C++ compilers support the C interface to assembly, so this isn't much of a problem.

The examples in this text will use the Borland C++ compiler and Microsoft's Visual C++ compiler. There may be some minor adjustments you need to make if you're using some other C/C++ compiler; please see the vendor's documentation for more details. This text will note differences between Borland's and Microsoft's offerings, as necessary.

---

### 12.4.1 Linking HLA Modules With C/C++ Programs

One big advantage of C/C++ over Delphi is that (most) C/C++ compiler vendors' products emit standard OBJ files. Well, almost standard. You wouldn't, for example, want to attempt to link the output of Microsoft's Visual C++ with TLINK (Borland's Turbo Linker) nor would you want to link the output of Borland C++ with Microsoft's linker. Nevertheless, working with OBJ files and a true linker is much nicer than having to deal with Delphi's built-in linker. As nice as the Delphi system is, interfacing with assembly language is much easier in C/C++ than in Delphi.

---

5. Note that the HLA Standard Library source code is available; feel free to modify the routines you want to use and remove any exception handling statements contained therein.

**Note:** the HLA Standard Library was created using Microsoft tools. This means that you will probably not be able to link this library module using the Borland TLINK program. Of course, you probably shouldn't be linking Standard Library code with C/C++ code anyway, so this shouldn't matter. However, if you really want to link some module from the HLA Standard Library with Borland C/C++, you should recompile the module and use the OBJ file directly rather than attempt to link the HLA.LIB file.

The Visual C++ compiler works with COFF object files. The Borland C++ compiler works with OMF object files. Both forms of object files use the OBJ extension, so you can't really tell by looking at a directory listing which form you've got. Fortunately, if you need to create a single OBJ file that will work with both, the Visual C++ compiler will also accept OMF files and convert them to a COFF file during the link phase. Of course, most of the time you will not be using both compilers, so you can pick whichever OBJ file format you're comfortable with and use that.

By default, HLA tells MASM to produce a COFF file when assembling the HLA output. This means that if you compile and HLA program using a command line like the following, you will not be able to directly link the code with Borland C++ code:

```
hla -c filename.hla // The "-c" option tells HLA to compile and assemble.
```

If you want to create an OMF file rather than a COFF file, you can do so by using the following two commands:

```
hla -omf filename.hla // The "-omf" option tells HLA to compile to OMF.
```

The execution of the above command produces an OMF object file that both VC++ and BCC (Borland C++) will accept (though VC++ prefers COFF, it accepts OMF).

Both BCC and VC++ look at the extension of the source file names you provide on the command line to determine whether they are compiling a C or a C++ program. There are some minor syntactical differences between the external declarations for a C and a C++ program. This text assumes that you are compiling C++ programs that have a ".cpp" extension. The difference between a C and a C++ compilation occurs in the external declarations for the functions you intend to write in assembly language. For example, in a C source file you would simply write:

```
extern char* RetHW(void);
```

However, in a C++ environment, you would need the following external declaration:

```
extern "C"
{
 extern char* RetHW(void);
};
```

The 'extern "C"' clause tells the compiler to use standard C linkage even though the compiler is processing a C++ source file (C++ linkage is different than C and definitely far more complex; this text will not consider pure C++ linkage since it varies so much from vendor to vendor). If you're going to compile C source files with VC++ or BCC (i.e., files with a ".c" suffix), simply drop the 'extern "C"' and the curly braces from around the external declarations.

The following sample program demonstrates this external linkage mechanism by writing a short HLA program that returns the address of a string ("Hello World") in the EAX register (like Delphi, C/C++ expects functions to return their results in EAX). The main C/C++ program then prints this string to the console device.

```
#include <stdlib.h>
#include "ratc.h"

extern "C"
{
 extern char* ReturnHW(void);
```

```

};

int main()
 _begin(main)

 printf("%s\n", ReturnHW());
 _return 0;

 _end(main)

```

---

---

### Program 12.19 Cex1 - A Simple Example of a Call to an Assembly Function from C++

---

---

```

unit ReturnHWUnit;

 procedure ReturnHW; external("_ReturnHW");
 procedure ReturnHW; nodisplay; noframe; noalignstk;
 begin ReturnHW;

 lea(eax, "Hello World");
 ret();

 end ReturnHW;

end ReturnHWUnit;

```

---

---

### Program 12.20 RetHW.hla - Assembly Code that Cex1 Calls

---

---

There are several new things in both the C/C++ and HLA code that might confuse you at first glance, so let's discuss these things real quick here.

The first strange thing you will notice in the C++ code is the `#include "ratc.h"` statement. RatC is a C/C++ macro library that adds several new features to the C++ language. RatC adds several interesting features and capabilities to the C/C++ language, but a primary purpose of RatC is to help make C/C++ programs a little more readable. Of course, if you've never seen RatC before, you'll probably argue that it's not as readable as pure C/C++, but even someone who has never seen RatC before can figure out 80% of RatC within a minutes. In the example above, the `_begin` and `_end` clauses clearly map to the "{" and "}" symbols (notice how the use of `_begin` and `_end` make it clear what function or statement associates with the braces; unlike the guesswork you've got in standard C). The `_return` statement is clearly equivalent to the C return statement. As you'll quickly see, all of the standard C control structures are improved slightly in RatC. You'll have no trouble recognizing them since they use the standard control structure names with an underscore prefix. This text promotes the creation of readable programs, hence the use of RatC in the examples appearing in this chapter<sup>6</sup>. You can find out more about RatC on Webster at <http://webster.cs.ucr.edu>.

The C/C++ program isn't the only source file to introduce something new. If you look at the HLA code you'll notice that the LEA instruction appears to be illegal. It takes the following form:

```
lea(eax, "Hello World");
```

The LEA instruction is supposed to have a memory and a register operand. This example has a register and a constant; what is the address of a constant, anyway? Well, this is a syntactical extension that HLA pro-

---

6. If RatC really annoys you, just keep in mind that you've only got to look at a few RatC programs in this chapter. Then you can go back to the old-fashioned C code and hack to your heart's content!

vides to 80x86 assembly language. If you supply a constant instead of a memory operand to LEA, HLA will create a static (readonly) object initialized with that constant and the LEA instruction will return the address of that object. In this example, HLA will emit the string to the constants (#const) segment and then load EAX with the address of the first character of that string. Since HLA strings always have a zero terminating byte, EAX will contain the address of a zero-terminated string which is exactly what C++ wants. If you look back at the original C++ code, you will see that *RetHW* returns a *char\** object and the main C++ program displays this result on the console device.

If you haven't figured it out yet, this is a round-about version of the venerable "Hello World" program.

Microsoft VC++ users can compile this program from the command line by using the following commands<sup>7</sup>:

```
hla -c RetHW.hla // Compiles and assembles RetHW.hla to RetHW.obj
cl Cex1.cpp RetHW.obj // Compiles C++ code and links it with RetHW.obj
```

If you're a Borland C++ user, you'd use the following command sequence:

```
hla -o:omf RetHW.hla // Compile HLA file to an OMF file.
bcc32i Cex1.cpp RetHW.obj // Compile and link C++ and assembly code.
 // Could also use the BCC32 compiler.
```

## 12.4.2 Register Preservation

Unlike Delphi, a single language with a single vendor, there is no single list of registers that you can freely use as scratchpad values within an assembly language function. The list changes by vendor and even changes between versions from the same vendor. However, you can safely assume that EAX is available for scratchpad use since C functions return their result in the EAX register. You should probably preserve everything else.

## 12.4.3 Function Results

C/C++ compilers universally seem to return ordinal and pointer function results in AL, AX, or EAX depending on the operand's size. The compilers probably return floating point results on the top of the FPU stack as well. Other than that, check your C/C++ vendor's documentation for more details on function return locations.

## 12.4.4 Calling Conventions

The standard C/C++ calling convention is probably the biggest area of contention between the C/C++ and HLA languages. VC++ and BCC both support multiple calling conventions. BCC even supports the Pascal calling convention that HLA uses, making it trivial to write HLA functions for BCC programs<sup>8</sup>. However, before we get into the details of these other calling conventions, it's probably a wise idea to first discuss the standard C/C++ calling convention.

Both VC++ and BCC *decorate* the function name when you declare an external function. For external "C" functions, the decoration consists of an underscore. If you look back at Program 12.20 you'll notice that the external name the HLA program actually uses is "\_RetHW" rather than simply "RetHW". The HLA program itself, of course, uses the symbol "RetHW" to refer to the function, but the external name (as specified by the optional parameter to the EXTERNAL option) is "\_RetHW". In the C/C++ program (Program

7. This text assumes you've executed the VCVARS32.BAT file that sets up the system to allow the use of VC++ from the command line.

8. Microsoft used to support the Pascal calling convention, but when they stopped supporting their QuickPascal language, they dropped support for this option.

12.19) there is no explicit indication of this decoration; you simply have to read the compiler documentation to discover that the compiler automatically prepends this character to the function name<sup>9</sup>. Fortunately, HLA's EXTERNAL option syntax allows us to *undecorate* the name, so we can refer to the function using the same name as the C/C++ program. Name decoration is a trivial matter, easily fixed by HLA.

The next big problem is the fact that C/C++ pushes parameters on the stack in the opposite direction of just about every other (non-C base) language on the planet; specifically, C/C++ pushes actual parameters on the stack from right to left instead of the more common left to right. This means that you cannot declare a C/C++ function with two or more parameters and use a simple translation of the C/C++ external declaration as your HLA procedure declaration, i.e., the following are not equivalent:

```
external void CToHLA(int p, unsigned q, double r);
procedure CToHLA(p:int32; q:uns32; r:real64); external("_CToHLA");
```

Were you to call *CToHLA* from the C/C++ program, the compiler would push the *r* parameter first, the *q* parameter second, and the *p* parameter third - exactly the opposite order that the HLA code expects. As a result, the HLA code would use the L.O. double word of *r* as *p*'s value, the H.O. double word of *r* as *q*'s value, and the combination of *p* and *q*'s values as the value for *r*. Obviously, you'd most likely get an incorrect result from this calculation. Fortunately, there's an easy solution to this problem: use the CDECL procedure option in the HLA code to tell it to reverse the parameters:

```
procedure CToHLA(p:int32; q:uns32; r:real64); cdecl; external("_CToHLA");
```

Now when the C/C++ code calls this procedure, it push the parameters on the stack and the HLA code will retrieve them in the proper order.

There is another big difference between the C/C++ calling convention and HLA: HLA procedures automatically clean up after themselves by removing all parameters pass to a procedure prior to returning to the caller. C/C++, on the other hand, requires the caller, not the procedure, to clean up the parameters. This has two important ramifications: (1) if you call a C/C++ function (or one that uses the C/C++ calling sequence), then your code has to remove any parameters it pushed upon return from that function; (2) your HLA code cannot automatically remove parameter data from the stack if C/C++ code calls it. The CDECL procedure option tells HLA not to generate the code that automatically removes parameters from the stack upon return. Of course, if you use the NOFRAME option, you must ensure that you don't remove these parameters yourself when your procedures return to their caller.

One thing HLA cannot handle automatically for you is removing parameters from the stack when you call a procedure or function that uses the CDECL calling convention; for example, you must manually pop these parameters whenever you call a C/C++ function from your HLA code.

Removing parameters from the stack when a C/C++ function returns to your code is very easy, just execute an "add( constant, esp );" instruction where *constant* is the number of parameter bytes you've pushed on the stack. For example, the *CToHLA* function has 16 bytes of parameters (two *int32* objects and one *real64* object) so the calling sequence (in HLA) would look something like the following:

```
CToHLA(pVal, qVal, rVal); // Assume this is the macro version.
add(16, esp); // Remove parameters from the stack.
```

Dealing with cleaning up after a call is easy enough. However, if you're writing the function that must leave it up to the caller to remove the parameters from the stack, then you've got a tiny problem - by default, HLA procedures always clean up after themselves. If you use the CDECL option and don't specify the NOFRAME option, then HLA automatically handles this for you. However, if you use the NOFRAME option, then you've got to ensure that you leave the parameter data on the stack when returning from a function/procedure that uses the CDECL calling convention.

If you want to leave the parameters on the stack for the caller to remove, then you must write the standard entry and exit sequences for the procedure that build and destroy the activation record (see "The Standard Entry Sequence" on page 789 and "The Standard Exit Sequence" on page 790). This means you've got

---

9. Most compilers provide an option to turn this off if you don't want this to occur. We will assume that this option is active in this text since that's the standard for external C names.

to use the NOFRAME (and NODISPLAY) options on your procedures that C/C++ will call. Here's a sample implementation of the CToHLA procedure that builds and destroys the activation record:

```
procedure _CToHLA(rValue:real64; q:uns32; p:int32); nodisplay; noframe;
begin _CToHLA;

 push(ebp); // Standard Entry Sequence
 mov(esp, ebp);
 // sub(_vars_, esp); // Needed if you have local variables.
 .
 . // Code to implement the function's body.
 .
 mov(ebp, esp); // Restore the stack pointer.
 pop(ebp); // Restore link to previous activation record.
 ret(); // Note that we don't remove any parameters.

end _CToHLA;
```

If you're willing to use some vendor extensions to the C/C++ programming language, then you can make the interface to HLA much simpler. For example, if you're using Borland's C++ product, it has an option you can apply to function declarations to tell the compiler to use the Pascal calling convention. Since HLA uses the Pascal calling convention, specifying this option in your BCC programs will make the interface to HLA trivial. In Borland C++ you can specify the Pascal calling convention for an external function using the following syntax:

```
extern type _pascal funcname(parameters)
```

Example:

```
extern void _pascal CToHLA(int p, unsigned q, double r);
```

The Pascal calling convention does not decorate the name, so the HLA name would not have a leading underscore. The Pascal calling convention uses case insensitive names; BCC achieves this by converting the name to all uppercase. Therefore, you'd probably want to use an HLA declaration like the following:

```
procedure CToHLA(p:int32; q:uns32; r:real64); external("CTOHLA");
```

Procedures using the Pascal calling convention push their parameters from left to right and leave it up to the procedure to clean up the stack upon return; exactly what HLA does by default. When using the Pascal calling convention, you could write the *CToHLA* function as follows:

```
procedure CToHLA(rValue:real64; q:uns32; p:int32); external("CTOHLA");

procedure CToHLA(rValue:real64; q:uns32; p:int32); nodisplay; noalignstk;
begin CToHLA;

 .
 . // Code to implement the function's body.
 .

end CToHLA;
```

Note that you don't have to supply the standard entry and exit sequences. HLA provides those automatically.

Of course, Microsoft isn't about to support the Pascal calling sequence since they don't have a Pascal compiler. So this option isn't available to VC++ users.

Both Borland and Microsoft (and HLA) support the so-called *StdCall* calling convention. This is the calling convention that Windows uses, so nearly every language that operates under Windows provides this calling convention. The StdCall calling convention is a combination of the C and Pascal calling conventions. Like C, the functions need to have their parameters pushed on the stack in a right to left order; like Pascal, it is the caller's responsibility to clean up the parameters when the function returns; like C, the function name is case sensitive; like Pascal, the function name is not decorated (i.e., the external name is the same as the

function declaration). The syntax for a StdCall function is the same in both VC++ and BCC, it is the following:

```
extern void _stdcall CToHLA(int p, unsigned q, double r);
```

HLA supports the StdCall convention using the STDCALL procedure option.. Because the name is undecorated, you could use a prototype and macro like the following:

```
procedure CToHLA(p:int32; q:uns32; r:real64); stdcall; external("CToHLA");
procedure CToHLA(p:int32; q:uns32; r:real64); nodisplay; nostkalign;
begin CToHLA;
.
. // Function body
.
end CToHLA;
.
.
.
CToHLA(pValue, qValue, rValue); // Demo of a call to CToHLA.
```

### 12.4.5 Pass by Value and Reference in C/C++

A C/C++ program can pass parameters to a procedure or function using one of two different mechanisms: pass by value and pass by reference. Since pass by reference parameters use pointers, this parameter passing mechanism is completely compatible between HLA and C/C++. The following two lines provide an external declaration in C++ and the corresponding external (public) declaration in HLA for a pass by reference parameter using the calling convention:

```
extern void HasRefParm(int& refparm); // C++
procedure HasRefParm(var refparm: int32); external; // HLA
```

Like HLA, C++ will pass the 32-bit address of whatever actual parameter you specify when calling the *HasRefParm* procedure. Don't forget, inside the HLA code, that you must dereference this pointer to access the actual parameter data. See the chapter on Intermediate Procedures for more details (see "Pass by Reference" on page 793).

Like HLA, C++ lets you pass untyped parameters by reference. The syntax to achieve this in C++ is the following:

```
extern void UntypedRefParm(void* parm1);
```

Actually, this is not a reference parameter, but a value parameter with an untyped pointer. Whenever you call this function you must explicitly take the address of the actual parameter using the "&" operator.

In HLA, you can use the VAR keyword as the data type to specify that you want an untyped reference parameter. Here's the corresponding prototype for the *UntypedRefParm* procedure in HLA:

```
procedure UntypedRefParm(var parm1:var);
external;
```

### 12.4.6 Scalar Data Type Correspondence Between Delphi and HLA

When passing parameters between C/C++ and HLA procedures and functions, it's very important that the calling code and the called code agree on the basic data types for the parameters. In this section we will draw a correspondence between the C/C++ scalar data types and the HLA (v1.x) data types.

Assembly language supports any possible data format, so HLA's data type capabilities will always be a superset of C/C++'s. Therefore, there may be some objects you can create in HLA that have no counterpart in C/C++, but the reverse is not true. Since the assembly functions and procedures you write are generally

manipulating data that C/C++ provides, you don't have to worry too much about not being able to process some data passed to an HLA procedure by C/C++.

C/C++ provides a wide range of different integer data types. Unfortunately, the exact representation of these types is implementation specific. The following table lists the C/C++ types as currently implemented by Borland C++ and Microsoft VC++. This table may very well change as 64-bit compilers become available.

**Table 5: Delphi and HLA Integer Types**

| C/C++          | HLA Equivalent | Range       |            |
|----------------|----------------|-------------|------------|
|                |                | Minimum     | Maximum    |
| int            | int32          | -2147483648 | 2147483647 |
| unsigned       | uns32          | 0           | 4294967295 |
| signed char    | int8           | -128        | 127        |
| short          | int16          | -32768      | 32767      |
| long           | int32          | -2147483648 | 2147483647 |
| unsigned char  | uns8           | 0           | 255        |
| unsigned short | uns16          | 0           | 65535      |

In addition to the integer values, C/C++ supports several non-integer ordinal types. The following table provides their HLA equivalents:

**Table 6: Non-integer Ordinal Types in C/C++ and HLA**

| C/C++        | HLA     | Range     |                   |
|--------------|---------|-----------|-------------------|
|              |         | Minimum   | Maximum           |
| wchar, TCHAR | word    | 0         | 65535             |
| BOOL         | boolean | false (0) | true ( not zero ) |

Like the integer types, C/C++ supports a wide range of real numeric formats. The following table presents these types and their HLA equivalents.

**Table 7: Real Types in C/C++ and HLA**

| C/C++                    | HLA    | Range      |            |
|--------------------------|--------|------------|------------|
|                          |        | Minimum    | Maximum    |
| double                   | real64 | 5.0 E-324  | 1.7 E+308  |
| float                    | real32 | 1.5 E-45   | 3.4 E+38   |
| long double <sup>a</sup> | real80 | 3.6 E-4951 | 1.1 E+4932 |

- a. This data type is 80 bits only in BCC. VC++ uses 64 bits for the long double type.

The last scalar type of interest is the pointer type. Both HLA and C/C++ use a 32-bit address to represent pointers, so these data types are completely equivalent in both languages.

## 12.4.7 Passing String Data Between C/C++ and HLA Code

C/C++ uses zero terminated strings. Algorithms that manipulate zero-terminated strings are not as efficient as functions that work on length-prefixed strings; on the plus side, however, zero-terminated strings are very easy to work with. HLA's strings are downwards compatible with C/C++ strings since HLA places a zero byte at the end of each HLA string. Since you'll probably not be calling HLA Standard Library string routines, the fact that C/C++ strings are not upwards compatible with HLA strings generally won't be a problem. If you do decide to modify some of the HLA string functions so that they don't raise exceptions, you can always translate the *str:cStrToStr* function that translates zero-terminated C/C++ strings to HLA strings.

A C/C++ string variable is typically a `char*` object or an array of characters. In either case, C/C++ will pass the address of the first character of the string to an external procedure whenever you pass a string as a parameter. Within the procedure, you can treat the parameter as an indirect reference and dereference to pointer to access characters within the string.

## 12.4.8 Passing Record/Structure Data Between HLA and C/C++

Records in HLA are (mostly) compatible with C/C++ structs. You can easily translate a C/C++ struct to an HLA record. In this section we'll explore how to do this and learn about the incompatibilities that exist between HLA records and C/C++ structures.

For the most part, translating C/C++ records to HLA is a no brainer. Just grab the "guts" of a structure declaration and translate the declarations to HLA syntax within a `RECORD..ENDRECORD` block and you're done.

Consider the following C/C++ structure type declaration:

```
typedef struct
{
 unsigned char day;
 unsigned char month;
 int year;
 unsigned char dayOfWeek;
} dateType;
```

The translation to an HLA record is, for the most part, very straight-forward. Just translate the field types accordingly and use the HLA record syntax (see "Records" on page 465) and you're in business. The translation is the following:

```
type
 recType:
 record

 day: byte;
 month: byte;
 year: int32;
 dayOfWeek: byte;

 endrecord;
```

There is one minor problem with this example: data alignment. Depending on your compiler and whatever defaults it uses, C/C++ might not pack the data in the structure as compactly as possible. Some C/C++

compilers will attempt to align the fields on double word or other boundaries. With double word alignment of objects larger than a byte, the previous C/C++ **typedef** statement is probably better modelled by

```
type
 recType:
 record

 day: byte;
 month: byte;
 padding:byte[2]; // Align year on a four-byte boundary.
 year:int32;
 dayOfWeek:byte;
 morePadding: byte[3]; // Make record an even multiple of four bytes.

 endrecord;
```

Of course, a better solution is to use HLA's ALIGN directive to automatically align the fields in the record:

```
type
 recType:
 record

 day: byte;
 month: byte;
 align(4); // Align year on a four-byte boundary.
 year:int32;
 dayOfWeek:byte;
 align(4); // Make record an even multiple of four bytes.

 endrecord;
```

Alignment of the fields is good insofar as access to the fields is faster if they are aligned appropriately. However, aligning records in this fashion does consume extra space (five bytes in the examples above) and that can be expensive if you have a large array of records whose fields need padding for alignment.

You will need to check your compiler vendor's documentation to determine whether it packs or pads structures by default. Most compilers give you several options for packing or padding the fields on various boundaries. Padded structures might be a bit faster while packed structures (i.e., no padding) are going to be more compact. You'll have to decide which is more important to you and then adjust your HLA code accordingly.

Note that by default, C/C++ passes structures by value. A C/C++ program must explicitly take the address of a structure object and pass that address in order to simulate pass by reference. In general, if the size of a structure exceeds about 16 bytes, you should pass the structure by reference rather than by value.

## 12.4.9 Passing Array Data Between HLA and C/C++

Passing array data between some procedures written in C/C++ and HLA is little different than passing array data between two HLA procedures. First of all, C/C++ can only pass arrays by reference, never by value. Therefore, you must always use pass by reference inside the HLA code. The following code fragments provide a simple example:

```
int CArray[128][4];

extern void PassedArray(int array[128][4]);
```

Corresponding HLA code:

```
type
 CArray: int32[128, 4];
```

```
procedure PassedArray(var ary: CArray); external;
```

As the above examples demonstrate, C/C++'s array declarations are similar to HLA's insofar as you specify the bounds of each dimension in the array.. Other than this difference, however, you can see that the two declarations are very similar.

C/C++ uses row-major ordering for arrays. So if you're accessing elements of a C/C++ multi-dimensional array in HLA code, be sure to use the row-major order computation (see "Row Major Ordering" on page 451).

---

## 12.5 Putting It All Together

Most real-world assembly code that is written consists of small modules that programmers link to programs written in other languages. Most languages provide some scheme for interfacing that language with assembly (HLA) code. Unfortunately, the number of interface mechanisms is sufficiently close to the number of language implementations to make a complete exposition of this subject impossible. In general, you will have to refer to the documentation for your particular compiler in order to learn sufficient details to successfully interface assembly with that language.

Fortunately, nagging details aside, most high level languages do share some common traits with respect to assembly language interface. Parameter passing conventions, stack clean up, register preservation, and several other important topics often apply from one language to the next. Therefore, once you learn how to interface a couple of languages to assembly, you'll quickly be able to figure out how to interface to others (given the documentation for the new language).

This chapter discusses the interface between the Delphi and C/C++ languages and assembly language. Although there are more popular languages out there (e.g., Visual Basic), Delphi and C/C++ introduce most of the concepts you'll need to know in order to interface a high level language with assembly language. Beyond that point, all you need is the documentation for your specific compiler and you'll be interfacing assembly with that language in no time.

# Questions, Projects, and Labs

# Chapter Thirteen

## 13.1 Questions

- 1) What is the purpose of the UNPROTECTED section in a TRY..ENDTRY statement?
- 2) Once a TRY..ENDTRY statement has handled an exception, how can it tell the system to let a nesting TRY..ENDTRY statement also handle that (same) exception?
- 3) What is the difference between static and dynamic nesting (e.g., with respect to the TRY..ENDTRY statement)?
- 4) How can you handle any exception that occurs without having to write an explicit EXCEPTION handler for each possible exception?
- 5) What HLA high level statement could you use immediately return from a procedure without jumping to the end of the procedure's body?
- 6) What is the difference between the CONTINUE and BREAK statements?
- 7) Explain how you could use the EXIT statement to break out of two nested loops (from inside the innermost loop). Provide an example.
- 8) The EXIT statement translates into a single 80x86 machine instruction. What is that instruction?
- 9) What is the algorithm for converting a conditional jump instruction to its opposite form?
- 10) Discuss how you could use the JF instruction and a label to simulate an HLA IF..ENDIF statement and a WHILE loop.
- 11) Which form requires the most instructions: complete boolean evaluation or short circuit evaluation?
- 12) Translate the following C/C++ statements into "pure" assembly language and complete boolean evaluation:
  - a) `if( (eax >= 0) && (ebx < eax) || (ebx < 0) ) ebx = ebx + 2;`
  - b) `while( (ebx != 0) && ( *ebx != 0) ) { *ebx = 'a'; ++ebx; }`
  - c) `if( al == 'c' || al == 'd' || bl == al ) al = 'a';`
  - d) `if( al >= 'a' && al <= 'z' ) al = al & 0x5f;`
- 13) Repeat question (12) using short circuit boolean evaluation.
- 14) Convert the following Pascal CASE statement to assembly language:

```

CASE I OF
 0: I := 5;
 1: J := J+1;
 2: K := I+J;
 3: K := I-J;
 Otherwise I := 0;
END;
```

- 15) Which implementation method for the CASE statement (jump table or IF form) produces the least amount of code (including the jump table, if used) for the following Pascal CASE statements?
  - a)

```

CASE I OF
 0: stmt;
 100: stmt;
 1000: stmt;
END;
```

b)

```

CASE I OF
 0:stmt;
 1:stmt;
 2:stmt;
 3:stmt;
 4:stmt;
END;
```

- 16) For question (15), which form produces the fastest code?
- 17) Implement the CASE statements in problem three using 80x86 assembly language.
- 18) What three components compose a loop?
- 19) What is the major difference between the WHILE, REPEAT..UNTIL, and FOREVER..ENDFOR loops?
- 20) What is a loop control variable?
- 21) Convert the following C/C++ WHILE loops to pure assembly language: (Note: don't optimize these loops, stick exactly to the WHILE loop format)

a)

```

I = 0;
while (I < 100)
 I = I + 1;
```

b)

```

CH = ' ';
while (CH <> '.')
{
 CH := getch();
 putch(CH);
}
```

- 22) Convert the following Pascal REPEAT..UNTIL loops into pure assembly language: (Stick exactly to the REPEAT..UNTIL loop format)

a)

```

I := 0;
REPEAT
 I := I + 1;
UNTIL I >= 100;
```

b)

```

REPEAT
 CH := GETC;
 PUTC(CH);
UNTIL CH = '.';
```

- 23) What are the differences, if any, between the loops in problems (21) and (22)? Do they perform the same operations? Which versions are most efficient?
- 24) By simply adding a JMP instruction, convert the two loops in problem (21) into REPEAT..UNTIL loops.
- 25) By simply adding a JMP instruction, convert the two loops in problem (22) to WHILE loops.
- 26) Convert the following C/C++ FOR loops into pure assembly language (Note: feel free to use any of the routines provided in the HLA Standard Library package):

a)

```

for(i = 0; i < 100; ++i) cout << "i = " << i << endl;
```

```

b) for(i = 0; i < 8; ++i)
 for(j = 0; j < 8; ++j)
 k = k * (i - j);

```

```

c) for(k = 255; k >= 16; --k)
 A [k] := A[240-k]-k;

```

- 27) How does moving the loop termination test to the end of the loop improve the performance of that loop?
- 28) What is a loop invariant computation?
- 29) How does executing a loop backwards improve the performance of the loop?
- 30) What does unraveling a loop mean?
- 31) How does unraveling a loop improve the loop's performance?
- 32) Give an example of a loop that cannot be unraveled.
- 33) Give an example of a loop that can be but shouldn't be unraveled.
- 34) What is the difference between unstructured and destructured code?
- 35) What is the principle difference between a state machine and a SWITCH statement?
- 36) What is the effect of the NODISPLAY procedure option?
- 37) What is the effect of the NOFRAME procedure option?
- 38) What is the effect of the NOSTKALIGN procedure option?
- 39) Why don't you normally use the RET instruction in a procedure that does not have the NOFRAME option?
- 40) What does the operand to the RET(n) instruction specify?
- 41) What is an activation record?
- 42) What part of the activation record does the *caller* construct?
- 43) What part of the activation record does the *callee* (the procedure) construct?
- 44) Provide a generic definition for "The Standard Entry Sequence."
- 45) What four instructions are typically found in an HLA Standard Entry Sequence?
- 46) Which instruction in the Standard Entry Sequence will HLA *not* generate if you specify the NOALIGN-STK option in the procedure?
- 47) Which instruction in the Standard Entry Sequence is optional if there are no automatic variables?
- 48) Provide a generic definition for "The Standard Exit Sequence."
- 49) What three instructions are typically found in an HLA Standard Exit Sequence?
- 50) What data in the activation record is probably being accessed by an address of the form "[ebp-16]"?
- 51) What data in the activation record is probably being accessed by an address of the form "[ebp+16]"?
- 52) What does the `_vars_` constant tell you?
- 53) What is the big advantage to using automatic variables in a procedure?
- 54) What is the difference between pass by reference parameters and pass by value parameters?
- 55) Name three different places *where* you can pass parameters.
- 56) Which parameter passing mechanism uses pointers?

57) For each of the following procedure prototypes and corresponding high level syntax procedure calls, provide an equivalent sequence of low-level assembly language statements. Assume all variables are *int32* objects unless otherwise specified. If the procedure call is illegal, simply state that fact and don't attempt to write any code for the call. Assume that you are passing all parameters on the stack.

a) procedure proc1( i:int32 ); forward;

a1) proc1( 10 );

a2) proc1( j );

a3) proc1( eax );

a4) proc1( [eax] );

b) procedure proc2( var v:int32 ); forward;

b1) proc2( 10 );

b2) proc2( j );

b3) proc2( eax );

b4) proc2( [eax] );

58) When passing parameters in the code stream, where do you find the pointer to the parameter data?

59) When passing parameter data immediately after a CALL instruction, how do you prevent the procedure call from attempting to execute the parameter data upon immediate return from the procedure?

60) Draw a picture of the activation record for each of the following procedure fragments. Be sure to label the size of each item in the activation record.

a)

```
procedure P1(val i:int16; var j:int16); nodisplay;
var
 c:char;
 k:uns32;
 w:word;
begin P1;
 .
 .
 .
end P1;
```

b)

```
procedure P2(r:real64; val b:boolean; var c:char); nodisplay;
begin P2;
 .
 .
 .
end P2;
```

c)

```
procedure P3; nodisplay;
var
 i:uns32;
 j:char;
 k:boolean;
 w:word;
 r:real64;
```

```
begin P3;
 .
 .
 .
end P3;
```

61) Fill in the pseudo-code (in comments) for the following procedures:

a)

```
procedure P4(val v:uns32); nodisplay;
var
 w:dword;
begin P4;

 // w = v;
 // print w;

end P4;
```

b)

```
procedure P5(var v:uns32); nodisplay;
var
 w:dword;
begin P5;

 // w = v;
 // print w;

end P5;
```

62) Given the procedures defined in question (61) above, provide the low-level code for each of the following (pseudo-code) calls to P4 and P5. You may assume that you can use any registers you need for temporary calculations. You may also assume that all variables are *uns32* objects.

- a) P4( i );
- b) P4( 10 );
- c) P4( eax+10 );
- d) P5( i );
- e) P5( i[ eax\*4 ] );
- f) P5( [eax+ebx\*4] );

63) This question also uses the procedure declarations for P4 and P5 in question (61). Write the low-level code for the statements in the P6 procedure below:

```
procedure p6(val v:uns32; var r:uns32); nodisplay;
begin P6;

 P4(v);
 P4(r);
 P5(v);
 P5(r);

end P6;
```

64) Describe the HLA hybrid parameter passing syntax and explain why you might want to use it over the low-level and high-level procedure call syntax provided by HLA.

- 65) 30)What is a procedure variable? Give some examples.
- 66) When you pass a procedure variable by value to a procedure, what do we typically call such a parameter?
- 67) How does an iterator return success? How does it return failure?
- 68) What does the *yield()* procedure do?
- 69) Why shouldn't you break out of a FOREACH..ENDFOR loop?
- 70) An extended precision ADD operation will set the carry flag, the overflow flag, and the sign flag properly. It does not set the zero flag properly. Explain how you can check to see if an extended precision ADD operation produces a zero result.
- 71) Since SUB and CMP are so closely related, why can't you use the SUB/SBB sequence to perform an extended precision compare? (hint: this has nothing to do with the fact that SUB/SBB actually compute a difference of their two operands.)
- 72) Provide the code to add together two 48-bit values, storing the sum in a third 48-bit variable. This should only take six instructions.
- 73) For 64-bit multiprecision operations, why is it more convenient to declare an uns64 variable as "uns32[2]" rather than as a *qword*?
- 74) The 80x86 INTMUL instruction provides an  $n \times n$  bit ( $n=16$  or  $32$ ) multiplication producing an  $n$ -bit result (ignoring any overflow). Provide a variant of the MUL64 routine in this chapter that produces a 64-bit result, ignoring any overflow (hint: mostly this involves removing instructions from the existing code).
- 75) When computing an extended precision NEG operation using the "subtract from zero" algorithm, does the algorithm work from the H.O. double word down to the L.O. double word, or from the L.O. double word to the H.O. double word?
- 76) When computing an extended precision logical operation (AND, OR, XOR, or NOT), does it matter what order you compute the result (H.O.->L.O. or L.O.->H.O.)? Explain.
- 77) Since the extended precision shift operations employ the rotate instructions, you cannot check the sign or zero flags after an extended precision shift (since the rotate instructions do not affect these flags). Explain how you could check the result of an extended precision shift for zero or a negative result.
- 78) Which of the two data operands does the SHRD and SHLD instructions leave unchanged?
- 79) What is the maximum number of digits a 128-bit unsigned integer will produce on output?
- 80) What is the purpose of the conv.getDelimiters function in the HLA Standard Library?
- 81) Why do the extended precision input routine always union in the EOS (#0) character into the HLA Standard Library delimiter characters when HLA, by default, already includes this character?
- 82) Suppose you have a 32-bit signed integer and a 32-bit unsigned integer, and both can contain an arbitrary value. Explain why an extended precision addition may be necessary to add these two values together.
- 83) Provide the code to add a 32-bit signed integer together with a 32-bit unsigned integer, producing a 64-bit result.
- 84) Why is binary representation more efficient than decimal (packed BCD) representation?
- 85) What is the one big advantage of decimal representation over binary representation?
- 86) How do you represent BCD literal constants in an HLA program?
- 87) What data type do you use to hold packed BCD values for use by the FPU?
- 88) How many significant BCD digits does the FPU support?
- 89) How does the FPU represent BCD values in memory? While inside the CPU/FPU?
- 90) Why are decimal operations so slow on the 80x86 architecture?
- 91) What are the repeat prefixes used for?
- 92) Which string prefixes are used with the following instructions?

- a) MOVS      b) CMPS      c) STOS      d) SCAS

- 93) Why aren't the repeat prefixes normally used with the LODS instruction?
- 94) What happens to the ESI, DDI, and DCX registers when the MOVSB instruction is executed (without a repeat prefix) and:  
 a) the direction flag is set.                      b) the direction flag is clear.
- 95) Explain how the MOVSB and MOVSW instructions work. Describe how they affect memory and registers with and without the repeat prefix. Describe what happens when the direction flag is set and clear.
- 96) How do you preserve the value of the direction flag across a procedure call?
- 97) How can you ensure that the direction flag always contains a proper value before a string instruction without saving it inside a procedure?
- 98) What is the difference between the "MOVSB", "MOVSW", and "MOVS oprnd1,oprnd2" instructions?
- 99) Consider the following Pascal array definition:

```

a:array [0..31] of record
 a,b,c:char;
 i,j,k:integer;
 end;

```

Assuming A[0] has been initialized to some value, explain how you can use the MOVS instruction to initialize the remaining elements of A to the same value as A[0].

- 100) Give an example of a MOVS operation which requires the direction flag to be:  
 a) clear                      b) set
- 101) How does the CMPS instruction operate? (what does it do, how does it affect the registers and flags, etc.)
- 102) Which segment contains the source string? The destination string?
- 103) What is the SCAS instruction used for?
- 104) How would you quickly initialize an array to all zeros?
- 105) How are the LODS and STOS instructions used to build complex string operations?
- 106) Write a short loop which multiplies each element of a single dimensional array by 10. Use the string instructions to fetch and store each array element.
- 107) Explain how to perform an extended precision integer comparison using CMPS
- 108) Explain the difference in execution time between compile-time programs and execution-time programs.
- 109) What is the difference between the *stdout.put* and the #PRINT statements?
- 110) What is the purpose of the #ERROR statement?
- 111) In what declaration section do you declare compile-time constants?
- 112) In what declaration section do you declare run-time constants?
- 113) Where do you declare compile-time variables?
- 114) Where do you declare run-time variables?

- 115) Explain the difference between the following two computations (assume appropriate declarations for each symbol in these two examples:
- a) `? i := j+k*m;`
  - b) `mov( k, eax );`  
`intmul( m, eax );`  
`add( j, eax );`  
`mov( eax, i );`
- 116) What is the purpose of the compile-time conversion functions?
- 117) What is the difference between `@sin(x)` and `fsin()`? Where would you use `@sin`?
- 118) What is the difference between the `#IF` and the `IF` statement?
- 119) Explain the benefit of using conditional compilation statements in your program to control the emission of debugging code in the run-time program.
- 120) Describe how you can use conditional compilation to configure a program for different run-time environments.
- 121) What compile-time statement could you use to fill in the entries in a read-only table?
- 122) The HLA compile-time language does not support a `#switch` statement. Explain how you could achieve the same result as a `#switch` statement using existing compile-time statements.
- 123) What HLA compile-time object corresponds to a compile-time procedure declaration?
- 124) What HLA compile-time language facility provides a looping construct?
- 125) HLA `TEXT` constants let you perform simple textual substitution at compile time. What other HLA language facility provides textual substitution capabilities?
- 126) Because HLA's compile-time language provides looping capabilities, there is the possibility of creating an infinite loop in the compile-time language. Explain how the system would behave if you create a compile-time infinite loop.
- 127) Explain how to create an HLA macro that allows a variable number of parameters.
- 128) What is the difference between a macro and a (run-time) procedure? (Assume both constructs produce some result at run-time.)
- 129) When declaring macro that allows a variable number of parameters, HLA treats those "extra" (variable) parameters differently than it does the fixed parameters. Explain the difference between these two types of macro parameters in an HLA program.
- 130) How do you declare local symbols in an HLA macro?
- 131) What is a multipart macro? What three components appear in a multipart macro? Which part is optional? How do you invoke multipart macros?
- 132) Explain how you could use the `#WHILE` statement to unroll (or unravel) a loop.
- 133) The `#ERROR` statement allows only a single string operation. Explain (and provide an example) how you can display the values of compile-time variable and constant expressions along with text in a `#ERROR` statement.
- 134) Explain how to create a Domain Specific Embedded Language (DSEL) within HLA.
- 135) Explain how you could use the `#WHILE` statement to unroll (or unravel) a loop.
- 136) What is lexical analysis?
- 137) Explain how to use HLA compile-time functions like `@OneOrMoreCSet` and `@OneCset` to accomplish lexical analysis/scanning.

- 138) The #ERROR statement allows only a single string operation. Explain (and provide an example) how you can display the values of compile-time variable and constant expressions along with text in a #ERROR statement.
- 139) What are some differences between a RECORD declaration and a CLASS declaration?
- 140) What declaration section may not appear within a class definition?
- 141) What is the difference between a class and an object?
- 142) What is inheritance?
- 143) What is polymorphism?
- 144) What is the purpose of the OVERRIDE prefix on procedures, methods, and iterators?
- 145) What is the difference between a virtual and a static routine in a class? How do you declare virtual routines in HLA? How do you declare static routines in HLA?
- 146) Are class iterators virtual or static in HLA?
- 147) What is the purpose of the virtual method table (VMT)?
- 148) Why do you implement constructors in HLA using procedures rather than methods?
- 149) Can destructors be procedures? Can they be methods? Which is preferable?
- 150) What are the two common activities that every class constructor should accomplish?
- 151) Although HLA programs do not automatically call constructors for an object when you declare the object, there is an easy work-around you can use to automate calling constructors. Explain how this works and give an example.
- 152) When writing a constructor for a derived class, you will often want to call the corresponding constructor for the base class within the derived class' constructor. Describe how to do this.
- 153) When writing overridden methods for a derived class, once in a great while you may need to call the base class' method that you're overriding. Explain how to do this. What are some limitations to doing this (versus calling class procedures)?
- 154) What is an abstract method? What is the purpose of an abstract method?
- 155) Explain why you would need Run-Time Type Information (RTTI) in a program. Describe how to access this information in your code.

---

## 13.2 Programming Problems

Note: unless otherwise specified, you may not use the HLA high level language statements (e.g., if..elseif..else..endif) in the following programming projects. One exception is the TRY..ENDTRY statement. If necessary, you may use TRY..ENDTRY in any of these programs.

- 1) Solve the following problem using only “pure” assembly language instructions (i.e., no high level statements).

Write a procedure, PrintArray( var ary:int32; NumRows:uns32; NumCols:uns32 ), that will print a two-dimensional array in matrix form. Note that calls to the PrintArray function will need to coerce the actual array to an int32. Assume that the array is always an array of INT32 values. Write the procedure as part of a UNIT with an appropriate header file. Also write a sample main program to test the PrintArray function. Include a makefile that will compile and run the program. Here is an example of a typical call to PrintArray:

```
static
 MyArray: int32 [4, 5];
 .
 .
 .
```

```
PrintArray((type int32 MyArray), 4, 5);
```

- 2) Solve problem (2) using HLA's hybrid control structures.
- 3) Solve the following problem using pure assembly language instructions (i.e., no high level language statements):

Write a program that inputs a set of grades for courses a student takes in a given quarter. The program should then compute the GPA for that student for the quarter. Assume the following grade points for each of the following possible letter grades:

- A+ 4.0
- A 4.0
- A- 3.7
- B+ 3.3
- B 3.0
- B- 2.7
- C+ 2.3
- C 2.0
- C- 1.7
- D+ 1.3
- D 1.0
- D- 0.7
- F 0

- 4) Solve problem (3) using HLA's hybrid control structures (see the description above).
- 5) Write a "number guessing" program that attempts to guess the number a user has chosen. The number should be limited to the range 0..100. A well designed program should be able to guess the answer with seven or fewer guesses. Use only pure assembly language statements for this assignment.
- 6) Write a "calendar generation" program. The program should accept a month and a year from the user. Then it should print a calendar for the specific month. You should use the `date.IsValid` library routine to verify that the user's input date is valid (supply a day value of one). You can also use `date.dateOfWeek(m, d, y)`; to determine whether a day is Monday, Tuesday, Wednesday, etc. Print the name of the month and the year above the calendar for that month. As usual, use only low-level "pure" machine instructions for this assignment.
- 7) A video producer needs a calculator to compute "time frame" values. Time on video tape is marked as HH:MM:SS:FF where HH is the hours (0..99), MM represents minutes (0..59), SS represents seconds (0..59), and FF represents frames (0..29). This producer needs to be able to add and subtract two time values. Write a pair of procedures that accept these four parameters and return their sum or difference in the following registers:

HH: DH

MM: DL

SS: AH

FF: AL

The main program for this project should ask the user to input two time values (a separate input for each component of these values is okay) and then ask whether the user wants to add these numbers or subtract them. After the inputs, the program should display the sum or difference, as appropriate, of these two times. Write this program using HLA's hybrid control structures.

- 8) Rewrite the code in problem (7) using only low-level, pure machine language instructions.
- 9) Write a program that reads an 80x25 block of characters from the screen (using `console.getRect`, see "Bonus Section: The HLA Standard Library CONSOLE Module" on page 184 for details) and then "scrolls" the characters up one line in the 80x25 array of characters you've copied the data into. Once the scrolling is complete (in the memory array), write the data back to the screen using the `console.putRect` routine. In your main program, write several lines of (different) text to the screen and call the scroll pro-

cedure several times in a row to test the program. As usual, use only low level machine language instructions in this assignment.

- 10) Write a program that reads an 80x25 block of characters from the screen (using `console.getRect`; see the previous problem) and horizontally “flips” the characters on the screen. That is, on each row of the screen swap the characters at positions zero and 79, positions one and 78, etc. After swapping the characters, write the buffer back to the display using the `console.putRect` procedure. Use only low level machine language statements for this exercise.

Note: Your instructor may require that you use all low-level control structures (except for `TRY..ENDTRY` and `FOREVER..ENDFOR`) in the following assignments. Check with your instructor to find out if this is the case. Of course, where explicitly stated, always use low level or high level code.

- 11) Write a Blackjack/21 card game. You may utilize the code from the iterator laboratory exercise (see “Iterator Exercises” on page 1202). The game should play “21” with two hands: one for the house and one for the player. The play should be given an account with \$5,000 U.S. at the beginning of the game. Before each hand, the player can bet any amount in multiples of \$5. If the dealer wins, the player loses the bet; if the player wins, the player is credited twice the amount of the bet. The player is initially dealt two cards. Each card has the following value:

2-10: Face value of card

J, Q, K: 10

A: 1 or 11. Whichever is larger and does not cause the player’s score to exceed 21.

The game should deal out the first four cards as follows:

1st: to the player.

2nd: to the dealer.

3rd: to the player

4th: to the dealer.

The game should let the player see the dealer’s first card but it should not display the dealer’s second card.

After dealing the cards and displaying the user’s cards and the dealer’s first card, the game should allow the user to request additional cards. The user can request as many additional cards as desired as long as the user’s total does not exceed 21. If the player’s total is exactly 21, the player automatically wins, regardless of the dealer’s hand. If the player’s total exceeds 21, the player automatically loses.

Once the player decides to stop accepting cards, the dealer must deal itself cards as long as the dealer’s point total is less than 17. Once the dealer’s total exceeds 17, the game ends. Whomever has the larger value that does not exceed 21 wins the hand. In the event of a tie, the player wins.

Do not reshuffle the deck after each hand. Place used cards in a storage array and reshuffle those once the card deck is exhausted. Complete the hand by dealing from the reshuffled deck. Once this hand is complete, reshuffle the entire deck and start over.

At the end of each hand, as the player if they want to “cash out” (quit) or continue. The game automatically ends if the player “goes broke” (that is, the cash account goes to zero). The house has an unlimited budget and never goes broke.

- 12) Modify program (11) to allow more than one card deck in play at a time. Let the player specify the number of card decks when the program first starts.
- 13) Modify program (12) to allow more than one player in the game. Let the initial user specify the number of players when the program first starts (hint: use HLA’s dynamic arrays for this). Any player may “cash out” and exit the game at any time; in such a case the game continues as long as there is at least one remaining player. If a player goes broke, that particular player automatically exits the game.

- 14) Modify the “Outer Product” sample program (see “Outer Product Computation with Procedural Parameters” on page 822) to support division (“/”), logical AND (“&”), logical OR (“|”), logical XOR (“^”), and remainder (“%”).
- 15) Modify project (14) to use the *uns32* values 0..7 to select the function to select the operation rather than a single character. Use a CALL-based SWITCH statement to call the actual function (see “Procedural Parameter Exercise” on page 1199 for details on a CALL-based SWITCH statement) rather than the current *if..elseif* implementation.
- 16) Generally, it is not a good idea to break out of a FOREACH..ENDFOR loop because of the extra data that the iterator pushes onto the stack (that it doesn’t clean up until the iterator fails). While it is possible to pass information back to the iterator from the FOREACH loop body (remember, the loop body is essentially a procedure that the iterator calls) and you can use this return information to force the iterator to fail, this technique is cumbersome. The program would be more readable if you could simply break out of a FOREACH loop as you could any other loop. One solution to this problem is to save the stack pointer’s value before executing the FOREACH statement and restoring this value to ESP immediately after the ENDFOR statement (you should keep the saved ESP value in a local, automatic, variable). Modify the Fibonacci number generation program in the Sample Programs section (see “Generating the Fibonacci Sequence Using an Iterator” on page 820) and eliminate the parameter to the iterator. Have the iterator return an infinite sequence of fibonacci numbers (that is, the iterator should never return failure unless there is an unsigned arithmetic overflow during the fibonacci computation). In the main program, prompt the user to enter the maximum value to allow in the sequence and let the FOREACH loop run until the iterator returns a value greater than the user-specified maximum value (or an unsigned overflow occurs). Be sure to clean up the stack after leaving the FOREACH loop.
- 17) Write a “Craps” game. Craps is played with two six-sided die<sup>1</sup> and the rules are the following:  
 A player rolls a pair of dice and sums up the total of the two die. If the sum is 7 or 11, the player automatically wins. If the sum is 2, 3, or 12 then the player automatically loses (“craps out”). If the total is any other value, this becomes the player’s “point.” The player continues to throw the die until rolling either a seven or the player’s point. If the player rolls a seven, the player loses. If the player rolls their point, they win. If the player rolls any other value, play continues with another roll of the die.  
 Write a function “dice” that simulates a roll of one dice (hint: take a look at the HLA Standard Library *rand.range* function). Call this function twice for each roll of the two die. In your program, display the value on each dice and their sum for each roll until the game is over. To make the game slightly more interesting, pause for user input (e.g., *stdin.ReadLn*) after each roll.
- 18) Modify program (17) to allow wagering. Initialize the player’s balance at \$5,000 U.S. For each game, let the user choose how much they wish to wager (up to the amount in their account balance). If the player wins, increase their account by the amount of the wager. If the player loses, decrease their account by the amount of the wager. The whole game ends when the player’s account drops to zero or the player chooses to “cash out” of the game.
- 19) Modify program (18) to allow multiple players. In a multi-player craps game only one player throws the dice. The other players take “sides” with the player or the house. Their wager is matched (and their individual account is credited accordingly) if they side with the winner. Their account is deducted by the amount of their wager if they side with the loser. When the program first begins execution, request the total number of players from the user and dynamically allocate storage for each of the players. After each game, rotate the player who “throws” the dice.
- 20) The “greatest common divisor” of two integer values A and B is the largest integer that evenly divides (that is, has a remainder of zero) both A and B. This function has the following recursive definition:  
 If either A or B is zero, then  $\text{gcd}(A, B)$  is equal to the non-zero value (or zero if they are both zero).  
 If A and B are not zero, then  $\text{gcd}(A, B)$  is equal to  $\text{gcd}(B, A \bmod B)$  where “mod” is the remainder of A divided by B.  
 Write a program that inputs two unsigned values A and B from the user and computes the greatest com-

---

1. “Die” is the plural of “dice” in case you’re wondering.

mon divisor of these two values.

- 21) Write a program that reads a string from the user and counts the number of characters belonging to a user-specified class. Use the HLA Standard Library character classification routines (`chars.isAlpha`, `chars.isLower`, `chars.isAlpha`, `chars.isAlphaNum`, `chars.isDigit`, `chars.isXDigit`, `chars.isGraphic`, `chars.isSpace`, `chars.isASCII`, and `chars.isCtrl`) to classify each character in the string. Let the user specify which character classification routine they wish to use when processing their input string. Use a single `CALL` instruction to call the appropriate `chars.XXXX` procedure (i.e., use a `CALL` table and a `CALL`-based switch statement, see “Procedural Parameter Exercise” on page 1199 for more details).
- 22) The HLA Standard Library arrays module (“array.hhf”) includes an `array.element` iterator that returns each element from an array (in row major order) and fails after returning the last element of the array. Write a program that demonstrates the use of this iterator when processing elements of a single dimension dynamic array.
- 23) The HLA Standard Library `array.element` iterator (see (22) above) has one serious limitation. It only returns sequential elements from an array; it ignores the shape of the array. That is, it treats two-dimensional (and higher dimensional) matrices as though they were a single dimensional array. Write a pair of iterators specifically designed to process elements of a two-dimensional array: `rowIn` and `elementInRow`. The prototypes for these two iterators should be the following:

```
type
 matrix: dArray(uns32, 2);

iterator rowIn(m:matrix);
iterator elementInRow(m:matrix; row:uns32);
```

The `rowIn` iterator returns success for each row in the matrix. It also returns a row number in the EAX register ( $0..n-1$  where  $n$  is the number of rows in the matrix). The `elementInRow` iterator returns success  $m$  times where  $m$  is the number of columns in the matrix. Note that the `uns32` value `m.dopeVector[0]` specifies the number of rows and the `uns32` value `m.dopeVector[4]` specifies the number of columns in the matrix (see the HLA Standard Library documentation for more details). The `elementInRow` iterator should return the value of each successive element in the specified row on each iteration of the corresponding `FOREACH` loop.

Write a program to test your iterators that reads the sizes for the dimensions from the user, dynamically allocates the storage for the matrix (using `array.daAlloc`), inputs the data for the matrix, and then uses the two iterators (in a pair of nested `FOREACH` loops) to display the data.

- 24) The sample program in the chapter on advanced arithmetic (BCDio, see “Sample Program” on page 876) “cheats” on decimal output by converting the output value to a signed 64-bit quantity and then calling `stdout.puti64` to do the actual output. You can use this same trick for input (i.e., call `stdin.geti64` and convert the input integer to BCD) if you check for BCD overflow (18 digits) prior to the conversion. Modify the sample program to use this technique to input BCD values. Be sure that your program properly handles 18 digits of ‘9’ characters on input but properly reports an error if the value is 19 digits or longer.
- 25) Write a procedure that multiplies two signed 64-bit integer values producing a 128-bit signed integer result. The procedure’s prototype should be the following:

```
type
 int64: dword[2];
 int128: dword[4];

procedure imul64(mcand:int64; mplier:int64; var product:int128);
```

The procedure should compute `mcand*mplier` and leave the result in `product`. Create a UNIT that contains this library module and write a main program (in a separate source file) that calls and tests your division routine.

- 26) Write an extended precision unsigned division procedure that divides a 128-bit unsigned integer by a 32-bit unsigned integer divisor. (hint: use the extended precision algorithm involving the DIV instruction.) The procedure's prototype should be the following:

```
type
 uns128: dword[4];

 procedure div128
 (
 dividend:uns128;
 divisor:dword;
 var quotient:uns128;
 var remainder:dword
);
```

- 27) Write an extended precision signed division procedure that divides one *int128* object by another *int128* object. Place this procedure in a UNIT and write a main program (in a separate module) that calls this routine in order to test it. Be sure to handle a division by zero error (raise the *ex.DivideError* exception if a division by zero occurs).

The procedure's prototype should be the following:

```
type
 int128: dword[4];

 procedure idiv128
 (
 dividend:int128;
 divisor:int128;
 var quotient:int128;
 var remainder:int128
);
```

- 28) Extend the *idiv128* procedure from (27) to use the fast division algorithm if the H.O. 96 bits of the divisor are all zero (the fast algorithm uses the DIV instruction). If the H.O. 96 bits are not all zero, fall back to the algorithm you wrote for problem (26).
- 29) Write a procedure, *shr128*, that shifts the bits in a 128-bit operand to the right *n* bit positions. Use the SHRD instruction to implement the shift. The procedure's prototype should be the following:

```
type
 uns128: dword[4];

 procedure shr128(var operand:uns128; n:uns32);
```

The function should leave the result in the *operand* variable and the carry flag should contain the value of the last bit the procedure shifts out of the *operand* parameter.

- 30) Write an extended precision ROR procedure, *ror128*, that does a ROR operation on a 128-bit operand. The prototype for the procedure is

```
type
 uns128: dword[4];

 procedure ror128(var operand:uns128; n:uns32);
```

The function should leave the result in the *operand* variable and the carry flag should contain the value of the last bit the procedure shifts out of bit zero of the *operand* parameter.

- 31) Write an extended precision ROL procedure, `ror128`, that does a ROR operation on a 128-bit operand. The prototype for the procedure is

```
type
 uns128: dword[4];

 procedure rol128(var operand:uns128; n:uns32);
```

The function should leave the result in the *operand* variable and the carry flag should contain the value of the last bit the procedure shifts out of bit 63 of the *operand* parameter.

- 32) Write a 256-bit unsigned integer extended precision output routine (`putu256`). Place the procedure in a UNIT (`IO256`) and write a main program that calls the procedure to test it. The procedure prototype should be the following:

```
type
 uns256: dword[8];

 procedure putu256(operand:uns256);
```

- 33) Extend the 256-bit output UNIT by adding a "`puti256`" procedure that prints 256-bit signed integer values. The procedure prototype should be the following:

```
type
 int256: dword[8];

 procedure puti256(operand:int256);
```

- 34) A 256-bit integer (signed or unsigned) value requires a maximum of approximately 80 to 100 digits to represent (this value was approximated by noting that every ten binary bits is roughly equivalent to three or four decimal digits). Write a pair of routines (and add them to the `IO256` UNIT) that will calculate the number of print positions for an *uns256* or *int256* object (don't forget to count the minus sign if the number is negative). These functions should return the result in the EAX register and they have the following procedure prototypes:

```
type
 uns256: dword[8];
 int256: dword[8]

 procedure isize256(operand:int256);
 procedure usize256(operand:uns256);
```

Probably the best way to determine how many digits the number will consume is to repeatedly divide the value by 10 (incrementing a digit counter) until the result is zero. Don't forget to negate negative numbers (*isize256*) prior to this process.

- 35) Extend the `IO256` UNIT by writing *puti256Size* and *putu256Size*. These procedures should print the value of their parameter to the standard output device adding padding characters as appropriate for the parameter's value and the number of specified print positions. The function prototypes should be the following:

```
procedure puti256Size(number:int256; width:int32; fill:char);
procedure putu256Size(number:uns256; width:int32; fill:char);
```

See the HLA Standard Library documentation for the *stdout.puti32Size* and *stdout.putu32Size* routine for more information about the parameters.

- 36) Extend the IO256 UNIT by writing an *uns256* input routine, *getu256*. The procedure should use the following prototype:

```
type
 uns256: dword[8];

 procedure getu256(var operand:uns256);
```

- 37) Add a *geti256* input routine to the IO256 UNIT. This procedure should read 256-bit signed integer values from the standard input device and store the two's complement representation in the variable the caller passes by reference. Don't forget to handle the leading minus sign on input. The prototype should be

```
type
 int256: dword[8];

 procedure geti256(var operand:int256);
```

- 38) Write a procedure that multiplies two four-digit unpacked decimal values utilizing the MUL and AAM instructions. Note that the result may require as many as eight decimal digits.
- 39) Modify Program 7.8 by changing the "PUT32" macro to handle 8, 16, and 32-bit integers, unsigned integer, or hex (byte, word, and dword) variables.
- 40) Modify Program 7.9 by changing the *puti32* macro to handle 8, 16, and 32-bit integers, unsigned integers, and hexadecimal (byte, word, dword) values. (rename the macro to *puti* so that the name is a little more appropriate). Of course, you should still handle multiple parameters (calling *putXXXsize* if more than one parameter).
- 41) Write a SubStr function that extracts a substring from a zero terminated string. Pass a pointer to the string in esi, a pointer to the destination string in edi, the starting position in the string in eax, and the length of the substring in ecx. Be sure to handle degenerate conditions.
- 42) Write a word *iterator* to which you pass a string (by reference, on the stack). Each each iteration of the corresponding FOREACH loop should extract a word from this string, *strmalloc* sufficient storage for this string on the heap, copy that word (substring) to the malloc'd location, and return a pointer to the word. Write a main program that calls the iterator with various strings to test it.
- 43) Write a *strncpy* routine that behaves like str.cpy except it copies a maximum of *n* characters (including the zero terminating byte). Pass the source string's address in edi, the destination string's address in esi, and the maximum length in ecx.
- 44) The MOVSB instruction may not work properly if the source and destination blocks overlap (see "The MOVS Instruction" on page 910). Write a procedure *bcopy* to which you pass the address of a source block, the address of a destination block, and a length, that will properly copy the data even if the source and destination blocks overlap. Do this by checking to see if the blocks overlap and adjusting the source pointer, destination pointer, and direction flag if necessary.
- 45) As you will discover in the lab experiments, the MOVSD instruction can move a block of data much faster than MOVSB or MOVSW can move that same block. Unfortunately, it can only move a block that contains an even multiple of four bytes. Write a "fastcopy" routine that uses the MOVSD instruction to copy all but the last one to three bytes of a source block to the destination block and then manually copies the remaining bytes between the blocks. Write a main program with several boundary test cases to verify correct operation. Compare the performance of your fastcopy procedure against the use of the MOVSB instruction.
- 46) Write a macro that computes the absolute value of an integer or floating point parameter. It should generate the appropriate code based on the type of the macro parameter.
- 47) Write a program that implements and tests the `_repeat.._until( expr )` statement using HLA's multi-part macros. The macros should expand into JT or JF statements (i.e., don't simply expand these into HLA's repeat..until statement).
- 48) Write a program that implements and tests the `_begin.._exit.._exitif.._end` statements using HLA's multi-part macros. Your macros should expand into JMP, JT, and/or JF instructions; do not expand the

text to HLA's BEGIN..EXIT..EXITIF..END statement. Note: you do not have to handle procedure or program exits in this assignment.

- 49) The HLA #PRINT statement does not provide numeric formatting facilities. If you specify a constant integer expression as an operand, for example, it will simply print that integer using the minimum number of print positions the integer output requires. If you wish to display columns of numbers in a compile-time program, this can be a problem. Write a macro, *fmtInt( integer, size )*, that accepts an integer expression as its first operand and a field width as its second operand and returns a string with the integer representation of that constant right justified in a field whose width the second parameter specifies. Note that you can use the @string function to convert the integer to a string and then you can use the string concatenation operator and the @strset function to build the formatted string. Test your macro thoroughly; make sure it works properly with the specified size is less than the size the integer requires.
- 50) Write a function and a macro that compute signum (Signum(i): -1 if i < 0, 0 if i=0, +1 if i>0). Write a short main program that invokes the macro three times within the body of a FOR loop: once with the value -10, once with the value zero, and once with the value +10. Adjust the loop control variable so the program requires approximately ten seconds to execute. Next, add a second loop to the main program that executes the same number of iterations as the first loop; in that loop body, however, place a call to signum function you've written. Compare the execution times of the two loops.
- 51) Add a remainder (modulo) operator to Program 9.7. Use "%" as the symbol for the mod operator (for you "C" programmers out there, "%" is already in use for binary numbers in this program). The mod operator should have the same precedence and associativity as the multiplication and division operators.
- 52) Modify Program 9.7 (or the program in problem (51), above) to support signed integers rather than unsigned integers.
- 53) Modify Program 13.21 in the lab exercises to add \_break and \_continue statements to the \_for..\_endfor and \_while..\_endwhile loops. Of course, your new control structures must provide the same tracing facilities as Program 13.21 currently provides.
- 54) Modify Program 13.21 to include an \_if..\_elseif..\_else..\_endif statement with the tracing facilities.
- 55) Modify Program 13.21 to include \_repeat..\_until and \_forever..\_endfor loops. Be sure to provide \_break and \_continue macros for each of these loops. Of course, your new control structures must provide the same tracing facilities that Program 13.21 currently provides.
- 56) Modify Program 13.21 to include an \_switch..\_case..\_default..\_endswitch statement with tracing facilities. The trace output (if engaged) should display entry into the \_switch statement, display the particular \_case (or \_default) the statement executes, and the display an appropriate message upon exit (i.e., executing \_endswitch).
- 57) Add a "triangle" class to the shapes class in the Classes chapter's sample program. The object should draw images that look like the following:

The minimum width and height of a triangle object should be  $2 \times 2$ . The object itself will always have a width that is equal to  $(\text{height} - 1) * 2$ .

See the *diamond* class implementation to get a good idea how to draw a triangle. Don't forget to handle filled and unfilled shapes (based on the *fillShape* field).

Modify the main program to draw several triangles in addition to the other shapes (demonstrate the correct operation of filled and unfilled triangles in your output).

- 58) Add a "parallelogram" class to the Classes chapter's sample program. The parallelogram class should draw images that look like the following:

The width of a parallelogram will always be equal to the width of the base plus the height minus one (e.g., in the example above, the base width is eight and the height is four, so the overall width is  $8 + (4 - 1) = 11$ ).

- 59) Modify the parallelogram class from the project above to include a boolean data field *slantRight* that draws the above parallelogram if true and draws the following if false:

Don't forget to initialize the *slantRight* field (to true) inside the constructor.

- 60) Add a "Tab" class to the Class chapter's sample program. The tab class should introduce a new boolean data field, *up*, and draw the following images based on the value of the *up* field.

up=false:

up=true:

Note that the width must always be an even value (just like diamonds and triangles). The height should always be at least width-2. If the height is greater than this, extend the size of the tab by drawing additional vertical bar sections.

- 5) (Term project) Add a mouse-based user interface to the ASCIIdraw drawing program (the sample program in the Classes chapter). See the HLA console library module for information about reading the mouse position and other console related routines you can use.

### 13.3 Laboratory Exercises

Accompanying this text is a significant amount of software. The software can be found in the AoA\_Software directory. Inside this directory is a set of directories with names like Vol3 and Vol4, each containing additional subdirectories like *Ch06* and *Ch07*, with the names obviously corresponding to chapters in this textbook. All the source code to the example programs in this chapter can be found in the Vol4\Ch08 subdirectory. Please see this directory for more details.

---

### 13.3.1 Dynamically Nested TRY..ENDTRY Statements

In this laboratory experiment you will explore the effect of dynamically nesting TRY..ENDTRY statements in an HLA program. This lab exercise uses the following program:

---

```

program DynNestTry;
#include("stdlib.hhf");

 // NestedINTO-
 //
 // This routine reads two hexadecimal values from
 // the user, adds them together (checking for
 // signed integer overflow), and then displays their
 // sum if there was no overflow.

 procedure NestedINTO;
 begin NestedINTO;

 try

 stdout.put("Enter two hexadecimal values: ");
 stdin.get(al, ah);
 add(ah, al);
 into();
 stdout.put("Their sum was $", al, nl);

 exception(ex.ValueOutOfRange)

 stdout.put("The values must be in the range $0..$FF" nl);

 exception(ex.ConversionError)

 stdout.put("There was a conversion error during input" nl);

 endtry;

 end NestedINTO;

begin DynNestTry;

 // The following code calls NestedINTO to read and add
 // two hexadecimal values. If an overflow occurs during
 // the addition, an INTO instruction triggers the following
 // exception.

 try

 stdout.put("Calling NestedINTO" nl);
 NestedINTO();
 stdout.put("Returned from NestedINTO" nl);

 exception(ex.IntoInstr);

 stdout.put("INTO detected an integer overflow" nl);

 endtry;

 stdout.put("After ENDTRY" nl);

```

```
end DynNestTry;
```

---

### Program 13.1 Dynamically Nested TRY..ENDTRY Statements

---

Exercise A: Compile and run this program. Supply as input the two values “12” and “34”. Describe the output, and why you got this particular output in your lab report.

Exercise B: Supply the two values “7F” and “10” as input to this program. Include the output from the program in your lab report and explain the results.

Exercise C: Supply the two values “AT” and “XY” as input to this program. Include the output from the program in your lab report and explain the results.

Exercise D: Supply the two values “1234” and “100” as input to this program. Include the output from the program in your lab report and explain the results.

Explain the difference between a statically nested control structure and a dynamically nested control structure in your lab report. Also explain why the TRY..ENDTRY statements in this program are dynamically nested.

---

### 13.3.2 The TRY..ENDTRY Unprotected Section

In this laboratory exercise you will explore what happens if you attempt to break out of a TRY..ENDTRY statement in an inappropriate fashion. This exercise makes use of the following program:

---

```
program UnprotectedClause;
#include("stdlib.hhf");

begin UnprotectedClause;

 // The following loop forces the user to enter
 // a pair of valid eight-bit hexadecimal values.
 // Note that the "unprotected" clause is commented
 // out (this is a defect in the code). Follow the
 // directions in the lab exercise concerning this
 // statement.

 forever

 try

 stdout.put("Enter two hexadecimal values: ");
 stdin.get(ah, al);

 //unprotected

 break;

 exception(ex.ValueOutOfRange)

 stdout.put("The values must be in the range $0..$FF" nl);

 exception(ex.ConversionError)

 stdout.put("There was a conversion error during input" nl);

 endtry;
```

```

endfor;
add(ah, al);
stdout.put("Their sum was $", al, nl);

stdout.put("Enter another hexadecimal value: ");
stdin.get(al);
stdout.put("The value you entered was $", al, nl);

end UnprotectedClause;

```

---

---

### Program 13.2 The TRY..ENDTRY Unprotected Section

---

---

Exercise A: Compile and run this program. When it asks for two hexadecimal values enter the values “12” and “34”. When this program asks for a third hexadecimal value, enter the text “xy”. Include the output of this program in your lab report and explain what happened.

Exercise B: The UNPROTECTED statement in this program is commented out. Remove the two slashes before the UNPROTECTED keyword and repeat exercise A. Explain the difference in output between the two executions of this program.

Exercise C: Put a TRY..ENDTRY block around the second stdin.get call in this program (it must handle the ex.ConversionError exception). Remove the UNPROTECTED clause (i.e., comment it out again) in the first TRY..ENDTRY block. Repeat exercise A. Include the source code and output of the program in your lab report. Explain the difference in execution between exercises A, B, and C in your lab report.

---

### 13.3.3 Performance of SWITCH Statement

In this laboratory exercise you will get an opportunity to explore the difference in performance between the jump table implementation of a SWITCH statement versus the IF.ELSEIF implementation of a switch. Note that this code relies upon the Pentium RDTSC instruction. If you do not have access to a CPU that supports this instruction you will have to skip this exercise or rewrite the code to use timing loops to approximate the running time (see “Timing Various Arithmetic Instructions” on page 690 to see how you can use loops to increase the running time to the point you can measure the difference between the two algorithms using a stopwatch).

```

program switchStmt;
#include("stdlib.hhf");

static
 Cycles: qword;

 JumpTbl:dword[11] :=
 [
 &CaseDefault, //0
 &case123, //1
 &case123, //2
 &case123, //3
 &case4, //4
 &CaseDefault, //5
 &CaseDefault, //6
 &case78, //7
 &case78, //8
 &case9, //9
 &case10 //10
];

```

```

begin switchStmt;

 stdout.put("Switch vs. IF/ELSEIF demo" nl nl);

 stdout.put
 (
 "Counting the cycles for 10 invocations of the SWITCH stmt:"
 nl
 nl
);

 // Start timing the number of cycles required by the following
 // loop. Note that this code requires a Pentium or compatible
 // processor that supports the RDTSC instruction.

 rdtsc();
 push(edx);
 push(eax);

 // The following loop cycles through the values 0..15
 // in order to ensure that we hit all the cases and
 // then some (not accounted for in the jump table).

 mov(15, esi);
 xor(edi, edi);
 Rpt16TimesA:

 cmp(esi, 10); // Cases beyond 10 go to the default label
 ja CaseDefault; // 'cause we only have 11 entries in the tbl.
 jmp(JumpTbl[esi*4]); // Jump to the specified case handler.

 case123: // Handles cases 1, 2, and 3.

 jmp EndCase;

 case4: // Handles case ESI = 4.

 jmp EndCase;

 case78: // Handles cases ESI = 7 or 8.

 jmp EndCase;

 case9: // Handle case ESI = 9.

 jmp EndCase;

 case10: // Handles case ESI = 10.

 jmp EndCase;

 CaseDefault: // Handles cases ESI = 0, 5, 6, and >=11.

 EndCase:
 dec(esi);
 jns Rpt16TimesA;

```

```

// Calculate the number of cycles required by the code above:
// Note: This requires a Pentium processor (or other CPU that
// has a RDTSC instruction).

rdtsc();
pop(ebx);
sub(ebx, eax);
mov(eax, (type dword Cycles[0]));

pop(eax);
sub(eax, edx);
mov(edx, (type dword Cycles[4]));
stdout.put("Cycles for SWITCH stmt: ");
stdout.putu64(Cycles);

stdout.put
(
 nl
 nl
 "Counting the cycles for 10 invocations of the IF/ELSEIF sequence:"
 nl
 nl
);

// Begin counting the number of cycles required by the IF..ELSEIF
// implementation of the SWITCH statement.

rdtsc();
push(edx);
push(eax);

mov(15, esi);
xor(edi, edi);
Rpt16TimesB:

 cmp(esi, 1);
 jb Try4;
 cmp(esi, 3);
 ja Try4;

 jmp EndElseIf;

Try4:
 cmp(esi, 4);
 jne Try78;

 jmp EndElseIf;

Try78:
 cmp(esi, 7);
 je Is78;
 cmp(esi, 8);
 jne Try9;

Is78:
 jmp EndElseIf;

```

```

Try9:
cmp(esi, 9);
jne Try10;

 jmp EndElseIf;

Try10:
cmp(esi, 10);
jne DefaultElseIf;

 jmp EndElseIf;

DefaultElseIf:

EndElseIf:
dec(esi);
jns Rpt16TimesB;

// Okay, compute the number of cycles required
// by the IF..ELSEIF version of the SWITCH.
rdtsc();
pop(ebx);
sub(ebx, eax);
mov(eax, (type dword Cycles[0]));

pop(eax);
sub(eax, edx);
mov(edx, (type dword Cycles[4]));
stdout.put("Cycles for IF/ELSEIF stmt: ");
stdout.putu64(Cycles);

end switchStmt;

```

---

### Program 13.3 Performance of SWITCH Statement.

---

Exercise A: Compile and run this program several times and average the cycles times for the two different implementations. Include the results in your lab report and discuss the difference in timings.

Exercise B: Remove the cases (from both implementations) one at a time until the running time is identical for both implementations. How many cases is the break-even point for using a jump table? Include the source code of the modified program in your lab report.

Exercise C: One feature of this particular program is that the loop control variable cycles through all the possible case values (and then some). Modify both loops so that they still repeat sixteen times, but they do not use the loop control variable as the value to select the particular case. Instead, fix the case so that it always uses the value one rather than the value of the loop control variable. Rerun the experiment and describe your findings.

Exercise D: Repeat exercise C, except fix the case value at 15 rather than zero. Report your findings in your lab report.

---

### 13.3.4 Complete Versus Short Circuit Boolean Evaluation

In this laboratory exercise you will measure the execution time of two instruction sequence. One sequence computes a boolean result using complete boolean evaluation; the other uses short circuit boolean evaluation. Like the previous exercises, the code for this exercise uses the Pentium RDTSC instruction. You will need to modify this code if you intend to run it on a processor that does not support RDTSC.

---

```

program booleanEvaluation;
#include("stdlib.hhf");

static

 Cycles: qword;
 theRslt: string;

 FalseCBE: string := "Complete Boolean Evaluation result was true";
 TrueCBE: string := "Complete Boolean Evaluation result was false";

 FalseSC: string := "Short Circuit Evaluation result was true";
 TrueSC: string := "Short Circuit Evaluation result was false";

 input: int8;

 a: boolean;
 b: boolean;
 c: boolean;
 d: boolean;

begin booleanEvaluation;

 // Get some input from the user that
 // we can use to initialize our boolean
 // variables with:

 forever

 try

 stdout.put("Enter an eight-bit signed integer value: ");
 stdin.get(input);
 unprotected break;

 exception(ex.ConversionError)

 stdout.put("Input contained illegal characters");

 exception(ex.ValueOutOfRange)

 stdout.put("Value must be between -128 and +127");

 endtry;
 stdout.put(", please reenter" nl);

 endfor;

 // Okay, set our boolean variables to the following
 // values:

```

```

//
// a := input < 0;
// b := input >= -10;
// c := input <= 10;
// d := input = 0;

cmp(input, 0);
setl(a);
cmp(input, -10);
setge(b);

---

---

### Program 13.4 Complete vs. Short Circuit Boolean Evaluation

---

---

Exercise A: Compile and run this program. Run the program several times in a row and compute the average execution time, in cycles, for each of the two methods. Be sure to specify the input value you use (use the same value for each run) in your lab report.

Exercise B: Repeat exercise A for each of the following input values: -100, -10, -5, 0, 5, 10, 100. Provide a graph of the average execution times for Complete Boolean Evaluation and Short Circuit Boolean evaluation in your laboratory report.

### 13.3.5 Conversion of High Level Language Statements to Pure Assembly

For this exercise you will write a short demonstration program that uses the following HLA statements: `if..elseif..else..endif`, `switch..case..default..endswitch` (from the HLA Standard Library `hll.hhf` module), `while..endwhile`, `repeat..until`, `forever..breakif..endfor`, `for..endfor`, and `begin..exit..end` (the program doesn't have to do anything particularly useful, though the bodies of these statements should not be empty).

Exercise A: Write, compile, run, and test your program. Describe what the program does in your lab report. Include a copy of the program in your lab report.

Exercise B: Convert the `if..elseif..else..endif`, `while..endwhile`, and `repeat..until` statements to the hybrid control statements that HLA provides (see "Hybrid Control Structures in HLA" on page 778). Rerun the program with appropriate inputs and verify that its behavior is the same as the original program. Describe the changes you've made and include the source code in your lab report.

Exercise C: Create a new version of the program you created in exercise A, this time convert the control structures to their low-level, pure assembly language form. Include the source code with your laboratory report. Comment on the readability of the three programs.

### 13.3.6 Activation Record Exercises

In this laboratory exercise you will construct and examine procedure activation records. This exercise involves letting HLA automatically construct the activation record for you as well as manual construction of activation records and manually accessing data in the activation record.

#### 13.3.6.1 Automatic Activation Record Generation and Access

The following program calls a procedure and returns the values of EBP and ESP from the procedure after it has constructed the activation record. The main program then computes the size of the activation record by subtracting the difference between ESP before the call and ESP during the call.

```
// This program computes and displays the size of
// a procedure's activation record at run-time.
// This code relies on HLA's high level syntax
// and code generation to automatically construct
// the activation record.

program ActRecSize;
#include("stdlib.hhf")

type
 rec:record

 u:uns32;
 i:int32;
 r:real64;

 endrecord;
```

```

// The following procedure allocates storage for the activation
// record on the stack and then returns the pointer to the bottom
// of the activation record (ESP) in the EAX register. It also
// returns the pointer to the activation record's base address (EBP)
// in the EBX register.

procedure RtnARptr(first:uns32; second:real64; var third:rec); nodisplay;
var
 b:byte;
 c:char;
 w:word;
 d:dword;
 a:real32[4];
 r:rec[4];

begin RtnARptr;

 mov(esp, eax);
 mov(ebp, ebx);

end RtnARptr;

var
 PassToRtnARptr: rec;

begin ActRecSize;

 // Begin by saving the ESP and EBP register values in
 // ECX and EDX (respectively) so we can display their
 // values and compute the size of RtnARptr's activation
 // record after the call to RtnARptr.

 mov(esp, ecx);
 mov(ebp, edx);
 RtnARptr(1, 2.0, PassToRtnARptr);

 // Display ESP/EBP value before and after the call to RtnARptr:

 mov(esp, edi);
 stdout.put("ESP before call: $", ecx, " ESP after call: $", edi, nl);

 mov(ebp, edi);
 stdout.put("EBP before call: $", edx, " EBP after call: $", edi, nl);

 // Display the activation record information:

 stdout.put("EBP value within RtnARptr: $", ebx, nl);
 stdout.put("ESP value within RtnARptr: $", eax, nl);
 sub(eax, ecx);
 stdout.put
 (
 "Size of RtnARptr's activation record: ",
 (type uns32 ecx),
 nl
);

end ActRecSize;

```

---

---

**Program 13.5 Computing the Size of a Procedure's Activation Record**

---

---

Exercise A: Execute this program and discuss the results in your lab report. Draw a stack diagram of *RtnARptr*'s activation record that carefully shows the position of each named variable in the *RtnARptr* procedure.

Exercise B: Change the parameter *third* from pass by reference to pass by value. Recompile and rerun this program. Discuss the differences between the results from Exercise A and the results in this exercise. Provide a stack diagram that describes the activation record for this version of the program.

---

### 13.3.6.2 The `_vars_` and `_parms_` Constants

Whenever the HLA compiler encounters a procedure declaration, it automatically defines two local *uns32* constants, `_vars_` and `_parms_`, in the procedure. The `_vars_` constant specifies the number of bytes of local (automatic) variables the procedure declares. The `_parms_` constant specifies the number of bytes of parameters the caller passes to the procedure. The following program displays these two values for a typical procedure.

---

---

```
// This program demonstrates the use of the _vars_
// and _parms_ constants in an HLA procedure.

program VarsParmsDemo;
#include("stdlib.hhf")

type
 rec:record
 u:uns32;
 i:int32;
 r:real64;
 endrecord;

// The following procedure allocates storage for the activation
// record and then displays the values of the _vars_ and _parms_
// constants that HLA automatically creates for the procedure.
// This procedure also returns the ESP/EBP values in the EAX
// and EBX registers (respectively).

procedure VarsAndParms
(
 first:uns32;
 second:real64;
 var third:rec
); nodisplay;

var
 b:byte;
 c:char;
 w:word;
 d:dword;
 a:real32[4];
```

```

 r:rec[4];

begin VarsAndParms;

 stdout.put
 (
 "_vars_ = ",
 vars,
 nl
);

 stdout.put
 (
 "_parms_ = ",
 parms,
 nl
);

 mov(esp, eax);
 mov(ebp, ebx);

end VarsAndParms;

var
 PassToProc: rec;

begin VarsParmsDemo;

 // Begin by saving the ESP and EBP register values in
 // ECX and EDX (respectively) so we can display their
 // values and compute the size of RtnARptr's activation
 // record after the call to RtnARptr.

 mov(esp, ecx);
 mov(ebp, edx);
 VarsAndParms(2, 3.1, PassToProc);

 // Display ESP/EBP value before and after the call to RtnARptr:

 mov(esp, edi);
 stdout.put("ESP before call: $", ecx, " ESP after call: $", edi, nl);

 mov(ebp, edi);
 stdout.put("EBP before call: $", edx, " EBP after call: $", edi, nl);

 // Display the activation record information:

 stdout.put("EBP value within VarsAndParms: $", ebx, nl);
 stdout.put("ESP value within VarsAndParms: $", eax, nl);
 sub(eax, ecx);
 stdout.put
 (
 "Size of VarsAndParms's activation record: ",
 (type uns32 ecx),
 nl
);
);

end VarsParmsDemo;

```

---

---

**Program 13.6 Demonstration of the `_vars_` and `_parms_` Constants**

---

---

Exercise A: Run this program and describe the output you obtain in your lab report. Explain why the sum of the two constants `_vars_` and `_parms_` does not equal the size of the activation record.

Exercise B: Comment out the “c:char;” declaration in the `VarsAndParms` procedure. Recompile and run the program. Note the output of the program. Now comment out the “d:dword;” declaration in the `VarsAndParms` procedure. In your lab report, explain why eliminating the first declaration did not produce any difference while commenting out the second declaration did (hint: see “The Standard Entry Sequence” on page 789).

---

### 13.3.6.3 Manually Constructing an Activation Record

The `_vars_` and `_parms_` constants come in real handy if you decide to construct and destroy activation records manually. The `_vars_` constant specifies how many bytes of local variables you must allocate in the standard entry sequence and the `_parms_` constant specifies how many bytes of parameters you need to remove from the stack in the standard exit sequence. The following program demonstrates the manual construction and destruction of a procedure’s activation record using these constants.

---

---

```

program ManActRecord;
#include("stdlib.hhf")

type
 rec:record

 u:uns32;
 i:int32;
 r:real64;

 endrecord;

// The following procedure manually allocates storage for the activation
// record. This procedure also returns the ESP/EBP values in the EAX
// and EBX registers (respectively).

procedure VarsAndParms
(
 first:uns32;
 second:real64;
 var third:rec
); nodisplay; noframe;

var
 b:byte;
 c:char;
 w:word;
 d:dword;
 a:real32[4];
 r:rec[4];

begin VarsAndParms;

```

```

// The standard entry sequence.
// Note that the stack alignment instruction is
// commented out because we know that the stack
// is properly dword aligned whenever the program
// calls this procedure.

push(ebp); // The standard entry sequence.
mov(esp, ebp);
sub(_vars_, esp); // Allocate storage for local variables.
//and($FFFF_FFC, esp); // Dword-align ESP.

stdout.put
(nl
 "VarsAndParms allocates ",
 vars,
 " bytes of local variables and " nl
 "automatically removes ",
 parms,
 " parameter bytes on return." nl
 nl
);
mov(esp, eax);
mov(ebp, ebx);

// Standard exit sequence:

mov(ebp, esp);
pop(ebp);
ret(_parms_); // Removes parameters from stack.

end VarsAndParms;

static
 PassToProc: rec;
 FourPt2: real64 := 4.2;

begin ManActRecord;

 // Begin by saving the ESP and EBP register values in
 // ECX and EDX (respectively) so we can display their
 // values and compute the size of RtnARptr's activation
 // record after the call to RtnARptr.

 mov(esp, ecx);
 mov(ebp, edx);

 // Though not really necessary for this example, the
 // following code manually constructs the parameters
 // portion of the activation record by pushing the
 // data onto the stack. This program could have used
 // the HLA high level syntax for the code as well.

 pushd(3); // Push value of "first" parameter.
 push((type dword FourPt2[4])); // Push value of "second" parameter.
 push((type dword FourPt2[0]));
 pushd(&PassToProc); // Push address of record item.
 call VarsAndParms;

 // Display ESP/EBP value before and after the call to RtnARptr:

 mov(esp, edi);

```

```

stdout.put("ESP before call: $", ecx, " ESP after call: $", edi, nl);

mov(ebp, edi);
stdout.put("EBP before call: $", edx, " EBP after call: $", edi, nl);

// Display the activation record information:

stdout.put("EBP value within VarsAndParms: $", ebx, nl);
stdout.put("ESP value within VarsAndParms: $", eax, nl);
sub(eax, ecx);
stdout.put
(
 "Size of VarsAndParms's activation record: ",
 (type uns32 ecx),
 nl
);

end ManActRecord;

```

---

### Program 13.7 Manual Construction and Destruction of an Activation Record

---

Exercise A: Compile and run this program. Discuss the output in your lab report. Especially note the values of ESP and EBP before and after the call to the procedure. Does the procedure properly restore all values?

Exercise B: Change the *third* parameter from pass by reference to pass by value. You will also need to change the call to *VarsAndParms* so that you pass the record by value (the easiest way to do this is to use the HLA high level procedure call syntax and let HLA generate the code that copies the record; if you manually write this code, be sure to push 16 bytes on the stack for the *third* parameter). Recompile and run the program. Describe the results in your lab manual.

Exercise C: Add several additional local (automatic) variables to the *VarsAndParms* procedure. Recompile and run the program. Explain why using the *\_vars\_* and *\_parms\_* constants when manually constructing the activation record is far better than specifying literal constants in the “sub( xxx, esp);” and “ret( yyy );” instructions in the standard entry and exit sequences.

---

### 13.3.7 Reference Parameter Exercise

In this laboratory exercise you will explore the behavior of pass by reference versus pass by value parameters. This program passes a pair of global static variables by value and by reference to some procedures that modify their formal parameters. The program prints the result of the modifications before and after the procedure calls (and the actual modifications). This program also demonstrates passing formal value parameters by reference and passing formal reference parameters by value.

---

```

// This program demonstrates pass by reference
// and pass by value parameters.

program PassByValRef;
#include("stdlib.hhf")

static
 GlobalV: uns32;
 GlobalR: uns32;

```

```

// ValParm-
//
// Demonstrates immutability of actual value parameters.

procedure ValParm(v:uns32);
begin ValParm;

 stdout.newln();
 stdout.put("ValParm, v(before) = ", v, nl);
 mov(1, v);
 stdout.put("ValParm, v(after) = ", v, nl);
 stdout.put("ValParm, GlobalV = ", GlobalV, nl);

end ValParm;

// RefParm-
//
// Demonstrates how to access the value of a pass by
// reference parameter. Also demonstrates the mutability
// of an actual parameter when passed by reference.
//
// Note that on all calls in this program, "r" and "GlobalR"
// are aliases of one another.

procedure RefParm(var r:uns32);
begin RefParm;

 push(eax);
 push(ebx);

 // Display the address and value of the reference parameter
 // "r" prior to making any changes to that value.

 mov(r, ebx); // Get address of value into EBX.
 mov([ebx], eax); // Fetch the value into EAX.
 stdout.newln();
 stdout.put("RefParm, Before assignment:" nl nl);
 stdout.put("r(address)= $", ebx, nl);
 stdout.put("r(value)= ", (type uns32 eax), nl);

 // Display the address and value of the GlobalR variable
 // so we can compare it against the "r" parameter.

 mov(&GlobalR, eax);
 stdout.put("GlobalR(address) =$", ebx, nl);
 stdout.put("GlobalR(value) = ", GlobalR, nl);

 // Okay, change the value of "r" from its current
 // value to "1" and redisplay everything.

 stdout.newln();
 stdout.put("RefParm, after assignment:" nl nl);

 mov(1, (type uns32 [ebx]));
 mov([ebx], eax);
 stdout.put("r(address)= $", ebx, nl);
 stdout.put("r(value)= ", (type uns32 eax), nl);

```

```

mov(&GlobalR, eax);
stdout.put("GlobalR(address) = $" , ebx, nl);
stdout.put("GlobalR(value) = ", GlobalR, nl);

pop(ebx);
pop(eax);

end RefParm;

// ValAndRef-
//
// This procedure has a pass by reference parameter and a pass
// by value parameter. It demonstrates what happens when you
// pass formal parameters in one procedure as actual parameters
// to another procedure.

procedure ValAndRef(v:uns32; var r:uns32);
begin ValAndRef;

push(eax);
push(ebx);

// Reset the global objects to some value other
// than one and then print the values and addresses
// of the local and global objects.

mov(25, GlobalV);
mov(52, v);
mov(75, GlobalR);

stdout.put(nl nl "ValAndRef: " nl);
lea(eax, v);
stdout.put("v's address is $" , eax, nl);
lea(eax, r);
stdout.put("r's address is $" , eax, nl);
stdout.put("r's value is $" , (type dword r), nl);
mov(r, ebx);
mov([ebx], eax);
stdout.put("r points at ", (type uns32 eax), nl nl);

// Pass value by value and reference by reference to
// the ValParm and RefParm procedures.

ValParm(v);
RefParm(r);

stdout.put
(
 nl
 "Inside ValAndRef after passing v by value, v=",
 v,
 nl
);

// Reset the global parameter values and then pass
// the reference parameter by value and pass the
// value parameter by reference.

```

```

mov(67, GlobalV);
mov(76, v);
mov(89, GlobalR);
ValParm(r);
RefParm(v);

// Display v's value before we leave.

stdout.put
(
 nl
 "Inside ValAndRef after passing v by reference, v=",
 v,
 nl
);

pop(ebx);
pop(eax);

end ValAndRef;

begin PassByValRef;

 mov(123435, GlobalV);
 mov(67890, GlobalR);
 ValParm(GlobalV);
 RefParm(GlobalR);

 ValAndRef(GlobalV, GlobalR);

end PassByValRef;

```

---

---

### Program 13.8 Parameter Passing Demonstration

---

---

Exercise A: Compile and run this program. Include the program output in your lab report. Annotate the output and explain the results it produces.

Exercise B: Modify the main program in this example to manually call ValParm, RefParm, and ValAndRef using the low-level syntax rather than the high level syntax (i.e., you must write the code to push the parameters onto the stack). Verify that you get the same results as before the modification.

---

### 13.3.8 Procedural Parameter Exercise

This exercise demonstrates an interesting feature of assembly language: the ability to create a SWITCH-like control structure that directly calls one of several functions rather than simply jumping to a statement via a jump table. This example takes advantage of the fact that the CALL instruction supports memory indirect forms, just like JMP, that allows an indexed addressing mode. The same logic you would use to simulate a SWITCH statement with an indirect JMP (see “SWITCH..CASE..DEFAULT..END-SWITCH” on page 725) applies to the indirect CALL as well.

This program requests two inputs from the user. The first is a value in the range ‘1’, ‘4’ that the program uses to select one of four different procedures to call. The second input is an arbitrary unsigned integer input that the program passes as a parameter to the procedure the user selects.

```
// This program demonstrates a CALL-based SWITCH statement.

program callSwitch;
#include("stdlib.hhf")

type
 tProcPtr: procedure(i:uns32);
 tProcPtrArray: tProcPtr[4];

 // Here is a set of procedure that we will
 // call indirectly (One, Two, Three, and Four).

 procedure One(i:uns32); nodisplay;
 begin One;

 stdout.put("One: ", i, nl);

 end One;

 procedure Two(i:uns32); nodisplay;
 begin Two;

 stdout.put("Two: ", i, nl);

 end Two;

 procedure Three(i:uns32); nodisplay;
 begin Three;

 stdout.put("Three: ", i, nl);

 end Three;

 procedure Four(i:uns32); nodisplay;
 begin Four;

 stdout.put("Four: ", i, nl);

 end Four;

static

 UserIn: uns32;

 // CallTbl is an array of pointers that this program uses
 // to create a "switch" statement that does a call rather
 // than a jump.

 CallTbl: tProcPtrArray := [&One, &Two, &Three, &Four];

begin callSwitch;
```

```

stdout.put("Call-based Switch Statement Demo: " nl nl);
repeat

 stdout.put("Enter a value in the range 1..4: ");
 stdin.flushInput();
 stdin.getc();
 if(al not in '1'..'4') then

 stdout.put("Illegal value, please reenter" nl);

 endif;

until(al in '1'..'4');
and($f, al); // Convert '1'..'4' to 1..4.
dec(al); // Convert 1..4 to 0..3.
movzx(al, eax); // Need a 32-bit value for use as index.

// Get a user input value for use as the parameter.

push(eax); // Preserve in case there's an exception.
forever

 try

 stdout.put("Enter a parameter value: ");
 stdin.get(UserIn);
 unprotected break;

 exception(ex.ValueOutOfRange)

 stdout.put("Value was out of range, please reenter" nl);

 exception(ex.ConversionError)

 stdout.put
 (
 "Input contained illegal characters, please reenter"
 nl
);

 endtry;

endfor;
pop(eax); // Restore index into "call table".

// Using an indirect call rather than an indirect jump,
// SWITCH off to the appropriate subroutine based on
// the user's input.

CallTbl[eax*4](UserIn); // Call the specified routine.

end callSwitch;

```

---

---

**Program 13.9 A CALL-based SWITCH Statement**

---

---

Exercise A: Compile and run this program four times. Select procedures One, Two, Three, and Four on each successive run of the program (you may supply any user input you desire). Include the program's output in your lab report.

Exercise B: Modify the program to print a short message immediately after the *CallTbl* procedure call. Recompile the program and verify that it really does return immediately after the "CallTbl[ eax\*4 ]( UserIn );" statement.

Exercise C: Add procedures *Six*, *Eight*, *Nine*, and *DefaultProc* to this program. Modify the program so that it lets the user input an *uns32* value rather than a single character to select the procedure to call. If the user inputs a value other than 1, 2, 3, 4, 6, 8, or 9, call the *DefaultProc* procedure. Be sure to test your program with input values zero and values beyond nine (e.g., 10234 ). See "SWITCH..CASE..DEFAULT..ENDSWITCH" on page 725 for details if you don't remember how to properly encode a SWITCH statement. Include the source code and the output of a sample run in your lab report. Explain how you designed the CALL/SWITCH statement.

### 13.3.9 Iterator Exercises

The HLA Standard Library includes several iterators. One such iterator appears in the random number generators package ("rand.hhf"). The *rand.deal* iterator takes a single integer parameter. It returns success the number of times specified by this parameter and then fails (e.g., *rand.deal*(10) will succeed ten times and fail on the eleventh iteration). On each iteration of the corresponding FOREACH loop, the *rand.deal* iterator will return a randomized value between zero and one less than the parameter value; however, *rand.deal* will return each value only once. That is, "*rand.deal*(n)" will return the values in the range 0..n-1 in a random order. This iterator was given the name *deal* because it simulates dealing a set of cards from a shuffled deck. of cards (indeed, if you iterate over "*rand.deal*(52)" you can deal out all 52 possible card values from a standard playing card deck). The following program uses the *rand.deal* function to shuffle a deck of standard playing cards and it displays four hands of five card dealt from this shuffled deck.

```
// This program demonstrates the use of the
// rand.deal iterator.

program dealDemo;
#include("stdlib.hhf")

type
 card: record
 face: string;
 suite: char;
 endrecord;

 deck: card[52];

readonly
 CardValue: string[13] :=
 ["A", "2", "3", "4", "5", "6", "7", "8", "9", "10", "J", "Q", "K"];

 CardGroup: char[4] :=
 [
 #3, // Symbol for hearts
```

```

 #4, // Symbol for diamonds
 #5, // Symbol for clubs
 #6 // Symbol for spades
];

procedure shuffle(var theDeck: deck); nodisplay;
begin shuffle;

 push(eax);
 push(ebx);
 push(ecx);
 push(edx);

 mov(theDeck, ecx);
 foreach rand.deal(52) do

 cdq(); // Zero extend EAX into EDX:EAX.
 div(13, edx:eax); // Divide into suites.

 // EAX contains the suite index (0..3) and EDX contains
 // the face index (0..12).
 //
 // Get the suite character and store it away into the
 // suite field of the current card.

 mov(CardGroup[eax], bl);
 mov(bl, (type card [ecx]).suite);

 // Get the face value and store it away into the
 // face field of the current card in the deck.

 mov(CardValue[edx*4], edx);
 mov(edx, (type card [ecx]).face);

 // Move on to the next card in the deck.

 add(@size(card), ecx);

 endfor;
 pop(edx);
 pop(ecx);
 pop(ebx);
 pop(eax);

end shuffle;

static
 Deck1: deck;
 Hands: card[4, 5];

begin dealDemo;

 // Call the randomize function so we don't deal out the same
 // hands each time this program runs.

 rand.randomize();

```

```

// Create a shuffled deck and deal out four hands of five cards each.
// Note that the outer loop selects which card a particular player
// receives while the inner loop alternates between the players.

shuffle(Deck1);
mov(0, edx); // EDX selects a card from Deck1.

for(mov(0, ebx); ebx < 5; inc(ebx)) do

 for(mov(0, ecx); ecx < 4; inc(ecx)) do

 // Compute row-major order into Hands to
 // select Hands[ecx, ebx]

 intmul(5, ecx, edi);
 add(ebx, edi);
 intmul(@size(card), edi);

 // Copy the next available card in Deck1 (selected by
 // EDX) to the current player:

 mov(Deck1.face[edx], eax);
 mov(eax, Hands.face[edi]);
 mov(Deck1.suite[edx], al);
 mov(al, Hands.suite[edi]);

 // Move on to the next card in Deck1.

 add(@size(card), edx);

 endfor;

endfor;

// Okay, display the hands dealt to each player:

stdout.newln();
for(mov(0, ecx); ecx < 4; inc(ecx)) do //Player loop.

 lea(eax, [ecx+1]); // EAX = ECX+1
 stdout.put("Player ", (type uns32 eax), ": ");
 for(mov(0, ebx); ebx < 5; inc(ebx)) do //Card loop.

 // Compute row-major order into Hands to
 // select Hands[ecx, ebx]

 intmul(5, ecx, edi);
 add(ebx, edi);
 intmul(@size(card), edi);

 // Display the current card for the current player.

 stdout.put(Hands.face[edi]:2, Hands.suite[edi], ' ');

 endfor;
 stdout.newln();

### Program 13.10 Card Shuffle/Deal Program that uses the rand.deal Iterator

---

Exercise A: Compile and run this program several times. Include the program output in your lab report. Verify that you get a different set of hands on each execution of the program.

Exercise B: Comment out the call to rand.randomize in the main program. Recompile and run the program several times. Discuss the output of this program versus the output from Exercise A.

Exercise C: Using the console.setOutputAttr function, modify this program so that it prints the player's hands with a white background. Cards from the hearts and diamonds suites should have a red foreground color and cards from the spades and clubs suites should have a black foreground color.

---

## 13.3.10 Performance of Multiprecision Multiplication and Division Operations

The extended precision multiplication and division routines appearing in the chapter on Advanced Arithmetic can be found in the files "div128.hla", "div128b.hla", and "mul64.hla" in the appropriate subdirectory. These sample programs contain a main program that provides a brief test of each of these functions. Extract the multiplication and divisions procedures (and any needed support routines) and place these procedure in a new program. In the main program, write some code that times the execution of the calls to these three procedures using the RDTSC instruction (see the laboratory exercises at the end of Chapter Six for details). If you are using a CPU that doesn't support the RDTSC instruction, then put the calls in a loop and measure their time using a stopwatch. Also include code in the main program that times the single precision 32-bit MUL, IMUL, DIV, and IDIV instructions.

Exercise A: Run the program and report the running times of the extended precision and standard operations in your lab report.

Exercise B: The multiplication and division operations take a varying amount of time depending on the values of their operands (both the extended precision procedures and the machine instructions exhibit this behavior). Modify the program to generate a pair of random operands for these operations. Repeatedly call the procedures (or execute the machine instructions) and report the average execution time for these operations. Note: be sure to check for division by zero and any other illegal operations that can occur when using random numbers. Use the random number generation facilities of the HLA Standard Library as your source of random numbers. You should measure about a 1,000 calls to the procedures (or 1,000 different executions of the machine instructions).

---

## 13.3.11 Performance of the Extended Precision NEG Operation

Write a program that uses the RDTSC instruction to time the execution of a 64-bit, a 128-bit and a 256-bit NEG operation using the two different algorithms presented in this chapter (NEG/SBB and subtract from zero).

Exercise A: Run the programs and report the timings for the two different forms in your lab report. Also point out which version is smaller in your lab report.

Exercise B: You can also perform an extended precision negation operation by applying the definition of the two's complement operation to an extended precision value (i.e., invert all the bits and add one). Add the code to implement this third form of extended precision negation to your program and report the results in your lab report. Also discuss the size of this third negation algorithm.

---

### 13.3.12 Testing the Extended Precision Input Routines

The file "uin128.hla" provides an input procedure to read 128-bit unsigned integers from the standard input device. It is not uncommon for such routines, during initial development to contain defects. Devise a set of tests to help verify that the getu128 procedure is operating properly. Your tests should check the range of possible values, properly processing of delimiter characters, proper rejection of illegal characters, proper overflow handling, and so on. Describe the tests, and the programs output with your test data, in your lab report.

---

### 13.3.13 Illegal Decimal Operations

The DAA, DAS, AAA, AAS, AAM, and AAD instructions generally assume that they are adjusting for the result of some operation whose operands were legal BCD values. For example, DAA adjusts the value in the AL register after an addition assuming that the packed BCD values added together were legal BCD values. In this laboratory exercise, you will force the use of illegal BCD values just to see what happens.

Exercise A: Add together two illegal decimal values (e.g., \$1F and \$A2) and follow their addition with the execution of the DAA instruction. Repeat this for several pairs of illegal BCD values. Include the results in your lab report. Try to explain the results in your lab report.

Exercise B: Repeat Exercise A using the SUB and DAS instructions.

Exercise C: Repeat Exercise A using the ADD and AAA instructions.

Exercise D: Repeat Exercise B using the SUB and AAS instructions.

---

### 13.3.14 MOVS Performance Exercise #1

The movsb, movsw, and movsd instructions operate at different speeds, even when moving around the same number of bytes. In general, the movsw instruction is twice as fast as movsb when moving the same number of bytes. Likewise, movsd is about twice as fast as movsw (and about four times as fast as movsb) when moving the same number of bytes. Ex15\_1.asm is a short program that demonstrates this fact. This program consists of three sections that copy 2048 bytes from one buffer to another 100,000 times. The three sections repeat this operation using the movsb, movsw, and movsd instructions. Run this program and time each phase. **For your lab report:** present the timings on your machine. Be sure to list processor type and clock frequency in your lab report. Discuss why the timings are different between the three phases of this program. Explain the difficulty with using the movsd (versus movsw or movsb) instruction in any program on an 80386 or later processor. Why is it not a general replacement for movsb, for example? How can you get around this problem?

---

```

program MovsDemo;
#include("stdlib.hhf")

static

 Buffer1: byte[2048];
 Buffer2: byte[2048];

begin MovsDemo;

 // Demo of the movsb, movsw, and movsd instructions

 stdout.put
 (

```

```

"The following code moves a block of 2,048 bytes "
"around 10,000,000 times."
nl
"The first phase does this using the movsb instruction; the second"
nl
"phase does this using the movsw instruction; the third phase does"
nl
"this using the movsd instruction."
nl
nl
"Press RETURN to begin phase one:"
);
stdin.readLn();

for(mov(10_000_000, edx); edx > 0; dec(edx)) do

---

---

### Program 13.11 MOVS Demonstration Program

---

---

#### 13.3.15 MOVS Performance Exercise #2

In this exercise you will once again time the computer moving around blocks of 2,048 bytes. Like Ex15\_1.asm in the previous exercise, Ex15\_2.asm contains three phases; the first phase moves data using the movsb instruction; the second phase moves the data around using the lodsb and stosb instructions; the third phase uses a loop with simple mov instructions. Run this program and time the three phases. **For your lab report:** include the timings and a description of your machine (CPU, clock speed, etc.). Discuss the timings and explain the results (consult Appendix D as necessary).

---

---

```

program MovsDemo2;
#include("stdlib.hhf")

static

 Buffer1: byte[2048];
 Buffer2: byte[2048];

begin MovsDemo2;

 // Demo of the movsb, movsw, and movsd instructions

 stdout.put
 (
 "The following code moves a block of 2,048 bytes "
 "around 1,000,000 times."
 nl
 "The first phase does this using the movsb instruction; the second"
 nl
 "phase does this using the lodsb/stosb instructions; "
 "the third phase does"
 nl
 "this using the movsb instruction in a loop."
 nl
 nl
 "Press RETURN to begin phase one:"
);
 stdin.readLine();

 for(mov(1_000_000, edx); edx > 0; dec(edx)) do

 lea(esi, Buffer1);
 lea(edi, Buffer2);
 cld();
 mov(2048, ecx);
 rep.movsb();
 endfor;

```

```

endfor;

stdout.put
(
 "Phase one complete"
 nl nl
 "Press any key to begin phase two:"
);
stdin.readLn();

for(mov(1_000_000, edx); edx > 0; dec(edx)) do

 lea(esi, Buffer1);
 lea(edi, Buffer2);
 cld();
 mov(2048, ecx);
 repeat

 lodsb();
 stosb();
 dec(ecx);

 until(@z);

endifor;

stdout.put
(
 "Phase two complete"
 nl nl
 "Press any key to begin phase two:"
);
stdin.readLn();

for(mov(1_000_000, edx); edx > 0; dec(edx)) do

 lea(esi, Buffer1);
 lea(edi, Buffer2);
 cld();
 mov(2048, ecx);
 repeat

 movsb();
 dec(ecx);

 until(@z);

endifor;

stdout.put("Phase Three Done!" nl);

end MovsDemo2;

```

---

---

Program 13.12 MOVSB Demonstration Program #2

---

---

---

### 13.3.16 Memory Performance Exercise

In the previous two exercises, the programs accessed a maximum of 4K of data. Since most modern on-chip CPU caches are at least this big, most of the activity took place directly on the CPU (which is very fast). The following exercise is a slight modification that moves the array data in such a way as to destroy cache performance. Run this program and time the results. **For your lab report:** based on what you learned about the 80x86's cache mechanism in Chapter Three, explain the performance differences.

---

```

program MovsDemo3;
#include("stdlib.hhf")

var

 Buffer1: byte[256*1024];
 Buffer2: byte[256*1024];

begin MovsDemo3;

 // Demo of the movsb, movsw, and movsd instructions

 stdout.put
 (
 "The following code moves a block of 256K bytes "
 "around 10,000 times."
 nl
 "The first phase does this using the movsb instruction; the second"
 nl
 "phase does this using the lodsb/stosb instructions; "
 "the third phase does"
 nl
 "this using the movsb instruction in a loop."
 nl
 nl
 "Press RETURN to begin phase one:"
);
 stdin.readLine();

 for(mov(10_000, edx); edx > 0; dec(edx)) do

 lea(esi, Buffer1);
 lea(edi, Buffer2);
 cld();
 mov(256*1024, ecx);
 rep.movsb();

 endfor;

 stdout.put
 (
 "Phase one complete"
 nl nl
 "Press any key to begin phase two:"
);
 stdin.readLine();

 for(mov(10_000, edx); edx > 0; dec(edx)) do

```

```

 lea(esi, Buffer1);
 lea(edi, Buffer2);
 cld();
 mov(256*1024, ecx);
 repeat

 lodsb();
 stosb();
 dec(ecx);

 until(@z);

 endfor;

 stdout.put
 (
 "Phase two complete"
 nl nl
 "Press any key to begin phase three:"
);
 stdin.readLn();

 for(mov(10_000, edx); edx > 0; dec(edx)) do

 lea(esi, Buffer1);
 lea(edi, Buffer2);
 cld();
 mov(256*1024, ecx);
 repeat

 movsb();
 dec(ecx);

 until(@z);

 endfor;

 stdout.put("Phase Three Done!" nl);

end MovsDemo3;

```

---

### Program 13.13 MOVS Demonstration Program #3

---

---

#### 13.3.17 The Performance of Length-Prefixed vs. Zero-Terminated Strings

The following program (Ex15\_4.asm on the companion CD-ROM) executes two million string operations. During the first phase of execution, this code executes a sequence of length-prefixed string operations 1,000,000 times. During the second phase it does a comparable set of operation on zero terminated strings. Measure the execution time of each phase. **For your lab report:** report the differences in execution times and comment on the relative efficiency of length prefixed vs. zero terminated strings. Note that the relative performances of these sequences will vary depending upon the processor you use. Based on what you learned in Chapter Three and the cycle timings in Appendix D, explain some possible reasons for relative performance differences between these sequences among different processors.

---

```

program StringComparisons;
#include("stdlib.hhf")

### Program 13.14 Performance Evaluation of String Formats

---

---

### 13.3.18 Introduction to Compile-Time Programs

In this laboratory exercise you will run a sample compile-time program that has no run-time component. This compile-time program demonstrates the use of the `#while` and `#print` statements as well as the declaration and use of compile-time constants and variables (VAL objects).

---

---

```
// Demonstration of a simple compile-time program:

program ctPgmDemo;
const
 MaxIterations:= 10;

val
 i:int32;

#print("Compile-time loop:");
#while(i < MaxIterations)

 #print("i=", i);
 ?i := i + 1;

#endwhile
#print("End of compile-time program");

begin ctPgmDemo;
end ctPgmDemo;
```

---

---

### Program 13.15 A Simple Compile-Time Program

---

Exercise A. Compile this program. Describe its output during compilation in your lab report.

Exercise B. Although this source contains only a compile-time program, its compilation also produces a run-time program. After compiling the code, execute the corresponding EXE file this program produces. Explain the result of executing this program in your lab report.

Exercise C. What happens if you move the compile-time program from its current location (in the declaration section) to the body of the main program (i.e., between the BEGIN and END clauses)? Do this and repeat exercises A and B. Include the source code and explain the results in your lab report.

---

### 13.3.19 Conditional Compilation and Debug Code

Although the conditional compilation statements (`#IF`, `#ELSE`, etc.) are quite useful for many tasks, a principle use for these compile-time statements is to control the emission of debugging code. By using a single constant (e.g., "debug") declared as *true* or *false* at the beginning of your program, you can easily control the compilation of statements that should only appear in the run-time code during debugging runs. The following program has a subtle bug (you will get the opportunity to discover this problem for yourself). The use of debugging statements make locating this problem much easier. You can easily enable or disable the debugging statements by changing the value of the *debug* variable (between *true* and *false*).

---

```
// Demonstration of conditional compilation:

program condCompileDemo;
#include("stdlib.hhf");

// The following constant declaration controls the automatic
// compilation of debug code in the program. Set "debug" to
// true in order to enable the compilation of the debugging
// code; set this constant to false to disable the debug code.

const debug := false;
```

```

// Normal variables and constants this program uses:

const
 MaxElements := 10;

static
 uArray:uns32[MaxElements];
 LoopControlVariable:uns32;

begin condCompileDemo;

 try

 for
 (
 mov(MaxElements-1, LoopControlVariable);
 LoopControlVariable >= 0;
 dec(LoopControlVariable)
) do

 #if(debug)

 stdout.put("LoopControlVariable = ", LoopControlVariable, nl);

 #endif
 mov(LoopControlVariable, ebx);
 mov(0, uArray[ebx*4]);

 endfor;

 anyexception

 stdout.put("Exception $", eax, " raised in loop", nl);
 endtry;

end condCompileDemo;

```

---

---

### Program 13.16 Using Conditional Compilation to Control Debugging Code

---

---

Exercise A. Set the *debug* constant to *false*. Run this program and explain the results in your lab report. Do not try to correct the defect yet (even if the defect is obvious to you).

Exercise B. Set the *debug* constant to *true*. Rerun the program and explain the results in your lab report (if you cannot figure out what the problem is, ask your instructor for help).

Exercise C. Correct the defect and rerun the program. The value of the *debug* constant should still be *true*. Include the program's output in your laboratory report.

Exercise D. Set the value of the *debug* constant to *false* and recompile and run your program. Include the program's output in your lab report. In your lab report, explain how you could use conditional compilation and this *debug* variable to help track down problems in your own programs. In particular, explain why conditional compilation is helpful here (i.e., why not simply insert and remove the debugging code without using conditional compilation?).

### 13.3.20 The Assert Macro

The HLA Standard Library "excepts.hhf"<sup>2</sup> header file contains a macro, *assert*, that is quite useful for debugging purposes. This macro is defined as follows:

```
macro assert(expr):
 skipAssertion,
 msg;

 #if(!ex.NDEBUG)

 readonly

 msg:string := @string:expr;

 endreadonly;
 jt(expr) skipAssertion;

 mov(msg, ex.AssertionStr);
 raise(ex.AssertionFailed);

 skipAssertion:

 #endif

endmacro;
```

The purpose of the *assert* macro is to test a boolean expression. If the boolean expression evaluates *true* then the *assert* macro does nothing; however, if the boolean expression evaluates *false*, then *assert* raises an exception (*ex.AssertionFailed*). This macro is quite handy for checking the validity of certain expressions while your program is running (e.g., checking to see if an array index is within the appropriate bounds).

If you take a close look at the *assert* macro definition, you'll discover that an *#IF* statement surrounds the body of the macro. If the symbol *ex.NDEBUG* (No DEBUG) is true, the *assert* macro does not generate any code; conversely, *assert* will generate the code to test the boolean expression if *ex.NDEBUG* is false. The reason for the *#IF* statement is to allow you to insert debugging assertions throughout your code and easily disable all of them with a single statement at the beginning of your program. By default, assertions are active and will generate code (i.e., the VAL object *ex.NDEBUG* initially contains *false*). You may disable code generation for assertions by including the following statement at the beginning of your program (after the *#Include*( "stdlib.hhf" ) or *#Include*( "excepts.hhf" ) directive which defines the *ex.NDEBUG* VAL object):

```
?ex.NDEBUG := true;
```

You can even sprinkle statements throughout your program to selective turn code emission for the *assert* macro on and off by setting *ex.NDEBUG* to false and true (respectively). However, turning on all asserts or turning off all asserts at the beginning of your program should prove sufficient.

During testing, you should leave all assertions active so the program can help you locate defects (by raising an exception if an assertion fails). Later, when you've debugged your code and are confident that it behaves correctly, you can eliminate the overhead of the *assert* macros by setting the *ex.NDEBUG* object to true.

The following sample program demonstrates how to detect a common error (array bounds violation) using an *assert* macro. This is the program from the previous exercise (with the same problem) adapted to use the *assert* macro rather than explicit debugging code.

---

2. The "stdlib.hhf" header file automatically includes the "excepts.hhf" header file.

---

---

```

// Demonstration of the Assert macro:

program assertDemo;
#include("stdlib.hhf");

// Set the following variable to true to tell HLA
// not to generate code for ASSERT debug macros
// (i.e., if NDEBUG [no debug] is true, turn off
// the debugging code).
//
// Conversely, set this to false to activate the
// debugging code associated with the assert macros.

val ex.NDEBUG := false;

// Normal variables and constants this program uses:

const
 MaxElements := 10;

static
 uArray:uns32[MaxElements];
 LoopControlVariable:uns32;

begin assertDemo;

 for
 (
 mov(MaxElements-1, LoopControlVariable);
 LoopControlVariable >= 0;
 dec(LoopControlVariable)
) do

 mov(LoopControlVariable, ebx);

 // The following assert verifies that
 // EBX is the range legal range for
 // elements of the uArray object:

 assert(ebx in 0..@elements(uArray)-1);
 mov(0, uArray[ebx*4]);

 endfor;

end assertDemo;

```

---

### Program 13.17 Demonstration of the Assert Macro

---

Exercise A. Compile and run this program. Describe the results in your laboratory report. (Do not correct the defect in the program.)

Exercise B. Change the statement "`?ex.NDEBUG := false;`" so that the `ex.NDEBUG` VAL object is set to true. Compile and run the program (with the defect still present). Describe the results in your laboratory report. If you were debugging this code and didn't know the cause of the error, which exception message do you think would help you locate the defect faster? Why? Explain this in your lab report.

Exercise C. Correct the defect (ask your instructor if you don't see the problem) and rerun the program with *ex.NDEBUG* set to *true* and *false* (on separate runs). How does this affect the execution of your (correct) program?

---

### 13.3.21 Demonstration of Compile-Time Loops (#while)

In this laboratory exercise you will use the #WHILE compile-time statement for two purposes. First, this program uses #WHILE to generate data for a table during the compilation of the program. Second, this program uses #WHILE in order to unroll a loop (see “Unraveling Loops” on page 776 for more details on unrolling loops). This sample program also uses the #IF compile-time statement, along with the *UnrollLoop* constant, in order to control whether this program generates a FOR loop to manipulate an array or unroll the FOR loop using the #WHILE statement. Here's the source code for this exercise:

---

```
// Demonstration of the #while statement:

program whileDemo;
#include("stdlib.hhf");

// Set the following constant to true in order to use loop unrolling
// when initializing the array at run-time. Set this constant to
// false to use a run-time FOR loop to initialize the data:

const UnrollLoop := true;

// Normal variables and constants this program uses:

const
 MaxElements := 16;

static
 index:uns32;
 iArray:int32[MaxElements] :=
 [

 // The following #while loop initializes
 // each element of the array (except the
 // last element) with the negative version
 // of the index into the array.

 ?i := 0;
 #while(i < MaxElements-1)

 -i,
 ?i := i + 1;

 #endwhile

 // Initialize the last element (special case here
 // because we can't have a comma at the end of the
 // list).

 -i
];

begin whileDemo;
```

```

// Display the current elements in the array:

stdout.put("Initialized elements of iArray:", nl, nl);
for(mov(0, ebx); ebx < MaxElements; inc(ebx)) do

 assert(ebx in 0..MaxElements-1);
 stdout.put("iArray[" , (type uns32 ebx), "]" = ", iArray[ebx*4], nl);

endfor;

#if(UnrollLoop)

 // Reset the array elements using an unrolled loop.

 ?i := 0;
 #while(i < MaxElements)

 mov(MaxElements-i, iArray[i*4]);
 ?i := i + 1;

 #endwhile

#else // Reset the array using a run-time FOR loop.

 for(mov(0, ebx); ebx < MaxElements; inc(ebx)) do

 mov(MaxElements, eax);
 sub(ebx, eax);
 assert(ebx < MaxElements);
 mov(eax, iArray[ebx*4]);

 endfor;

#endif

// Display the new array elements (should be MaxElements downto 1):

stdout.put(nl, "Reinitialized elements of iArray:", nl, nl);
for(mov(0, ebx); ebx < MaxElements; inc(ebx)) do

 assert(ebx in 0..MaxElements-1);
 stdout.put("iArray[" , (type uns32 ebx), "]" = ", iArray[ebx*4], nl);

endfor;
stdout.put(nl, "All done!", nl, nl);

end whileDemo;

```

---

---

### Program 13.18 #While Loop Demonstration

---

---

Exercise A. Compile and execute this program. Include the output in your laboratory report.

Exercise B. Change the *UnrollLoop* constant from true to false. Recompile and run the program. Include the output in your laboratory report. Describe the differences between the two programs (in particular, you should take care to describe how these two runs produce their output).

### 13.3.22 Writing a Trace Macro

When debugging HLA programs, especially in the absence of a good debugging tool, a common need is to print a brief message that effectively says "here I am" while the program is running. The execution of such a statement lets you know that the program has reached a certain point in the source code during execution.

If you only need a single such statement, probably the easiest way to achieve this is to use the *stdout.put* statement as follows:

```
stdout.put("Here I am" nl);
```

Of course, if you have more than one such statement in your program you will need to modify the string your print so that each *stdout.put* statement prints a different message (so you can easily identify which statements execute in the program). A typical solution is to print a unique number with each string, e.g.,

```
stdout.put("Here I am at point 1" nl);
.
.
.
stdout.put("Here I am at point 2" nl);
.
.
.
stdout.put("Here I am at point 3" nl);
.
.
.
```

There is a big problem with this approach: it's very easy to become confused and repeat the same number twice. This, of course, does you no good when the program prints that particular value. One way to handle this is to print the line number of the *stdout.put* statement. Unless you put two such statements on the same line (which would be very unusual), each call to *stdout.put* would produce a unique output value. You can easily display the line number of the statement using the HLA *@LineNumber* compile-time function:

```
stdout.put("Here I am at line ", @LineNumber, nl);
```

There is a problem with inserting code like this into your program: you might forget to remove it later. As noted in section 6.7, you can use the conditional compilation directives to let you easily turn debugging code on and off in your program. E.g., you could replace the statement above by

```
#if(debug)

 stdout.put("Here I am at line ", @LineNumber, nl);

#endif
```

Now, by setting the constant *debug* to *true* or *false* at the beginning of your program, you can easily turn the code generation of these "trace" statements on and off.

While this is very close to what we need, there is still a problem with this approach: it's a lot of code. That makes it difficult to write and the amount of incidental code in your program obscures the statements that do actual work, making your program harder to read and understand. What would really be nice is a single, short, statement that automatically generates code like the above if *debug* is *true* (and doesn't generate anything if *debug* is *false*). I.e., what would really like is to be able to write something like the following:

```
trace;
```

Presumably, *trace* expands into code similar to the above.

In this laboratory exercise you will get to use just such a macro. The actual definition of *trace* is somewhat complicated by the behavior of eager vs. deferred macro parameter expansion (See “Eager vs. Deferred Macro Parameter Evaluation” on page 949.). Also, *trace* is actually a TEXT object rather than a macro so that *trace* can automatically expand to a macro invocation and pass in a line number parameter (this saves having to type something like “trace( @LineNumber)” manually). Here is a program that defines and uses *trace* as described above:

---

---

```
// Demonstration of macros and the development of a debugging tool:

program macroDemo;
#include("stdlib.hhf");

// The TRACE "macro".
//
// Putting "trace;" at a point in an executable section of
// your program tells HLA to print the line number of that
// statement when it encounters the statement during program
// execution. Setting the "traceOn" variable to true or false
// turns on and off the display of the trace line numbers
// during execution.
//
// Note that the "trace" object is actually a text constant
// that expands to the "tracestmt" macro invocation. This
// saves you from having to type "@linenumber" as a parameter
// to every tracestmt invocation (see the text to learn why
// you can't simply bury "@linenumber" within the tracestmt
// macro body).

const traceOn := true;

const trace:text := "tracestmt(@eval(@LineNumber))";
macro tracestmt(LineNumber);

 #if(traceOn)

 stdout.put("line: ", LineNumber, nl);

 #endif

endmacro;

// Normal variables and constants this program uses:

const
 MaxElements := 16;

static
 index:uns32;
 iArray:int32[MaxElements];

begin macroDemo;

 trace;
 mov(0, ebx);
```

```

trace;
while(ebx < MaxElements) do

 mov(MaxElements, eax);
 sub(ebx, eax);
 assert(ebx < MaxElements);
 mov(eax, iArray[ebx*4]);
 inc(ebx);

endwhile;
trace;

// Display the new array elements (should be MaxElements downto 1):

stdout.put(nl, "Elements of iArray:", nl, nl);
trace;
for(mov(0, ebx); ebx < MaxElements; inc(ebx)) do

 assert(ebx in 0..MaxElements-1);
 stdout.put("iArray[" , (type uns32 ebx), "]" = ", iArray[ebx*4], nl);

endfor;
trace;
stdout.put(nl, "All done!", nl, nl);

end macroDemo;

```

---

### Program 13.19 Trace Macro

---

Exercise A. Compile and run this program. Include the output in your laboratory report.

Exercise B. Add additional "trace;" statements to the program (e.g., stick them inside the WHILE and FOR loops). Recompile and run the program. Include the output in your lab report. Comment on the usefulness of the *trace* macro in your lab report.

Exercise C. Change the *traceOn* constant to *false*. Recompile and run your program. Explain the output in your lab report.

---

### 13.3.23 Overloading

A nifty feature in the C++ language is *function overloading*. Function overloading lets you use the same function (procedure) name for different functions leaving the compiler to differentiate the functions by the number and types of the function's parameters. Although HLA does not directly support procedure overloading, it is very easy to simulate this using HLA's compile-time language. The following sample program demonstrates how to write a *Max* "function" that computes the maximum of two values whose types can be *uns32*, *int32*, or *real32*.

---

```

// Demonstration of using macros to implement function overloading:

program overloadDemo;
#include("stdlib.hhf");

procedure i32Max(val1:int32; val2:int32; var dest:int32);
begin i32Max;

```

```

push(eax);
push(ebx);

mov(val1, eax);
mov(dest, ebx);
if(eax < val2) then

 mov(val2, eax);

endif;
mov(eax, [ebx]);
pop(ebx);
pop(eax);

end i32Max;

procedure u32Max(val1:uns32; val2:uns32; var dest:uns32);
begin u32Max;

 push(eax);
 push(ebx);

 mov(val1, eax);
 mov(dest, ebx);
 if(eax < val2) then

 mov(val2, eax);

 endif;
 mov(eax, [ebx]);
 pop(ebx);
 pop(eax);

end u32Max;

procedure r32Max(val1:real32; val2:real32; var dest:real32);
begin r32Max;

 push(eax);
 push(ebx);

 mov(dest, ebx);
 fld(val1);
 fld(val2);
 fcompp();
 fstsw(ax);
 sahf();
 if(@b) then

 mov(val1, eax); // Since real32 fit in EAX, just use EAX

 else

 mov(val2, eax);

 endif;
 mov(eax, [ebx]);
 pop(ebx);
 pop(eax);

```

```

end r32Max;

macro Max(val1, val2, dest);

 #if(@typeName(val1) = "uns32")

 u32Max(val1, val2, dest);

 #elseif(@typeName(val1) = "int32")

 i32Max(val1, val2, dest);

 #elseif(@typeName(val1) = "real32")

 r32Max(val1, val2, dest);

 #else

 #error
 (
 "Unsupported type in 'Max' function: '" +
 @typeName(val1) +
 "'"
)

 #endif

endmacro;

static
 u1:uns32 := 5;
 u2:uns32 := 6;
 ud:uns32;

 i1:int32 := -5;
 i2:int32 := -6;
 id:int32;

 r1:real32 := 5.0;
 r2:real32 := -6.0;
 rd:real32;

begin overloadDemo;

 Max(u1, u2, ud);
 Max(i1, i2, id);
 Max(r1, r2, rd);

 stdout.put
 (
 "Max(", u1, ", ", u2, ") = ", ud, nl,
 "Max(", i1, ", ", i2, ") = ", id, nl,
 "Max(", r1, ", ", r2, ") = ", rd, nl
);

```

```
end overloadDemo;
```

---

---

### Program 13.20 Procedure Overloading Demonstration

---

---

Exercise A. Compile and run this program. Include the output in your laboratory report.

Exercise B. Add an additional statement to the main program that attempts to compute the maximum of an *int32* and *real32* object (storing the result in an *uns32* object). Compile the program and explain the results in your lab report.

Exercise C. Extend the *Max* macro so that it can handle *real64* objects in addition to *uns32*, *int32*, and *real32* objects. Note that you will have to write an *r64Max* function as well as modify the *Max* macro (hint: you will not be able to simply clone the *r32Max* procedure to achieve this).

---

### 13.3.24 Multi-part Macros and RatASM (Rational Assembly)

While the *trace* macro of the previous section is very nice and quite useful for debugging purpose, it does have one major drawback, you have to explicitly insert *trace* macro invocations into your source code in order to take advantage of this debugging facility. If you have an existing program, into which you have not inserted any *trace* invocations, it might be a bit of effort to instrument your program by inserting dozens or hundreds of *trace* invocations into the program. Wouldn't it be nice if HLA code do this for you automatically?

Unfortunately, HLA cannot automatically insert *trace* invocations into your program for you. However, with a little preparation, you can almost achieve this goal. To do this, we'll define a special Domain Specific Embedded Language (See "Domain Specific Embedded Languages" on page 975.) that defines some of the high level language statements found in HLA (similar to what appears in "Implementing the Standard HLA Control Structures" on page 975). However, rather than simply mimic the existing control structures, our new control structures will also automatically inject some output statements into the code if the *traceOn* constant is *true*. We'll call this DSEL *RatASM* (after *RatC*, which adds the same type of tracing features to the C/C++ language). *RatASM* is short for Rational Assembly (note that the names *RatASM* and *RatC* are derivations of RATFOR, Kernighan and Plauger's RATIONAL FORtran preprocessor).

*RatASM* works as follows: rather than using statements like *WHILE..DO..ENDWHILE* or *FOR..DO..ENDFOR*, you use the *\_while..\_do..\_endwhile* and *\_for..\_do..\_endfor* macros to do the same thing. These macros essentially expand into the equivalent HLA high level language statements. If the *traceOn* constant is *true*, then these macros also emit some additional code to display the name of the control structure and the corresponding line number. The following sample program provides multi-part macros for the *\_for* and *\_while* statements that support this tracing feature:

---

---

```
// Demonstration of multi-part macros and the development
// of yet another debugging tool:

program RatASMDemo;
#include("stdlib.hhf");

// The TRACE "macro".
//
// Putting "trace;" at a point in an executable section of
// your program tells HLA to print the line number of that
// statement when it encounters the statement during program
// execution. Setting the "traceOn" variable to true or false
```

```

// turns on and off the display of the trace line numbers
// during execution.
//
// Note that the "trace" object is actually a text constant
// that expands to the "tracestmt" macro invocation. This
// saves you from having to type "@linenumber" as a parameter
// to every tracestmt invocation (see the text to learn why
// you can't simply bury "@linenumber" within the tracestmt
// macro body).

const traceOn := true;

const trace:text := "tracestmt(@eval(@LineNumber))";
macro tracestmt(LineNumber);

 #if(traceOn)

 stdout.put("trace(", LineNumber, ")", nl);

 #endif

endmacro;

macro traceRatASM(LineNumber, msg);

 #if(traceOn)

 stdout.put(msg, ": ", LineNumber, nl);

 #endif

endmacro;

// The "RatASM" (rational assembly) "FOR" statement.
//
// Behaves just like the standard HLA FOR statement
// except it provides the ability to transparently
// trace the execution of FOR statements in a program.

const _for:text := "?_CurStmtLineNumber := @LineNumber; raFor";
macro raFor(init, expr, increment):ForLineNumber;
 ?ForLineNumber := _CurStmtLineNumber;
 traceRatASM(_CurStmtLineNumber, "FOR");
 for(init; expr; increment) do

 traceRatASM(_CurStmtLineNumber, "for");

 keyword _do;
 terminator _endfor;

 endfor;
 traceRatASM(_CurStmtLineNumber, "endfor");

endmacro;

// The "RatASM" (rational assembly) "WHILE" statement.
//
// Behaves just like the standard HLA WHILE statement

```

```

// except it provides the ability to transparently
// trace the execution of WHILE statements in a program.

const _while:text := "?_CurStmtLineNumber := @LineNumber; raWhile";
macro raWhile(expr):WhileLineNumber;
 ?WhileLineNumber := _CurStmtLineNumber;
 traceRatASM(_CurStmtLineNumber, "WHILE");
 while(expr) do

 traceRatASM(_CurStmtLineNumber, "while");

 keyword _do;
 terminator _endwhile;

 endwhile;
 traceRatASM(_CurStmtLineNumber, "endwhile");

endmacro;

// Normal variables and constants this program uses:

const
 MaxElements := 16;

static
 index:uns32;
 iArray:int32[MaxElements];

begin RatASMDemo;

 trace;
 mov(0, ebx);
 _while(ebx < MaxElements) _do

 mov(MaxElements, eax);
 sub(ebx, eax);
 assert(ebx < MaxElements);
 mov(eax, iArray[ebx*4]);
 inc(ebx);

 _endwhile;

 // Display the new array elements (should be MaxElements downto 1):

 stdout.put(nl, "Elements of iArray:", nl, nl);
 _for(mov(0, ebx), ebx < MaxElements, inc(ebx)) _do

 assert(ebx in 0..MaxElements-1);
 stdout.put("iArray[" , (type uns32 ebx), "]" = ", iArray[ebx*4], nl);

 _endfor;
 stdout.put(nl, "All done!", nl, nl);

end RatASMDemo;

```

---

---

### Program 13.21 Demonstration of RatASM \_WHILE and \_FOR Loops

---

---

Exercise A. Compile and run this program. Include the output in your lab report. Note that some trace messages display their text in uppercase while others display their text in lowercase. Figure out the difference between these two messages and describe the difference in your lab report.

Exercise B. Set the *traceOn* constant to *false*. Recompile and run the program. Describe the output in your lab report.

Exercise C. Using the *\_while* and *\_for* definitions as a template, create a *\_repeat..\_until* RatASM statement and modify the main program by adding this statement (your choice what the loop will actually do). Include the source code in your lab report. Compile and run the program with the *traceOn* constant set to *true* and then set to *false*. Include the output of the program in your lab report.

### 13.3.25 Virtual Methods vs. Static Procedures in a Class

Class methods and procedures are generally interchangeable in a program. One exception occurs with polymorphism. If you have a pointer to an object rather than a standard object variable, the semantics of method versus procedure calls are different. In this exercise you will explore those differences.

```

program PolyMorphDemo;
#include("stdlib.hhf");

type
 baseClass: class

 procedure Create; returns("esi");
 procedure aProc;
 method aMethod;

 endclass;

 derivedClass: class inherits(baseClass)

 override procedure Create;
 override procedure aProc;
 override method aMethod;

 endclass;

// Methods for the baseClass class type:

procedure baseClass.Create; nodisplay; noframe;
begin Create;

 stdout.put("called baseClass.Create", nl);

 push(eax);
 if(esi = 0) then

 mov(malloc(@size(baseClass)), esi);

 endif;
 mov(&baseClass._VMT_, this._pVMT_);
 pop(eax);
 ret();

end Create;

```

```

procedure baseClass.aProc; nodisplay; noframe;
begin aProc;

 stdout.put("Called baseClass.aProc" nl);
 ret();

end aProc;

method baseClass.aMethod; nodisplay; noframe;
begin aMethod;

 stdout.put("Called baseClass.aMethod" nl);
 ret();

end aMethod;

// Methods for the derivedClass class type:

procedure derivedClass.Create; nodisplay; noframe;
begin Create;

 stdout.put("called derivedClass.Create", nl);

 push(eax);
 if(esi = 0) then

 mov(malloc(@size(derivedClass)), esi);

 endif;
 mov(&derivedClass._VMT_, this._pVMT_);
 pop(eax);
 ret();

end Create;

procedure derivedClass.aProc; nodisplay; noframe;
begin aProc;

 stdout.put("Called derivedClass.aProc" nl);
 ret();

end aProc;

method derivedClass.aMethod; nodisplay; noframe;
begin aMethod;

 stdout.put("Called derivedClass.aMethod" nl);
 ret();

end aMethod;

static
 vmt(baseClass);
 vmt(derivedClass);

```

```
var
 b: baseClass;
 d: derivedClass;

 bPtr: pointer to baseClass;
 dPtr: pointer to derivedClass;

 generic: pointer to baseClass;

begin PolyMorphDemo;

 // Deal with the b and d objects:

 stdout.put("Manipulating 'b' object:" nl);

 b.Create();
 b.aProc();
 b.aMethod();

 stdout.put(nl "Manipulating 'd' object:" nl);

 d.Create();
 d.aProc();
 d.aMethod();

 // Now work with pointers to the objects:

 stdout.put(nl "Manipulating 'bPtr' object:" nl);

 mov(baseClass.Create(), bPtr);
 bPtr.aProc();
 bPtr.aMethod();

 stdout.put(nl "Manipulating 'dPtr' object:" nl);

 mov(derivedClass.Create(), dPtr);
 dPtr.aProc();
 dPtr.aMethod();

 // Demonstrate polymorphism using the 'generic' pointer.

 stdout.put(nl "Manipulating 'generic' object:" nl);

 mov(bPtr, generic);
 generic.aProc();
 generic.aMethod();

 mov(dPtr, generic);
 generic.aProc();
 generic.aMethod();

end PolyMorphDemo;
```

---

---

**Program 13.22 Polymorphism Demonstration**

---

---

Exercise A: Compile and run the program. Include the output in your lab report. Describe the output and explain why you got the output you did. Especially explain the output of the *generic* procedure and method invocations.

Exercise B: Add a second pointer variable, *generic2*, whose type is a pointer to *derivedClass*. Initialize this pointer with the value from the *dPtr* variable and invoke the *dPtr.aProc* procedure and *dPtr.aMethod* method. Run the program and include the output in your lab report. Explain why these procedure/method invocations produce different output than the output from the *generic* procedure and method invocations.

### 13.3.26 Using the `_initialize_` and `_finalize_` Strings in a Program

Although HLA does not provide a mechanism that automatically invokes an object's constructors when the procedure, iterator, method, or program that contains the object's declaration begins execution, you can simulate this by using HLA's `_initialize_` string. Likewise, HLA does not automatically call a class destructor associated with an object when that object goes out of scope; still, you can simulate this by using the `_finalize_` string. In this laboratory exercise you will experiment with these two string values.

Note: the following program demonstrates the use of a class definition macro that manipulates the `_initialize_` string in order to automatically invoke a class' constructor. Adding a class destructor and modifying the value of the `_finalize_` string is one of the activities you will do in this laboratory exercise.

```
// Using _initialize_ and _finalize_ in a program.

program InitFinalDemo;
#include("stdlib.hhf");

// Define a simple class with a constructor and
// a method to demonstrate the use of the _initialize
// string.
type
 _myClass: class
 var
 s:string;

 procedure Create; returns("esi");
 method put;
 method assign(theValue:string);

 endclass;

// Define a "pseudo-type". That is a macro that we use
// in place of the "_myClass" name. In addition to actually
// defining the macro name, this macro will modify the
// _initialize_ string so that the procedure/program/whatever
// containing the object declaration does an automatic call to
// the constructor.

macro myClass:theID;

 forward(theID);
 ?_initialize_ := _initialize_ + @string:theID + ".Create()";
 theID:_myClass

endmacro;
```

```

// Methods for the baseClass class type:

procedure _myClass.Create; nodisplay; noframe;
begin Create;

 push(eax);
 if(esi = 0) then

 mov(malloc(@size(_myClass)), esi);

 endif;
 mov(&_myClass._VMT_, this._pVMT_);

 // Within the constructor, initialize the string
 // to a reasonable value:

 mov(str.a_cpy(""), this.s);

 pop(eax);
 ret();

end Create;

method _myClass.assign(theValue:string); nodisplay;
begin assign;

 push(eax);

 // First, free the current value of the s field.

 strfree(this.s);

 // Now make a copy of the parameter value and point
 // the s field at this copy:

 mov(str.a_cpy(theValue), this.s);

 pop(eax);

end assign;

method _myClass.put; nodisplay; noframe;
begin put;

 stdout.put(this.s);
 ret();

end put;

static
 vmt(_myClass);

var
 mc:myClass;

begin InitFinalDemo;

```

```

stdout.put("Initial value of mc.s = "");
mc.put();
stdout.put("" nl);

mc.assign("Hello World");
stdout.put("After mc.assign("Hello World"), mc.s="");
mc.put();
stdout.put("" nl);

end InitFinalDemo;

```

---

### Program 13.23 Code for `_initialize_/_finalize_` Laboratory Exercise

---

Exercise A: compile and run this program. Include the output of this program in your laboratory report. Explain the output you obtain (and, in particular, explain why you get the output that you do). Specifically, describe how this code automatically calls the constructor for the *mc* object.

Exercise B: the *myClass* class does not have a destructor. Write a destructor for this class. Note that class objects have a string variable that is allocated on the heap. Therefore, one of the tasks for this destructor is to free the storage associated with that string. You should also print a short message in the destructor to let you know that it has been called. Modify the main program to call *mc.Destroy* (*Destroy* being the conventional name for a class destructor) at the very end of the program.

For extra credit: this program assumes that the *s* field always points at an object that has been allocated on the heap. In the HLA Standard Library memory allocation module there is a function that will tell you whether a pointer is pointing into the heap. Use this function to verify that *s* contains a valid pointer you can free before freeing the storage associated with this string point. To test this, try initializing the *s* field with an address that is not on the heap and then call the destructor to see how it responds.

Exercise C: modify the *myClass* macro so that the program automatically calls the destructor when the object loses scope. To do this, you will need to modify the value of the `_finalize_` string. Use the existing modification of the `_initialize_` string as a template (and, of course, look up how to do this earlier in this chapter). Include a sample run in your lab report and explain what is happening and how the destructor is activating.

Exercise D: using a macro to simulate automatic constructor and destructor calls is not a panacea. Try declaring the following and compiling your program and explain what happens during the compilation:

- Declare a “pointer to myClass” variable.
- Declare a new type name which simply renames the “myClass” type.

Bonus exercise: declare an array of *myClass* objects. Syntactically the compiler should accept this. Explain the problem with this declaration considering the purpose of this exercise. Include a sample program with your lab report that demonstrates the problem when declaring arrays of *myClass* objects.

---

## 13.3.27 Using RTTI in a Program

Run-time type information (RTTI) lets you determine the specific type of a generic object. This is quite useful when you might need to do some special processing for certain objects if they have a given type. In this exercise you will see a simple demonstration of RTTI in a generic program that demonstrates how you can use RTTI to achieve this goal.

---

```
// Using RTTI in a program.
```

```

program RTTIdemo;
#include("stdlib.hhf");

// Define some classes so we can demonstrate RTTI:

type
 baseClass: class

 procedure Create; returns("esi");
 procedure aProc;
 method aMethod;

 endclass;

 derivedClass: class inherits(baseClass)

 override procedure Create;
 override procedure aProc;

### Program 13.24 Code for RTTI Laboratory Exercise

---

---

Exercise A: Run this program and include the output in your laboratory report. Explain the results that you're getting.

Exercise B: Run the program a second time. Is the output the same as the first run? If not, explain this in your laboratory report.

Optional: If your CPU does not support the RDTSC instruction, modify the *randomSelect* function to read a "random" value from the user in order to make the selection.

**Advanced Assembly Language Programming**

## 1.1 Chapter Overview

This chapter discusses thunks which are special types of procedures and procedure calls you can use to defer the execution of some procedure call. Although the use of thunks is not commonplace in standard assembly code, their semantics are quite useful in AI (artificial intelligence) and other programs. The proper use of thunks can dramatically improve the performance of certain programs. Perhaps a reason thunks do not find extensive use in assembly code is because most assembly language programmers are unaware of their capabilities. This chapter will solve that problem by presenting the definition of thunks and describe how to use them in your assembly programs.

## 1.2 First Class Objects

The actual low-level implementation of a thunk, and the invocation of a thunk, is rather simple. However, to understand why you would want to use a thunk in an assembly language program we need to jump to a higher level of abstraction and discuss the concept of *First Class Objects*.

A first class object is one you can treat like a normal scalar data variable. You can pass it as a parameter (using any arbitrary parameter passing mechanism), you can return it as a function result, you can change the object's value via certain legal operations, you can retrieve its value, and you can assign one instance of a first class object to another. An *int32* variable is a good example of a first class object.

Now consider an array. In many languages, arrays are not first class objects. Oh, you can pass them as parameters and operate on them, but you can't assign one array to another nor can you return an array as a function result in many languages. In other languages, however, all these operations are permissible on arrays so they are first class objects (in such languages).

A statement sequence (especially one involving procedure calls) is generally not a first class object in many programming languages. For example, in C/C++ or Pascal/Delphi you cannot pass a sequence of statements as a parameter, assign them to a variable, return them as a function result, or otherwise operate on them as though they were data. You cannot create arbitrary arrays of statements nor can you ask a sequence of statements to execute themselves except at their point of declaration.

If you've never used a language that allows you to treat executable statements as data, you're probably wondering why anyone would ever want to do this. There are, however, some very good reasons for wanting to treat statements as data and execute them on demand. If you're familiar with the C/C++ programming language, consider the C/C++ "?" operator:

```
expr ? Texpr : Fexpr
```

For those who are unfamiliar with the "?" operator, it evaluates the first expression (*expr*) and then returns the value of *Texpr* if *expr* is true, it evaluates and returns *Fexpr* if *expr* evaluates false. Note that this code does not evaluate *Fexpr* if *expr* is true; likewise, it does not evaluate *Texpr* if *expr* is false. Contrast this with the following C/C++ function:

```
int ifexpr(int x, int t, int f)
{
 if(x) return t;
 return f;
}
```

A function call of the form "ifexpr( expr, Texpr, Fexpr);" is not semantically equivalent to "expr ? Texpr : Fexpr". The *ifexpr* call always evaluates all three parameters while the conditional expression operator ("?") does not. If either *Texpr* or *Fexpr* produces a side-effect, then the call to *ifexpr* may produce a different result than the conditional operator, e.g.,

```
i = (x==y) ? a++ : b--;
j = ifexpr(x==y, c++, d--);
```

In this example either *a* is incremented or *b* is decremented, but not both because the conditional operator only evaluates one of the two expressions based on the values of *x* and *y*. In the second statement, however, the code both increments *c* and decrements *d* because C/C++ always evaluates all value parameters before calling the function; that is, C/C++ eagerly evaluates function parameter expressions (while the conditional operator uses deferred evaluation).

Supposing that we wanted to defer the execution of the statements "c++" and "d--" until inside the function's body, this presents a classic case where it would be nice to treat a pair of statements as first class objects. Rather than pass the value of "c++" or "d--" to the function, we pass the actual statements and expand these statements inside the function wherever the format parameter occurs. While this is not possible in C/C++, it is possible in certain languages that support the use of statements as first class objects. Of course, if it can be done in any particular language, then it can be done in assembly language.

Of course, at the machine code level a statement sequence is really nothing more than a sequence of bytes. Therefore, we could treat those statements as data by directly manipulating the object code associated with that statement sequence. Indeed, in some cases this is the best solution. However, in most cases it will prove too cumbersome to manipulate a statement sequence by directly manipulating its object code. A better solution is to use a pointer to the statement sequence and CALL indirectly to that sequence whenever we want to execute it. Using a pointer in this manner is usually far more efficient than manipulating the code directly, especially since you rarely change the instruction sequence itself. All you really want to do is defer the execution of that code. Of course, to properly return from such a sequence, the sequence must end with a RET instruction. Consider the following HLA implementation of the "ifexpr" function given earlier:

```
procedure ifexpr(expr:boolean; trueStmts:dword; falseStmts:dword);
 returns("eax");

begin ifexpr;

 if(expr) then

 call(trueStmts);

 else

 call(falseStmts);

 endif;

end ifexpr;
.
.
.
 jmp overStmt1;
stmt1: mov(c, eax);
 inc(c);
 ret();

overStmt1:
 jmp overStmt2
stmt2: mov(d, eax);
 dec(d);
 ret();

overStmt2:
ifexpr(exprVal, &stmt1, &stmt2);
```

(for reasons you'll see shortly, this code assumes that the *c* and *d* variables are global, static, objects.)

Notice how the code above passes the addresses of the *stmt1* and *stmt2* labels to the *ifexpr* procedure. Also note how the code sequence above jumps over the statement sequences so that the code only executes them in the body of the *ifexpr* procedure.

As you can see, the example above creates two mini-procedures in the main body of the code. Within the *ifexpr* procedure the program calls one of these mini-procedures (*stmt1* or *stmt2*). Unlike standard HLA procedures, these mini-procedures do not set up a proper activation record. There are no parameters, there are no local variables, and the code in these mini-procedures does not execute the standard entry or exit sequence. In fact, the only part of the activation record present in this case is the return address.

Because these mini-procedures do not manipulate EBP's value, EBP is still pointing at the activation record for the *ifexpr* procedure. For this reason, the *c* and *d* variables must be global, static objects; you must not declare them in a VAR section. For if you do, the mini-procedures will attempt to access these objects in *ifexpr*'s activation record, not and the caller's activation record. This, of course, would return the wrong value.

Fortunately, there is a way around this problem. HLA provides a special data type, known as a thunk, that eliminates this problem. To learn about thunks, keep reading...

### 1.3 Thunks

A *thunk* is an object with two components: a pointer containing the address of some code and a pointer to an execution environment (e.g., an activation record). Thunks, therefore, are an eight-byte (64-bit) data type, though (unlike a *qword*) the two pieces of a thunk are independent. You can declare thunk variables in an HLA program, assign one thunk to another, pass thunks as parameters, return them as function results, and, in general, do just about anything that is possible with a 64-bit data type containing two double word pointers.

To declare a thunk in HLA you use the *thunk* data type, e.g.,

```
static
myThunk: thunk;
```

Like other 64-bit data types HLA does not provide a mechanism for initializing thunks you declare in a static section. However, you'll soon see that it is easy to initialize a thunk within the body of your procedures.

A *thunk* variable holds two pointers. The first pointer, in the L.O. double word of the thunk, points at some execution environment, that is, an activation record. The second pointer, in the H.O. double word of the thunk, points at the code to execute for the thunk.

To "call" a thunk, you simply apply the "()" suffix to the thunk's name. For example, the following "calls" *myThunk* in the procedure where you've declared *myThunk*:

```
myThunk ();
```

Thunks never have parameters, so the parameter list must be empty.

A thunk invocation is a bit more involved than a simple procedure call. First of all, a thunk invocation will modify the value in EBP (the pointer to the current procedure's activation record), so the thunk invocation must begin by preserving EBP's value on the stack. Next, the thunk invocation must load EBP with the address of the thunk's execution environment; that is, the code must load the L.O. double word of the thunk value into EBP. Next, the thunk must call the code at the address specified by the H.O. double word of the thunk variable. Finally, upon returning from this code, the thunk invocation must restore the original activation record pointer from the stack. Here's the exact sequence HLA emits to a statement like "myThunk();":

```
push((type dword myThunk)); // Pass execution environment as parm.
call((type dword myThunk[4])); // Call the thunk
```

The body of a thunk, that is, the code at the address found in the H.O. double word of the thunk variable, is not a standard HLA procedure. In particular, the body of a thunk does not execute the standard entry or exit sequences for a standard procedure. The calling code passes the pointer to the execution environment (i.e., an activation record) on the stack.. It is the thunk's responsibility to preserve the current value of EBP

and load EBP with this value appearing on the stack. After the thunk loads EBP appropriately, it can execute the statements in the body of the thunk, after which it must restore EBP's original value.

Because a thunk variable contains a pointer to an activation record to use during the execution of the thunk's code, it is perfectly reasonable to access local variables and other local objects in the activation record active when you define the thunk's body. Consider the following code:

```
procedure SomeProc;
var
 c: int32;
 d: int32;
 t: thunk;
begin SomeProc;

 mov(ebp, (type dword t));
 mov(&thunk1, (type dword t[4]));
 jmp OverThunk1;
thunk1:
 push(EBP); // Preserve old EBP value.
 mov([esp+8], ebp); // Get pointer to original thunk environment.
 mov(d, eax);
 add(c, eax);
 pop(ebp); // Restore caller's environment.
 ret(4); // Remove EBP value passed as parameter.
OverThunk1:
 .
 .
 .
 t(); // Computes the sum of c and d into EAX.
```

This example initializes the *t* variable with the value of *SomeProc*'s activation record pointer (EBP) and the address of the code sequence starting at label *thunk1*. At some later point in the code the program invokes the thunk which begins by pushing the pointer to *SomeProc*'s activation record. Then the thunk executes the PUSH/MOV/MOV/ADD/POP/RET sequence starting at address *thunk1*. Since this code loads EBP with the address of the activation record containing *c* and *d*, this code sequence properly adds these variables together and leaves their sum in EAX. Perhaps this example is not particularly exciting since the invocation of *t* occurs while EBP is still pointing at *SomeProc*'s activation record. However, you'll soon see that this isn't always the case.

---

## 1.4 Initializing Thunks

In the previous section you saw how to manually initialize a thunk variable with the environment pointer and the address of an in-line code sequence. While this is a perfectly legitimate way to initialize a thunk variable, HLA provides an easier solution: the THUNK statement.

The HLA THUNK statement uses the following syntax:

```
thunk thunkVar := #{ code sequence }#;
```

*thunkVar* is the name of a thunk variable and *code\_sequence* is a sequence of HLA statements (note that the sequence does not need to contain the thunk entry and exit sequences. Specifically, it doesn't need the "push(ebp);" and "mov( [esp+8]);" instructions at the beginning of the code, nor does it need to end with the "pop(ebp);" and "ret(4);" instructions. HLA will automatically supply the thunk's entry and exit sequences.

Here's the example from the previous section rewritten to use the THUNK statement:

```
procedure SomeProc;
var
 c: int32;
 d: int32;
 t: thunk;
```

```

begin SomeProc;

 thunk t :=
 #{
 mov(d, eax);
 add(c, eax);
 }#;
 .
 .
 .
 t(); // Computes the sum of c and d into EAX.

```

Note how much clearer and easier to read this code sequence becomes when using the THUNK statement. You don't have to stick in statements to initialize *t*, you don't have to jump over the thunk body, you don't have to include the thunk entry/exit sequences, and you don't wind up with a bunch of statement labels in the code. Of course, HLA emits the same code sequence as found in the previous section, but this form is much easier to read and work with.

---

## 1.5 Manipulating Thunks

Since a thunk is a 64-bit variable, you can do anything with a thunk that you can do, in general, with any other *qword* data object. You can assign one thunk to another, compare thunks, pass thunks a parameters, return thunks as function results, and so on. That is to say, thunks are first class objects. Since a thunk is a representation of a sequence of statements, those statements are effectively first class objects. In this section we'll explore the various ways we can manipulate thunks and the statements associated with them.

---

### 1.5.1 Assigning Thunks

To assign one thunk to another you simply move the two double words from the source thunk to the destination thunk. After the assignment, both thunks specify the same sequence of statements and the same execution environment; that is, the thunks are now aliases of one another. The order of assignment (H.O. double word first or L.O. double word first) is irrelevant as long as you assign both double words before using the thunk's value. By convention, most programmers assign the L.O. double word first. Here's an example of a thunk assignment:

```

mov((type dword srcThunk), eax);
mov(eax, (type dword destThunk));
mov((type dword srcThunk[4]), eax);
mov(eax, (type dword destThunk[4]));

```

If you find yourself assigning one thunk to another on a regular basis, you might consider using a macro to accomplish this task:

```

macro movThunk(src, dest);

 mov((type dword src), eax);
 mov(eax, (type dword dest));
 mov((type dword src[4]), eax);
 mov(eax, (type dword dest[4]));

endmacro;

```

If the fact that this macro's side effect of disturbing the value in EAX is a concern to you, you can always copy the data using a PUSH/POP sequence (e.g., the HLA extended syntax MOV instruction):

```

macro movThunk(src, dest);

```

```

mov((type dword src), (type dword dest));
mov((type dword src[4]), (type dword dest[4]));

endmacro;

```

If you don't plan on executing any floating point code in the near future, or you're already using the MMX instruction set, you can also use the MMX MOVQ instruction to copy these 64 bits with only two instructions:

```

movq(src, mm0);
movq(mm0, dest);

```

Don't forget, however, to execute the EMMS instruction before calling any routines that might use the FPU after this sequence.

## 1.5.2 Comparing Thunks

You can compare two thunks for equality or inequality using the standard 64-bit comparisons (see "Extended Precision Comparisons" on page 831). If two thunks are equal then they refer to the same code sequence with the same execution environment; if they are not equal, then they could have different code sequences or different execution environments (or both) associated with them. Note that it doesn't make any sense to compare one thunk against another for less than or greater than. They're either equal or not equal.

Of course, it's quite easy to have two thunks with the same environment pointer and different code pointers. This occurs when you initialize two thunk variables with separate code sequences in the same procedure, e.g.,

```

thunk t1 :=
 #{
 mov(0, eax);
 mov(i, ebx);
 }#;

thunk t2 :=
 #{
 mov(4, eax);
 mov(j, ebx);
 }#;

// At this point, t1 and t2 will have the same environment pointer
// (EBP's value) but they will have different code pointers.

```

Note that it is quite possible for two thunks to refer to the same statement sequence yet have different execution environments. This can occur when you have a recursive function that initializes a pair of thunk variables with the same instruction sequence on different recursive calls of the function. Since each recursive invocation of the function will have its own activation record, the environment pointers for the two thunks will be different even though the pointers to the code sequence are the same. However, if the code that initializes a specific thunk is not recursive, you can sometimes compare two thunks by simply comparing their code pointers (the H.O. double words of the thunks) if you're careful about never using thunks once their execution environment goes away (i.e., the procedure in which you originally assigned the thunk value returns to its caller).

## 1.5.3 Passing Thunks as Parameters

Since the *thunk* data type is effectively equivalent to a *qword* type, there is little you can do with a *qword* object that you can't also do with a *thunk* object. In particular, since you can pass *qwords* as parameters you can certainly pass *thunks* as parameters to procedures.

To pass a thunk by value to a procedure is very easy, simply declare a formal parameter using the *thunk* data type:

```

procedure HasThunkParm(t:thunk);
var
 i:integer;
begin HasThunkParm;

 mov(1, i);
 t(); // Invoke the thunk passed as a parameter.
 mov(i, eax); // Note that t does not affect our environment.

end HasThunkParm;

.
.
.
thunk thunkParm :=
 #{
 mov(0, i); // Not the same "i" as in HasThunkParm!
 }#;

HasThunkParm(thunkParm);

```

Although a thunk is a pointer (a pair of pointers, actually), you can still pass thunks by value. Passing a thunk by value passes the values of those two pointer objects to the procedure. The fact that these values are the addresses of something else is not relevant, you're passing the data by value.

HLA automatically pushes the value of a thunk on the stack when passing a thunk by value. Since thunks are 64-bit objects, you can only pass them on the stack, you cannot pass them in a register<sup>1</sup>. When HLA passes a thunk, it pushes the H.O. double word (the code pointer) of the thunk first followed by the L.O. double word (the environment pointer). This way, the two pointers are situated on the stack in the same order they normally appear in memory (the environment pointer at the lowest address and the code pointer at the highest address).

If you decide to manually pass a thunk on the stack yourself, you must push the two halves of the thunk on the stack in the same order as HLA, i.e., you must push the H.O. double word first and the L.O. double word second. Here's the call to *HasThunkParm* using manual parameter passing:

```

push((type dword thunkParm[4]));
push((type dword thunkParm));
call HasThunkParm;

```

You can also pass thunks by reference to a procedure using the standard pass by reference syntax. Here's a typical procedure prototype with a pass by reference thunk parameter:

```

procedure refThunkParm(var t:thunk); forward;

```

When you pass a thunk by reference, you're passing a pointer to the thunk itself, not the pointers to the thunk's execution environment or code sequence. To invoke such a thunk you must manually dereference the pointer to the thunk, push the pointer to the thunk's execution environment, and indirectly call the code sequence. Here's an example implementation of the *refThunkParm* prototype above:

```

procedure refThunkParm(var t:thunk);
begin refThunkParm;

 push(eax);
 .
 .

```

---

1. Technically, you could pass a thunk in two 32-bit registers. However, you will have to do this manually; HLA will not automatically move the two pointers into two separate registers for you.

The following code manually creates and destroys the function's activation record so that it can specify the thunk result as the first two parameters of the function's parameter list:

```

procedure RtnThunkResult
(
 ThunkCode:dword; // H.O. dword of return result goes here.
 ThunkEnv:dword; // L.O. dword of return result goes here.
 selection:boolean; // First actual parameter.
 tTrue: thunk; // Return this thunk if selection is true.
 tFalse:thunk // Return this thunk if selection is false.
); nodisplay; noframe;
begin RtnThunkResult;

 push(ebp); // Set up the activation record.
 mov(esp, ebp);
 push(eax);

 if(selection) then

 mov((type dword tTrue), eax);
 mov(eax, ThunkEnv);
 mov((type dword tTrue[4]), eax);
 mov(eax, ThunkCode);

 else

 mov((type dword tFalse), eax);
 mov(eax, ThunkEnv);
 mov((type dword tFalse[4]), eax);
 mov(eax, ThunkCode);

 endif;

 // Clean up the activation record, but leave the eight
 // bytes of the thunk return result on the stack when this
 // function returns.

 pop(eax);
 pop(ebp);
 ret(_parms_ - 8); // _parms_ is total # of bytes of parameters (28).

end RtnThunkResult;
.
.
.
// Example of call to RtnThunkResult and storage of return result.
// (Note passing zeros as the thunk values to reserve storage for the
// thunk return result on the stack):

RtnThunkResult(0, 0, ChooseOne, t1, t2);
pop((type dword SomeThunkVar));
pop((type dword SomeThunkVar[4]));

```

If you prefer not to list the thunk parameter as a couple of pseudo-parameters in the function's parameter list, you can always manually allocate storage for the parameters prior to the call and refer to them using the "[ESP+disp]" or "[EBP+disp]" addressing mode within the function's body.

## 1.6 Activation Record Lifetimes and Thunks

There is a problem that can occur when using thunks in your applications: it's quite possible to invoke a thunk long after the associated execution environment (activation record) is no longer valid. Consider the following HLA code that demonstrates this problem:

```
static
 BadThunk: thunk;

 procedure proc1;
 var
 i:int32;
 begin proc1;

 thunk BadThunk :=
 #{
 stdout.put("i = ", i, nl);
 };
 mov(25, i);

 end proc1;

 procedure proc2;
 var
 j:int32;
 begin proc2;

 mov(123, j);
 BadThunk();

 end proc2;
 .
 .
 .
```

If the main program in this code fragment calls *proc1* and then immediately calls *proc2*, this code will probably print "i = 123" although there is no guarantee this will happen (the actual result depends on a couple of factors, although "i = 123" is the most likely output).

The problem with this code example is that *proc1* initializes *BadThunk* with the address of an execution environment that is no longer "live" when the program actually executes the thunk's code later on. The *proc1* procedure constructs its own activation record and initializes the variable *i* in this activation record with the value 25. This procedure also initializes *BadThunk* with the address of the code sequence containing the *stdout.put* statement and it initializes *BadThunk*'s execution environment pointer with the address of *proc1*'s activation record. Then *proc1* returns to its caller. Unfortunately upon returning to its caller, *proc1* also obliterates its activation record even though *BadThunk* still contains a pointer into this area of memory. Later, when the main program calls *proc2*, *proc2* builds its own activation record (most likely over the top of *proc1*'s old activation record). When *proc2* invokes *BadThunk*, *BadThunk* uses the original pointer to *proc1*'s activation record (which is now invalid and probably points at *proc2*'s activation record) from which to fetch *i*'s value. If nothing extra was pushed or popped between the *proc1* invocation and the *proc2* invocation, then *j*'s value in *proc2* is probably at the same memory location as *i* was in *proc1*'s invocation. Hence, the *stdout.put* statement in the thunk's code will print *j*'s value.

This rather trivial example demonstrates an important point about using thunks – you must always ensure that a thunk's execution environment is still valid whenever you invoke a thunk. In particular, if you use HLA's THUNK statement to automatically initialize a thunk variable with the address of a code sequence and the execution environment of the current procedure, you must not invoke that thunk once the procedure returns to its caller; for at that point the thunk's execution environment pointer will not be valid.

This discussion does not suggest that you can only use a thunk within the procedure in which you assign a value to that thunk. You may continue to invoke a thunk, even from outside the procedure whose activation record the thunk references, until that procedure returns to its caller. So if that procedure calls some other procedure (or even itself, recursively) then it is legal to call the thunk associated with that procedure.

## 1.7 Comparing Thunks and Objects

Thunks are very similar to objects insofar as you can easily implement an abstract data type with a thunk. Remember, an abstract data type is a piece of data and the operation(s) on that data. In the case of a thunk, the execution environment pointer can point at the data while the code address can point at the code that operates on the data. Since you can also use objects to implement abstract data types, one might wonder how objects and thunks compare to one another.

Thunks are somewhat less "structured" than objects. An object contains a set of data values and operations (methods) on those data values. You cannot change the data values an object operates upon without fundamentally changing the object (i.e., selecting a different object in memory). It is possible, however, to change the execution environment pointer in a thunk and have that thunk operate on fundamentally different data. Although such a course of action is fraught with difficulty and very error-prone, there are some times when changing the execution environment pointer of a thunk will produce some interesting results. This text will leave it up to you to discover how you could abuse thunks in this fashion.

## 1.8 An Example of a Thunk Using the Fibonacci Function

By now, you're probably thinking "thunks may be interesting, but what good are they?" The code associated with creating and invoking thunks is not spectacularly efficient (compared, say, to a straight procedure call). Surely using thunks must negatively impact the execution time of your code, eh? Well, like so many other programming constructs, the misuse and abuse of thunks can have a negative impact on the execution time of your programs. However, in an appropriate situation thunks can dramatically improve the performance of your programs. In this section we'll explore one situation where the use of thunks produces an amazing performance boost: the calculation of a Fibonacci number.

Earlier in this text there was an example of a Fibonacci number generation program (see "Fibonacci Number Generation" on page 41). As you may recall, the Fibonacci function `fib(n)` is defined recursively for  $n \geq 1$  as follows:

```
fib(1) = 1;
fib(2) = 1;
fib(n) = fib(n-1) + fib(n-2)
```

One problem with this recursive definition for *fib* is that it is extremely inefficient to compute. The number of clock cycles this particular implementation requires to execute is some exponential factor of  $n$ . Effectively, as  $n$  increases by one this algorithm takes twice as long to execute.

The big problem with this recursive definition is that it computes the same values over and over again. Consider the statement "`fib( n ) = fib( n-1 ) + fib( n-2 )`". Note that the computation of `fib(n-1)` also computes `fib(n-2)` (since `fib(n-1) = fib(n-2) + fib(n-3)` for all  $n \geq 4$ ). Although the computation of `fib(n-1)` computes the value of `fib(n-2)` as part of its calculation, this simple recursive definition doesn't save that result, so it must recompute `fib(n-2)` upon returning from `fib(n-1)` in order to complete the calculation of `fib(n)`.

Since the calculation of `Fib(n-1)` generally computes `Fib(n-2)` as well, what would be nice is to have this function return both results simultaneously; that is, not only should `Fib(n-1)` return the Fibonacci number for  $n-1$ , it should also return the Fibonacci number for  $n-2$  as well. In this example, we will use a thunk to store the result of `Fib(n-2)` into a local variable in the Fibonacci function.

**Figure 1.1 Using a Thunk to Set the Fib(n-2) Value in a Different Activation Record**

The following program provides two versions of the Fibonacci function: one that uses thunks to pass the Fib(n-2) value back to a previous invocation of the function. Another version of this function computes the Fibonacci number using the traditional recursive definition. The program computes the running time of both implementations and displays the results. Without further ado, here's the code:

```

program fibThunk;
#include("stdlib.hhf")

// Fibonacci function using a thunk to calculate fib(n-2)
// without making a recursive call.

procedure fib(n:uns32; nm2:thunk); nodisplay; returns("eax");
var
 n2: uns32; // A recursive call to fib stores fib(n-2) here.
 t: thunk; // This thunk actually stores fib(n-2) in n2.

begin fib;

 // Special case for n = 1, 2. Just return 1 as the
 // function result and store 1 into the fib(n-2) result.

 if(n <= 2) then

 mov(1, eax); // Return as n-1 value.
 nm2(); // Store into caller as n-2 value.

 else

 // Create a thunk that will store the fib(n-2) value
 // into our local n2 variable.

 thunk t :=
 #{
 mov(eax, n2);
 }#;

```

```

 mov(n, eax);
 dec(eax);
 fib(eax, t); // Compute fib(n-1).

 // Pass back fib(n-1) as the fib(n-2) value to a previous caller.

 nm2();

 // Compute fib(n) = fib(n-1) [in eax] + fib(n-2) [in n2]:
 add(n2, eax);

endif;

end fib;

// Standard fibonacci function using the slow recursive implementation.

procedure slowfib(n:uns32); nodisplay; returns("eax");
begin slowfib;

 // For n= 1,2 just return 1.

 if(n <= 2) then

 mov(1, eax);

 else

 // Return slowfib(n-1) + slowfib(n-2) as the function result:

 dec(n);
 slowfib(n); // compute fib(n-1)
 push(eax); // Save fib(n-1);

 dec(n); // compute fib(n-2);
 slowfib(n);

 add([esp], eax); // Compute fib(n-1) [on stack] + fib(n-2) [in eax].
 add(4, esp); // Remove old value from stack.

 endif;

end slowfib;

var
 prevTime:dword[2]; // Used to hold 64-bit result from RDTSC instr.
 qw: qword; // Used to compute difference in timing.
 dummy:thunk; // Used in original calls to fib.

begin fibThunk;

 // "Do nothing" thunk used by the initial call to fib.
 // This thunk simply returns to its caller without doing
 // anything.

 thunk dummy := #{ }#;

```

```

// Call the fibonacci routines to "prime" the cache:

fib(1, dummy);
slowfib(1);

// Okay, compute the times for the two fibonacci routines for
// values of n from 1 to 32:

for(mov(1, ebx); ebx < 32; inc(ebx)) do

 // Read the time stamp counter before calling fib:
 rdtsc();
 mov(eax, prevTime);
 mov(edx, prevTime[4]);

 fib(ebx, dummy);
 mov(eax, ecx);

 // Read the timestamp counter and compute the approximate running
 // time of the current call to fib:

 rdtsc();
 sub(prevTime, eax);
 sbb(prevTime[4], edx);
 mov(eax, (type dword qw));
 mov(edx, (type dword qw[4]));

 // Display the results and timing from the call to fib:

 stdout.put
 (
 "n=",
 (type uns32 ebx):2,
 " fib(n) = ",
 (type uns32 ecx):7,
 " time="
);
 stdout.putu64size(qw, 5, ' ');

 // Okay, repeat the above for the slowfib implementation:

 rdtsc();
 mov(eax, prevTime);
 mov(edx, prevTime[4]);

 slowfib(ebx);
 mov(eax, ecx);
 rdtsc();
 sub(prevTime, eax);
 sbb(prevTime[4], edx);
 mov(eax, (type dword qw));
 mov(edx, (type dword qw[4]));

 stdout.put(" slowfib(n) = ", (type uns32 ecx):7, " time = ");
 stdout.putu64size(qw, 8, ' ');
 stdout.newln();

endfor;

```

```
end fibThunk;
```

---

---

**Program 1.1 Fibonacci Number Generation Using Thunks**

---

---

This (relatively) simple modification to the Fibonacci function produces a dramatic difference in the run-time of the code. The run-time of the thunk implementation is now well within reason. The following table lists the same run-times of the two functions (thunk implementation vs. standard recursive implementation). As you can see, this small change to the program has made a very significant difference.

**Table 1: Running Time of the FIB and SlowFib Functions**

| n  | Fib Execution Time<br>(Thunk Implementation) <sup>a</sup> | SlowFib Execution<br>Time (Recursive<br>Implementation) |
|----|-----------------------------------------------------------|---------------------------------------------------------|
| 1  | 60                                                        | 97                                                      |
| 2  | 152                                                       | 100                                                     |
| 3  | 226                                                       | 166                                                     |
| 4  | 270                                                       | 197                                                     |
| 5  | 302                                                       | 286                                                     |
| 6  | 334                                                       | 414                                                     |
| 7  | 369                                                       | 594                                                     |
| 8  | 397                                                       | 948                                                     |
| 9  | 432                                                       | 1513                                                    |
| 10 | 473                                                       | 2421                                                    |
| 11 | 431                                                       | 3719                                                    |
| 12 | 430                                                       | 6010                                                    |
| 13 | 467                                                       | 9763                                                    |
| 14 | 494                                                       | 15758                                                   |
| 15 | 535                                                       | 25522                                                   |
| 16 | 564                                                       | 41288                                                   |
| 17 | 614                                                       | 66822                                                   |
| 18 | 660                                                       | 108099                                                  |
| 19 | 745                                                       | 174920                                                  |
| 20 | 735                                                       | 283001                                                  |
| 21 | 791                                                       | 457918                                                  |
| 22 | 886                                                       | 740894                                                  |

**Table 1: Running Time of the FIB and SlowFib Functions**

| n  | Fib Execution Time (Thunk Implementation) <sup>a</sup> | SlowFib Execution Time (Recursive Implementation) |
|----|--------------------------------------------------------|---------------------------------------------------|
| 23 | 943                                                    | 1198802                                           |
| 24 | 919                                                    | 1941077                                           |
| 25 | 966                                                    | 3138466                                           |
| 26 | 1015                                                   | 5094734                                           |
| 27 | 1094                                                   | 8217396                                           |
| 28 | 1101                                                   | 13297000                                          |
| 29 | 1158                                                   | 21592819                                          |
| 30 | 3576 <sup>b</sup>                                      | 34927400                                          |
| 31 | 1315                                                   | 56370705                                          |

a. All times are in CPU cycles as measured via RDTSC on a Pentium II processor.

b. This value was not recorded properly because of OS overhead.

Note that a thunk implementation of the Fibonacci function is not the only way to improve the performance of this function. One could have just as easily (more easily, in fact) passed the address of the local  $n2$  variable by reference and had the recursive call store the  $\text{Fib}(n-2)$  value directly into the  $n2$  variable. For that matter, one could have written an interactive (rather than recursive) solution to this problem that computes the Fibonacci number very efficiently. However, alternate solutions to Fibonacci aside, this example does clearly demonstrate that the use of a thunk in certain situations can dramatically improve the performance of an algorithm.

---

## 1.9 Thunks and Artificial Intelligence Code

Although the use of thunks to compute the Fibonacci number in the previous section produced a dramatic performance boost, thunks clearly were not necessary for this operation (indeed, not too many people really need to compute Fibonacci numbers, for that matter). Although this example demonstrates that thunks can improve performance in various situations, it does not demonstrate the need for thunks. After all, there are even more efficient implementations of the Fibonacci function (though nothing quite so dramatic as the difference between Fib and SlowFib, which went from exponential to linear execution time) that do not involve the use of thunks. So although the use of thunks can increase the performance of the Fibonacci function (over the execution time of the standard recursive implementation), the example in the previous section does not demonstrate the need for thunks since there are better implementations of the Fibonacci function that do not use thunks. In this section we will explore some types of calculations for which thunks present a very good, if not the best, solution.

In the field of Artificial Intelligence (AI from this point forward) researchers commonly use interpreted programming languages such as LISP or Prolog to implement various algorithms. Although you could write an AI program in just about any language, these interpreted languages like LISP and Prolog have a couple of benefits that help make writing AI programs much less difficult. Among a long list of other features, two important features stand out: (1) statements in these languages are first class objects, (2) these languages can defer the evaluation of function parameters until the parameters' values are actually needed (lazy evalua-

tion). Since thunks provide exactly these two features in an HLA program, it should come as no surprise that you can use thunks to implement various AI algorithm in assembly language.

Before going too much farther, you should realize that AI programs usually take advantage of many other features in LISP and Prolog besides the two noted above. Automatic dynamic memory allocation and garbage collection are two big features that many AI programs use, for example. Also, the run-time interpretation of language statements is another big feature (i.e., the user of a program can input a string containing a LISP or Prolog statement and the program can execute this string as part of the program). Although it is certainly possible to achieve all this in an assembly language program, such support built into languages like LISP and Prolog may require (lots of) additional coding in assembly language. So please don't allow this section to trivialize the effort needed to write AI programs in assembly language; writing (good) AI programs is difficult and tools like LISP and Prolog can reduce that effort.

Of course, a major problem with languages like LISP and Prolog is that programs written in these (interpreted) languages tend to run very slow. Some people may argue that there isn't a sufficient difference in performance between programs written in C/C++ and assembly to warrant the extra effort of writing the code in assembly; such a claim is difficult to make about LISP or Prolog programs versus an assembly equivalent. Whereas a well-written assembly program may be only a couple of times faster than a well-written C/C++ program, a well-written assembly program will probably be tens, if not hundreds or thousands, of times faster than the equivalent LISP or Prolog code. Therefore, reworking at least a portion of an AI program written in one of these interpreted languages can produce a very big boost in the performance of the AI application.

Traditionally, one of the big problem areas AI programmers have had when translating their applications to a lower-level language has been the issue of "function calls (statements) as first class objects and the need for lazy evaluation." Traditional third generation programming languages like C/C++ and Pascal simply do not provide these facilities. AI applications that make use of these facilities in languages like LISP or Prolog often have to be rewritten in order to avoid the use of these features in the lower-level languages. Assembly language doesn't suffer from this problem. Oh, it may be difficult to implement some feature in assembly language, but if it can be done it can be done in assembly language. So you'll never run into the problem of assembly language being unable to implement some feature from LISP, Prolog, or some other language.

Thunks are a great vehicle for deferring the execution of some code until a later time (or, possibly, forever). One application area where deferred execution is invaluable is in a game. Consider a situation in which the current state of a game suggests one of several possible moves a piece could make based on a decision made by an adversary (e.g., a particular chess piece could make one of several different moves depending on future moves by the other color). You could represent these moves as a list of thunks and executing the move by selecting and executing one of the thunks from the list at some future time. You could base the selection of the actual thunk to execute on adversarial moves that occur at some later time.

Thunks are also useful for passing results of various calculations back to several different points in your code. For example, in a multi-player strategy game the activities of one player could be broadcast to a list of interested players by having those other players "register" a thunk with the player. Then, whenever the player does something of interest to those other players, the program could execute the list of thunks and pass whatever data is important to those other players via the thunks.

## 1.10 Thunks as Triggers

Thunks are also useful as *triggers*. A trigger is a device that fires whenever a certain condition is met. Probably the most common example of a trigger is a database trigger that executes some code whenever some condition occurs in the database (e.g., the entry of an invalid data or the update of some field). Triggers are useful insofar as they allow the use of *declarative programming* in your assembly code. Declarative programming consists of some declarations that automatically execute when a certain condition exists. Such declarations do not execute sequentially or in response to some sort of call. They are simply part of the programming environment and automatically execute whenever appropriate. At the machine level, of course, some sort of call or jump must be made to such a code sequence, but at a higher level of abstraction the code seems to "fire" (execute) all on its own.

To implement declarative programming using triggers you must get in the habit of writing code that always calls a "trigger routine" (i.e., a thunk) at any given point in the code where you would want to handle some event. By default, the trigger code would be an empty thunk, e.g.:

```
procedure DefaultTriggerProc; nodisplay; noframe;
begin DefaultTriggerProc;

 // Immediately return to the caller and pop off the environment
 // pointer passed to us (probably a NULL pointer).

 ret(4);

end DefaultTriggerProc;

static
 DefaultTrigger: thunk: nostorage;
 dword 0, &DefaultTriggerProc;
```

The code above consists of two parts: a procedure that corresponds to the default thunk code to execute and a declaration of a default trigger thunk object. The procedure body consists of nothing more than a return that pops the EBP value the thunk invocation pushes and then returns back to the thunk invocation. The default trigger thunk variable contains NULL (zero) for the EBP value and the address of the *DefaultTriggerProc* code as the code pointer. Note that the value we pass as the environment pointer (EBP value) is irrelevant since *DefaultTriggerProc* ignores this value.

To use a trigger, you simply declare a thunk variable like *DefaultTrigger* above and initialize it with the address of the *DefaultTriggerProc* procedure. You will need a separate thunk variable for each trigger event you wish to process; however, you will only need one default trigger procedure (you can initialize all trigger thunks with the address of this same procedure). Generally, these trigger thunks will be global variables so you can access the thunk values throughout your program. Yes, using global variables is often a no-no from a structured point of view, but triggers tend to be global objects that several different procedures share, so using global objects is appropriate here. If using global variables for these thunks offends you, then bury them in a class and provide appropriate accessor methods to these thunks.

Once you have a thunk you want to use as a trigger, you invoke that thunk from the appropriate point in your code. As a concrete example, suppose you have a database function that updates a record in the database. It is common (in database programs) to trigger an event after the update and, possibly, before the update. Therefore, a typical database update procedure might invoke two thunks – one before and one after the body of the update procedure's code. The following code fragment demonstrates how you code do this:

```
static
 preUpdate: thunk: nostorage;
 dword 0, &DefaultTriggerProc;

 postUpdate: thunk: nostorage;
 dword 0, &DefaultTriggerProc;

 .
 .
 .
procedure databaseUpdate(<< appropriate parameters >>);
 << declarations >>
begin databaseUpdate;

 preUpdate(); // Trigger the pre-update event.

 << Body of update procedure >>

 postUpdate(); // Trigger the post-update event.

end databaseUpdate;
```

As written, of course, these triggers don't do much. They call the default trigger procedure that immediately returns. Thus far, the triggers are really nothing more than a waste of time and space in the program. However, since the *preUpdate* and *postUpdate* thunks are variables, we can change their values under program control and redirect the trigger events to different code.

When changing a trigger's value, it's usually a good idea to first preserve the existing thunk data. There isn't any guarantee that the thunk points at the default trigger procedure. Therefore, you should save the value so you can restore it when you're done handling the trigger event (assuming you are writing an event handler that shuts down before the program terminates). If you're setting and restoring a trigger value in a procedure, you can copy the global thunk's value into a local variable prior to setting the thunk and you can restore the thunk from this local variable prior to returning from the procedure:

```
procedure DemoRestoreTrigger;
var
 RestoreTrigger: dword[2];
begin DemoRestoreTrigger;

 // The following three statements "register" a thunk as the
 // "GlobalEvent" trigger:

 mov((type dword GlobalEvent[0]), RestoreTrigger[0]);
 mov((type dword GlobalEvent[4]), RestoreTrigger[4]);
 thunk GlobalEvent := #{ <<thunk body >> }#;

 << Body of DemoRestoreTrigger procedure >>

 // Restore the original thunk as the trigger event:

 mov(RestoreTrigger[0], (type dword GlobalEvent[0]));
 mov(RestoreTrigger[4], (type dword GlobalEvent[4]));

end DemoRestoreTrigger;
```

Note that this code works properly even if *DemoRestoreTrigger* is recursive since the *RestoreTrigger* variable is an automatic variable. You should always use automatic (VAR) objects to hold the saved values since static objects have only a single instance (which would fail in a multi-threaded environment or if *DemoRestoreTrigger* is recursive).

One problem with the code in the example above is that it replaces the current trigger with a new trigger. While this is sometimes desirable, more often you'll probably want to *chain* the trigger events. That is, rather than having a trigger call the most recent thunk, which returns to the original code upon completion, you'll probably want to call the original thunk you replaced before or after the current thunk executes. This way, if several procedures register a trigger on the same global event, they will all "fire" when the event occurs. The following code fragment shows the minor modifications to the code fragment above needed to pull this off:

```
procedure DemoRestoreTrigger;
var
 PrevTrigger: thunk;
begin DemoRestoreTrigger;

 // The following three statements "register" a thunk as the
 // "GlobalEvent" trigger:

 mov((type dword GlobalEvent[0]), (type dword PrevTrigger[0]));
 mov((type dword GlobalEvent[4]), (type dword PrevTrigger[4]));
 thunk GlobalEvent :=
 #{
 PrevThunk();
 <<thunk body >>
 }#;
```

```

<< Body of DemoRestoreTrigger procedure >>

// Restore the original thunk as the trigger event:

mov((type dword PrevTrigger[0]), (type dword GlobalEvent[0]));
mov((type dword PrevTrigger[4]), (type dword GlobalEvent[4]));

end DemoRestoreTrigger;

```

The principal differences between this version and the last is that *PrevTrigger* (a thunk) replaces the *RestoreTrigger* (two double words) variable and the thunk code invokes *PrevTrigger* before executing its own code. This means that the thunk's body will execute *after* all the previous thunks in the chain. If you would prefer to execute the thunks body before all the previous thunks in the chain, then simply invoke the thunk *after* the thunk's body, e.g.,

```

thunk GlobalEvent :=
 #{
 <<thunk body >>
 PrevThunk();
 }#;

```

In practice, most programs set a trigger event once and let a single, global, trigger handler process events from that point forward. However, if you're writing more sophisticated code that enables and disables trigger events throughout, you might want to write a macro that helps automate saving, setting, and restore thunk objects. Consider the following HLA macro:

```

macro EventHandler(Event, LocalThunk);

 mov((type dword Event[0]), (type dword LocalThunk[0]));
 mov((type dword Event[4]), (type dword LocalThunk[4]));
 thunk Event :=

 terminator EndEventHandler;

 mov((type dword LocalThunk[0]), (type dword Event[0]));
 mov((type dword LocalThunk[4]), (type dword Event[4]));

endmacro;

```

This macro lets you write code like the following:

```

procedure DemoRestoreTrigger;
var
 PrevTrigger: thunk;
begin DemoRestoreTrigger;

 EventHandler(GlobalEvent, PrevTrigger) // Note: no semicolon here!

 #{
 PrevThunk();
 <<thunk body >>
 }#;

 << Body of DemoRestoreTrigger procedure >>

 EndEventHandler;

end DemoRestoreTrigger;

```

Especially note the comment stating that no semicolon follows the *EventHandler* macro invocation. If you study the *EventHandler* macro carefully, you'll notice that macro ends with the first half of a THUNK statement. The body of the *EventHandler.EndEventHandler* statement (macro invocation) must begin with a thunk body declaration that completes the THUNK statement begun in *EventHandler*. If you put a semicolon at the end of the *EventHandler* statement, this will insert the semicolon into the middle of the THUNK statement, resulting in a syntax error. If these syntactical gymnastics bother you, you can always remove the THUNK statement from the macro and require the end user to type the full THUNK statement at the beginning of the macro body. However, saving this extra type is what macros are all about; most users would probably rather deal with remembering not to put a semicolon at the end of the *EventHandler* statement rather than do this extra typing.

---

## 1.11 Jumping Out of a Thunk

Because a thunk is a procedure nested within another procedure's body, there are some interesting situations that can arise during program execution. One such situation is jumping out of a thunk and into the surrounding code during the execution of that thunk. Although it is possible to do this, you must exercise great caution when doing so. This section will discuss the precautions you must take when leaving a thunk other than via a RET instruction.

Perhaps the best place to start is with a couple of examples that demonstrate various ways to abnormally exit a thunk. The first thunk in the example below demonstrates a simple JMP instruction while the second thunk in this example demonstrates leaving a thunk via a BREAK statement.

```

procedure ExitThunks;
var
 jmpFrom:thunk;
 breakFrom:thunk;
begin ExitThunks;

 thunk jmpFrom :=
 #{
 // Just jump out of this thunk and back into
 // the ExitThunks procedure:

 jmp XTlabel;
 }#;

 // Execute the thunk above (which winds up jumping to the
 // XTlabel label below:

 jmpFrom();

 XTlabel:

 // Create a loop inside the ExitThunks procedure and
 // define a thunk within this loop. Use a BREAK statement
 // within the thunk to exit the thunk (and loop).

 forever

 thunk breakFrom :=
 #{
 // Break out of this thunk and the surrounding
 // loop via the following BREAK statement:

 break;
 }#;

 // Invoke the thunk (which causes use to exit from the

```

```

 // surrounding loop):

 breakFrom();

 endfor;

end ExitThunks;

```

Obviously, you should avoid constructs like these in your thunks. The control flow in the procedure above is very unusual, to say the least, and others reading this code will have a difficult time fully comprehending what is going on. Of course, like other structured programming techniques that make programs easier to read, you may discover the need to write code like this under special circumstances. Just don't make a habit of doing this gratuitously.

There is a problem with breaking out of the thunks as was done in the code above: this scheme leaves a bunch of data on the stack (specifically, the thunk's parameter, the return address, and the saved EBP value in this particular example). Had *ExitThunks* pushed some registers on the stack that it needed to preserve, ESP would not be properly pointing at those register upon reaching the end of the function. Therefore, popping these registers off the stack would load garbage into the registers. Fortunately, the HLA standard exit sequence reloads ESP from EBP prior to popping EBP's value and the return address off the stack; this resynchronizes ESP prior to returning from the procedure. However, anything you push on the stack after the standard entry sequence will not be on the top of stack if you prematurely bail out of a thunk as was done in the previous example.

The only reasonable solution is to save a copy of the stack pointer's value in a local variable after you push any important data on the stack. Then restore ESP from this local (automatic) variable before attempting to pop any of that data off the stack. The following implementation of *ExitThunks* demonstrates this principle in action:

```

procedure ExitThunks;
var
 jmpFrom: thunk;
 breakFrom: thunk;
 ESPsave: dword;

begin ExitThunks;

 push(eax); // Registers we wish to preserve.
 push(ebx);
 push(ecx);
 push(edx);
 mov(esp, ESPsave); // Preserve ESP's value for return.

 thunk jmpFrom :=
 #{
 << Code, as appropriate, for this thunk >>

 // Just jump out of this thunk and back into
 // the ExitThunks procedure:

 jmp XTlabel;
 }#;

 // Execute the thunk above (which winds up jumping to the
 // XTlabel label below:

 jmpFrom();

 XTlabel:

 // Create a loop inside the ExitThunks procedure and

```

```

// define a thunk within this loop. Use a BREAK statement
// within the thunk to exit the thunk (and loop).

forever

 thunk breakFrom :=
 #{
 << Code, as appropriate, for this thunk >>

 // Break out of this thunk and the surrounding
 // loop via the following BREAK statement:

 break;
 }#;

 // Invoke the thunk (which causes use to exit from the
 // surrounding loop):

 breakFrom();

endfor;

<< Any other code required by the procedure >>

// Restore ESP's value from ESPsave in case one of the thunks (or both)
// above have prematurely exited, leaving garbage on the stack.

mov(ESPsave, esp);

// Restore the registers and leave:

pop(edx);
pop(ecx);
pop(ebx);
pop(eax);

end ExitThunks;

```

This scheme will work properly because the thunks always set up EBP to point at *ExitThunks*' activation record (this is true even if the program calls these thunks from some other procedures). The *ESPsave* variable must be an automatic (VAR) variable if this code is to work properly in all cases.

---

## 1.12 Handling Exceptions with Thunks

Thunks are also useful for passing exception information back to some code in the calling tree when the HLA exception handling code would be inappropriate (e.g., if you don't want to immediately abort the operation of the current code, you just want to pass data back to some previous code in the current call chain). Before discussing how to implement some exception handler with a thunk, perhaps we should discuss why we would want to do this. After all, HLA has an excellent exception handling mechanism – the TRY..ENDTRY and RAISE statements; why not use those instead of processing exceptions manually with thunks? There are two reasons for using thunks to handle exceptions – you might want to bypass the normal exception handling code (i.e., skip over TRY..ENDTRY blocks for a certain event and pass control directly to some fixed routine) or you might want to resume execution after an exception occurs. We'll look at these two mechanisms in this section.

One of these uses for thunks in exception handling code is to bypass any intermediate TRY..ENDTRY statements between the point of the exception and the handler you'd like to use for the exception. For example, suppose you have the following call chain in your program:

`HasExceptionHandler->MayHaveOne->MayHaveAnother->CausesTheException`

In this sequence the procedure *CausesTheException* encounters some exceptional condition. Were you to write the code using the standard RAISE and TRY..ENDTRY statements, then the last TRY..ENDTRY statement (that handles the specific exception) would execute its EXCEPT clause and deal with this exception. In the current example, that means that *MayHaveOne* or *MayHaveAnother* could trap and attempt to handle this exception. Using the standard exception handling mechanism, it is very difficult to ensure that *HasExceptionHandler* is the only procedure that responds to this exception.

One way to avoid this problem is to use a thunk to transfer control to *HasExceptionHandler* rather than the RAISE statement. By declaring a global thunk and initializing it within *HasExceptionHandler* to execute the exception handler, you can bypass any intermediate procedures in the call chain and jump directly to *HasExceptionHandler* from the offending code. Don't forget to save ESP's value and restore it if you bail out of the exception handler code inside the thunk and jump directly into the *HasExceptionHandler* code (see "Jumping Out of a Thunk" on page 1267).

Granted, needing to skip over exception handlers is a bit of a synthetic problem that you won't encounter very often in real-life programs. However, the second feature raised above, resuming the original code after handling an exception, is something you may need to do from time to time. HLA's exceptions do not allow you to resume the code that raised the exception, so if you need this capability thunks provide a good solution. To resume the interrupted code when using a thunk, all you have to do is return from the thunk in the normal fashion. If you don't want to resume the original code, then you can jump out of the thunk and into the surrounding procedure code (don't forget to save and restore ESP in that surrounding code, see "Jumping Out of a Thunk" on page 1267 for details). The nice thing about a thunk is that you don't have to decide whether you're going to bail out of the thunk or resume the execution of the original code while writing your program. You can write some code within the thunk to make this decision at run-time.

### 1.13 Using Thunks in an Appropriate Manner

This chapter presents all sorts of novel uses for thunks. Thunks are really neat and you'll find all kinds of great uses for them if you just think about them for a bit. However, it's also easy to get carried away and use thunks in an inappropriate fashion. Remember, thunks are not only a pointer to a procedure but a pointer to an execution environment as well. In many circumstances you don't need the execution environment pointer (i.e., the pointer to the activation record). In those cases you should remember that you can use a simple procedure pointer rather than a thunk to indirectly call the "thunk" code. A simple indirect call is a bit more efficient than a thunk invocation, so unless you really need all the features of the thunk, just use a procedure pointer instead.

### 1.14 Putting It All Together

Although thunks are quite useful, you don't see them used in many programs. There are two reasons for this – most high level languages don't support thunks and, therefore, few programmers have sufficient experience using thunks to know how to use this appropriately. Most people learning assembly language, for example, come from a standard imperative programming language background (C/C++, Pascal, BASIC, FORTRAN, etc.) and have never seen this type of programming construct before. Those who are used to programming in languages where thunks are available (or a similar construct is available) tend not to be the ones who learn assembly language.

If you happen to lack the prerequisite knowledge of thunks, you should not write off this chapter as unimportant. Thunks are definitely a programming tool you should be aware of, like recursion, that's really handy in lots of situations. You should watch out for situations where thunks are applicable and use them as appropriate.

We'll see additional uses for thunks in the next chapter on iterators and in the chapter on advanced parameter passing techniques, later in this volume.

---

# Iterators

# Chapter Two

---

## 2.1 Chapter Overview

This chapter discusses the low-level implementation of iterators. Earlier, this text briefly discussed iterators and the FOREACH loop in the chapter on intermediate procedures (see “Iterators and the FOREACH Loop” on page 818). This chapter will review that information, discuss some uses for iterators, and then present the low-level implementation of this interesting control structure.

---

## 2.2 Iterators

An iterator is a cross between a control structure and a function. Although common high level languages do not support iterators, they are present in some very high level languages<sup>1</sup>. Iterators provide a combination state machine/function call mechanism that lets a function pick up where it last left off on each new call. Iterators are also part of a loop control structure, with the iterator providing the value of the loop control variable on each iteration.

To understand what an iterator is, consider the following for loop from Pascal:

```
for I := 1 to 10 do <some statement>;
```

When learning Pascal you were probably taught that this statement initializes *i* with one, compares *i* with 10, and executes the statement if *i* is less than or equal to 10. After executing the statement, the FOR statement increments *i* and compares it with 10 again, repeating the process over and over again until *i* is greater than 10.

While this description is semantically correct, and indeed, it’s the way that most Pascal compilers implement the FOR loop, this is not the only point of view that describes how the for loop operates. Suppose, instead, that you were to treat the TO reserved word as an operator. An operator that expects two parameters (one and ten in this case) and returns the range of values on each successive execution. That is, on the first call the TO operator would return one, on the second call it would return two, etc. After the tenth call, the TO operator would fail which would terminate the loop. This is exactly the description of an iterator.

In general, an iterator controls a loop. Different languages use different names for iterator controlled loops, this text will just use the name FOREACH as follows:

```
foreach iterator() do
 statements;
endfor;
```

An iterator returns two values: a boolean success or failure value and a function result. As long as the iterator returns success, the FOREACH statement executes the statements comprising the loop body. If the iterator returns failure, the FOREACH loop terminates and executes the next sequential statement following the FOREACH loop’s body.

Iterators are considerably more complex than normal functions. A typical function call involves two basic operations: a call and a return. Iterator invocations involve four basic operations:

- 1) Initial iterator call
- 2) Yielding a value
- 3) Resumption of an iterator

---

<sup>1</sup>. Ada and PL/I support very limited forms of iterators, though they do not support the type of iterators found in CLU, SETL, Icon, and other languages.

## 4) Termination of an iterator.

To understand how an iterator operates, consider the following short example:

```
iterator range(start:int32; stop:int32);
begin range;

 forever

 mov(start, eax);
 breakif(eax > stop);
 yield();
 inc(start);

 endfor;

end range;
```

In HLA, iterator calls may only appear in the FOREACH statement. With the exception of the "yield();" statement above, anyone familiar with HLA should be able to figure out the basic logic of this iterator.

An iterator in HLA may return to its caller using one of two separate mechanisms, it can return to the caller by exiting through the "end Range;" statement or it may yield a value by executing the "yield();" statement. An iterator succeeds if it executes the "yield();" statement, it fails if it simply returns to the caller. Therefore, the FOREACH statement will only execute its corresponding statement if you exit an iterator with a "yield();". The FOREACH statement terminates if you simply return from the iterator. In the example above, the iterator returns the values *start..stop* via a "yield();" statement and then the iterator terminates. The loop

```
foreach Range(1,10) do

 stdout.put((type uns32 eax), nl);

endfor;
```

is comparable to the code:

```
for(mov(1, eax); eax <= 10; inc(eax)) do

 stdout.put((type uns32 eax), nl);

endfor;
```

When an HLA program first executes the FOREACH statement, it makes an initial call to the iterator. The iterator runs until it executes a "yield();" or it returns. If it executes the "yield();" statement, it returns the value in EAX as the iterator result and it succeeds. If it simply returns, the iterator returns failure and no iterator result. In the current example, the initial call to the iterator returns success and the value one.

Assuming a successful return (as in the current example), the FOREACH statement returns the current result in EAX and executes the FOREACH loop body. After executing the loop body, the FOREACH statement calls the iterator again. However, this time the FOREACH statement resumes the iterator rather than making an initial call. An iterator resumption continues with the first statement following the last "yield();" it executes. In the *range* example, a resumption would continue execution at the "inc( start );" statement. On the first resumption, the *range* iterator would add one to *start*, producing the value two. Two is less than ten (*stop*'s value) so the FOREACH loop would repeat and the iterator would yield the value two. This process would repeat over and over again until the iterator yields ten. Upon resuming after yielding ten, the iterator would increment start to eleven and then return, rather than yield, since this new value is not less than or equal to ten. When the *Range* iterator returns (fails), the FOREACH loop terminates.

## 2.2.1 Implementing Iterators Using In-Line Expansion

The implementation of an iterator is rather complex. To begin with, consider a first attempt at an assembly implementation of the FOREACH statement above:

```

 push(1); // Manually pass 1 and 10 as parameters.
 push(10);
 call Range_initial;
 jc Failure;
ForLp: stdout.put((type uns32 eax), nl);
 call Range_Resume;
 jnc ForLp;
Failure:
```

Although this looks like a straight-forward implementation project, there are several issues to consider. First, the call to *Range\_Resume* above looks simple enough, but there is no fixed address that corresponds to the resume address. While it is certainly true that this *Range* example has only one resume address, in general you can have as many "yield();" statements as you like in an iterator. For example, the following iterator returns the values 1, 2, 3, and 4:

```

iterator OneToFour;
begin OneToFour;

 mov(1, eax); yield();
 mov(2, eax); yield();
 mov(3, eax); yield();
 mov(4, eax); yield();

end OneToFour;
```

The initial call would execute the "mov( 1, eax );" and "yield();" statements. The first resumption would execute the "mov( 1, eax );" and "yield();" statements, the second resumption would execute "mov( 1, eax );" and "yield();", etc. Obviously there is no single resume address the calling code can count on.

There are a couple of additional details left to consider. First, an iterator is free to call procedures and functions<sup>2</sup>. If such a procedure or function executes the "yield();" statement then resumption by the FOREACH statement continues execution within the procedure or function that executed the "yield();"<sup>3</sup>. Second, the semantics of an iterator require all local variables and parameters to maintain their values until the iterator terminates. That is, yielding does not deallocate local variables and parameters. Likewise, any return addresses left on the stack (e.g., the call to a procedure or function that executes the "yield();" statement) must not be lost when a piece of code yields and the corresponding FOREACH statement resumes the iterator. In general, this means you cannot use the standard call and return sequence to yield from or resume to an iterator because you have to preserve the contents of the stack.

While there are several ways to implement iterators in assembly language, perhaps the most practical method is to have the iterator call the loop controlled by the iterator and have the loop return back to the iterator function. Of course, this is counter-intuitive. Normally, one thinks of the iterator as the function that the loop calls on each iteration, not the other way around. However, given the structure of the stack during the execution of an iterator, the counter-intuitive approach turns out to be easier to implement.

Some high level languages support iterators in exactly this fashion. For example, Metaware's Professional Pascal Compiler for the PC supports iterators<sup>4</sup>. Were you to create a Professional Pascal code sequence as follows:

```

iterator OneToFour:integer;
begin
```

2. In Panacea an iterator could also call other types of program units, including other iterators, but you can ignore this for now.

3. This requires the use of nested procedures, a subject we will discuss in a later chapter.

4. Obviously, this is a non-standard extension to the Pascal programming language provided in Professional Pascal.

```

 yield 1;
 yield 2;
 yield 3;
 yield 4;
end;

```

and call it in the main program as follows:

```

for i in OneToFour do writeln(i);

```

Professional Pascal would completely rearrange your code. Instead of turning the iterator into an assembly language function and calling this function from within the FOR loop body, this code would turn the FOR loop body into a function, expand the iterator in-line (much like a macro) and call the FOR loop body function on each yield. That is, Professional Pascal would probably produce assembly language that looks something like the following:

```

// The following procedure corresponds to the for loop body
// with a single parameter (I) corresponding to the loop
// control variable:

procedure ForLoopCode(i:int32); nodisplay;
begin ForLoopCode;

 mov(i, eax);
 stdout.put(i, nl);

end ForLoopCode;

// The follow code would be emitted in-line upon encountering the
// for loop in the main program, it corresponds to an in-line
// expansion of the iterator as though it were a macro,
// substituting a call for the yield instructions:

 ForLoopCode(1);
 ForLoopCode(2);
 ForLoopCode(3);
 ForLoopCode(4);

```

This method for implementing iterators is convenient and produces relatively efficient (fast) code. It does, however, suffer from a couple drawbacks. First, since you must expand the iterator in-line wherever you call it, much like a macro, your program could grow large if the iterator is not short and you use it often. Second, this method of implementing the iterator completely hides the underlying logic of the code and makes your assembly language programs difficult to read and understand.

## 2.2.2 Implementing Iterators with Resume Frames

In-line expansion is not the only way to implement iterators. There is another method that preserves the structure of your program at the expense of a slightly more complex implementation. Several high level languages, including Icon and CLU, use this implementation.

To start with, you will need another stack frame: the *resume frame*. A resume frame contains two entries: a yield return address (that is, the address of the next instruction after the yield statement) and a *dynamic link*, that is a pointer to the iterator's activation record. Typically the dynamic link is just the value in the EBP register at the time you execute the yield statement. This version implements the four parts of an iterator as follows:

- 1) A CALL instruction for the initial iterator call,
- 2) A CALL instruction for the YIELD statement,
- 3) A RET instruction for the resume operation, and

## 4) A RET instruction to terminate the iterator.

To begin with, an iterator will require two return addresses rather than the single return address you would normally expect. The first return address appearing on the stack is the termination return address. The second return address is where the subroutine transfers control on a YIELD operation. The calling code must push these two return addresses upon initial invocation of the iterator. The stack, upon initial entry into the iterator, should look something like Figure 2.1.

**Figure 2.1** Iterator Activation Record

As an example, consider the *Range* iterator presented earlier. This iterator requires two parameters, a starting value and an ending value:

```
foreach range(1,10) do

 stdout.put(i, nl);

endfor;
```

The code to make the initial call to the *range* iterator, producing a stack like the one above, could be the following:

```
push(1); // Push start parameter value.
push(10); // Push stop parameter value.
push(&ForDone); // Push termination address.
call range; // Call the iterator.
.
.
.
ForDone:
```

FORDONE is the first statement immediately following the FOREACH loop, that is, the instruction to execute when the iterator returns failure. The FOREACH loop body must begin with the first instruction following the call to *range*. At the end of the FOREACH loop, rather than jumping back to the start of the loop, or calling the iterator again, this code should just execute a RET instruction. The reason will become clear in a moment. So the implementation of the above FOREACH statement could be the following:

```
push(1); // Push start parameter value.
push(10); // Push stop parameter value.
push(&ForDone); // Push termination address.
call range; // Call the iterator.
push(ebp); // Preserve iterator's ebp value.
mov([esp+8], ebp); // Get original EBP value passed to us by range.
stdout.put(i, nl); // Display i's value.
```

```

 pop(ebp); // Restore iterator's EBP value.
 ret(4); // Return and clean EBP value off stack.
ForDone:

```

Granted, this doesn't look anything at all like a loop. However, by playing some major tricks with the stack, you'll see that this code really does iterate the loop body (*stdout.put*) as intended.

Now consider the *range* iterator itself, here's the (mostly) low-level code to do the job:

```

iterator range(start:int32; stop:int32); nodisplay; noframe;
begin range;

```

```

 push(ebp); // Standard Entry Sequence
 mov(esp, ebp);

```

```

ForEverLbl:

```

```

 mov(start, eax);
 cmp(eax, stop);
 jng ForDone;

```

```

 yield();
 inc(start);
 jmp ForEverLbl;

```

```

ForDone:

```

```

 pop(ebp);
 add(4, esp);
 ret(8);

```

```

end range;

```

Although this routine is rather short, don't let its size deceive you; it's quite complex. The best way to describe how this iterator operates is to take it a few instructions at a time. The first two instructions are the standard entry sequence for a procedure. Upon execution of these two instructions, the stack looks like that in Figure 2.2.

**Figure 2.2** Range Activation Record

The next three statements in the *range* iterator, at label *ForEverLbl*, implement the termination test of the loop. When the *start* parameter contains a value greater than the *stop* parameter, control transfers to the *ForDone* label at which point the code pops the value of EBP off the stack, pops the success return address off the stack (since this code will not return back to the body of the iterator loop) and then returns via the termination return address that is immediately above the success return address on the stack. The return instruction also pops the two parameters (eight bytes) off the stack.

The real work of the iterator occurs in the body of the loop. The main question here is "what is this *yield* procedure and what is it doing?". To understand what *yield* is, we must consider what it is that *yield* does. Whenever the iterator executes the *yield* statement, it calls the body of the FOREACH loop that invoked the iterator. Since the body of the FOREACH loop is the first statement following the call to the iterator, it turns out that the iterator's return address points at that body of code. Therefore, the *yield* statement does the unusual operation of calling a subroutine pointed at by the iterator's (success) return address.

Simply calling the body of the FOREACH loop is not all the *yield* call must do. The body of the FOREACH loop is in a different procedure with its own activation record. That FOREACH loop body may very well access variables that are local to the procedure containing that loop body; therefore, the *yield* statement must also pass the original procedure's EBP value as a parameter so that the loop body can restore EBP to point at the FOREACH loop body's activation record (while, of course, preserving EBP's value within the iterator itself). The caller's EBP value (also known as the dynamic link) was the value the iterator pushes on the stack in the standard entry sequence. Therefore, [EBP+0] will point at this dynamic link value. To properly implement the *yield* operation, the iterator must emit the following code:

```
push(ebp); // Save iterator's activation record pointer.
call((type dword [ebp+4])); // Call the return address.
```

The PUSH and CALL instructions build the resume frame and then return control to the body of the FOREACH loop. The CALL instruction is not calling a subroutine. What it is really doing here is finishing off the resume frame (by storing the YIELD resume address into the resume frame) and then it returns control back to the body of the FOREACH loop by jumping indirect through the success return address pushed on the stack by the initial call to the iterator. After the execution of this call, the stack frame looks like that in Figure 2.3.

**Figure 2.3** Range Resume Record

By convention, the EAX register contains the return value for the iterator. As with functions, EAX is a good place to return the iterator return result.

Immediately after yielding back to the FOREACH loop, the code must reload EBP with the original value prior to the iterator invocation. This allows the calling code to correctly access parameters and local variables in its own activation record rather than the activation record of the iterator. The FOREACH loop body begins by preserving EBP's value (the pointer to iterator's activation record) and then loading EBP with the value pushed on the stack by the YIELD statement. Of course, in this example reloading EBP isn't necessary because the body of the FOREACH loop does not reference any memory locations off the EBP register, but in general you will need to save EBP's value and load EBP with the value pushed on the stack by the yield statement.

At the end of the FOREACH loop body the "pop( ebp );" and "ret( 4 );" instructions restore EBP's value, cleans up the environment pointer passed as a parameter, and resumes the iterator. The RET instruction pops the return address off the stack which returns control back to the iterator immediately after the call emitted by the YIELD statement.

Of course, this is a lot of work to create a piece of code that simply repeats a loop ten times. A simple FOR loop would have been much easier and quite a bit more efficient than the FOREACH implementation described in this section. This section used the *range* iterator because it was easy to show how iterators work using *range*, not because actually implementing *range* as an iterator is a good idea.

Note that HLA does not provide an actual YIELD statement. If you look carefully at this code, and you think back to the last chapter, you will notice that the YIELD "statement" generates exactly the same code as a thunk invocation. Indeed, were you to dump the HLA symbol table when compiling a program containing the *range* iterator, you'd discover that *yield* is actually a local variable of type *thunk* within the *range* iterator code. The offset of this thunk is zero (from EBP) in the iterator's activation record (see Figure 2.4):

**Figure 2.4 Yield Thunk in the *range* Iterator's Activation Record**

This thunk value is somewhat unusual. If you look closely, you'll realize that this thunk's value is actually the return address the original call to *range* pushes along with the old EBP value that the *range* iterator code pushes as part of the standard entry sequence. In other words, the call to *range* and the standard entry sequence automatically initializes the *yield* thunk! How's that for elegance? All the HLA compiler has to do to create the *yield* thunk is to automatically create this "yield" symbol and associate yield with the address of the old EBP value that the *range* standard entry sequence pushes on the stack.

As you may recall from the chapter on Thunks, the calling sequence for a thunk is the following:

```
push(<< Thunk's Environment Pointer >>);
call(<< Thunk's Code Pointer >>);
```

In the case of the *yield* thunk in an iterator, the calling sequence looks like this:

```
pushd([ebp]); // Pass iterator caller's EBP as parameter.
call((type dword [ebp+4])); // Call the FOREACH loop's body.
```

The body of the FOREACH loop, like any thunk, must preserve EBP's value and load EBP with the value pushed on the stack in the code sequence above. Prior to returning (resuming) back to the iterator, the FOREACH loop body must restore the iterator's EBP value and it must remove the environment pointer parameter from the stack upon return. The code given earlier for the FOREACH loop does this:

```
// "FOREACH range(1, 10) do" statement:

push(1); // Push start parameter value.
push(10); // Push stop parameter value.
push(&ForDone); // Push termination address.
call range; // Call the iterator.

// FOREACH loop body (a thunk):

push(ebp); // Preserve iterator's ebp value.
mov([esp+8], ebp); // Get original EBP value passed to us by range.
stdout.put(i, nl); // Display i's value.
pop(ebp); // Restore iterator's EBP value.
ret(4); // Return and clean EBP value off stack.

// endfor;

ForDone:
```

Of course, HLA does not make you write this low-level code. You can actually use a FOREACH statement in your program. The above code is the low-level implementation of the following high-level HLA code:

```
foreach range(1, 10) do

 stdout.put(i, nl);

endifor;
```

The HLA compiler automatically emits the code to preserve and set up EBP at the beginning of the FOREACH loop's body; HLA also automatically emits the code to restore EBP and return to the iterator (removing the environment pointer parameter from the stack).

---

## 2.3 Other Possible Iterator Implementations

Thus far, this text has given two different implementations for iterators and the FOREACH loop. Although the resume frame/thunk implementation of the previous section is probably the most common implementation in HLA programs (since the HLA compiler automatically generates this type of code for FOREACH loops and iterators), don't get the impression that this is the only, or best, way to implement iterators and the FOREACH loop. Other possible implementations certainly exist and in some specialized situations some other implementation may offer some advantages. In this section we'll look at a couple of ways to implement iterators and the FOREACH loop.

The standard HLA implementation of iterators uses two separate return address for an iterator call: a success/yield address and a failure address. This organization is elegant given the thunk implementation of HLA's FOREACH statement, but there are other ways to return success/failure from an iterator. For exam-

ple, you could use the value of the carry flag upon return from the iterator call to denote success or failure. Then a call to the iterator might take the following form:

```
ForEachLoopLbl:
 << Push any Necessary Parameters >>
 call iter;
 jc iterFails;

 << Code for the body of the iterator >>

 jmp ForEachLoopLbl;

iterFails:
```

One problem with this approach is that the code reenters the iterator on each iteration of the loop. This means it always passes the same parameters and reconstructs the activation record on each call of the iterator. Clearly, you cannot use this scheme if the iterator needs to maintain state information in its activation record between calls to the iterator. Furthermore, if the iterator yields from different points, then transferring control to the first statement after each yield statement will be a problem. There is a trick you can pull to tell the iterator whether this is the first invocation or some other invocation - pass a special parameter to indicate the first call of an iterator. You can do this as follows:

```
 pushd(0); // Zero indicates the first call to iter.
ForEachLoopLbl:
 << Push Any Other Necessary Parameters >>
 call iter; // iter is a standard HLA procedure, not an iterator.
 jc iterFails;

 << Code for the body of the iterator >>

 pushd(1); // One indicates a re-entry into the iterator.
 jmp ForEachLoopLbl;

iterFails:
```

Notice how this code pushes a zero as the first parameter on the first call to *iter* and it pushes a one on each invocation thereafter.

What if the iterator needs to maintain state information (i.e., local variable values) between calls? Well, the easiest way to handle this using the current scheme is to pass extra parameters by value and use those parameters as the local variables. When the iterator returns success, it should not clean up the parameters on the stack, instead, it will leave them there for the next iteration of the "FOREACH" loop. E.g., consider the following implementation and invocation of the *ArithRange* iterator (this iterator returns the sum of all the values between the *start* and *stop* parameters):

```
// Note: we have to use a procedure, not an iterator, here because we don't
// want HLA generating funny code for us.
//
// "sum" is actually a local variable in which we maintain state information.
// It must contain zero on the first entry to denote the initial entry into
// this code.

procedure ArithRange(start:uns32; stop:uns32; sum:uns32); nodisplay; noframe;
begin ArithRange;

 push(ebp); // Standard entry sequence.
 mov(esp, ebp);

 mov(start, eax);
 if(eax <= stop) then
```

```

 add(sum, eax); // Compute arithmetic sum of values.
 mov(eax, sum); // Save for the next time through and return in EAX.
 pop(ebp); // Restore pointer to caller's environment.
 cld; // Indicate success on return.
 ret(); // Note that we don't pop parameters!

endif;
pop(ebp); // Restore pointer to caller's environment.
stc; // Indicate return on failure.
ret(12); // On failure, remove the parameters from the stack.

end ArithRange;
.
.
.
 pushd(1); // Pass the start parameter value.
 pushd(10); // Pass the stop parameter value.
 pushd(0); // Must pass zero in for sum value.
ForEachLoop:
 call ArithRange; // Call our "iterator".
 jc ForEachDone; // Quit on failure, fall through on success.

 << Foreach loop body code >>

 jmp ForEachLoop;

ForEachDone:

```

Notice how this code pushes the parameters on the stack for the first invocation of the *ArithRange* iterator, but it does not push the parameters on the stack on successive iterations of the loop. That's because the code does not remove these parameter values until it fails. Therefore, on each iteration of the loop, the parameter values left on the stack by the previous invocation of *ArithRange* are still on the stack for the next invocation. When the iterator fails, it pops the parameters off the stack so the stack is clean on exit from the "FOREACH" loop above.

If you can spare a register, there is a slightly more efficient way to implement iterators and the FOREACH loop (HLA doesn't use this scheme by default because it promise not to monkey with your register set in the code generation for the high level control structures). Consider the following code that HLA emits for a *yield* call:

```

 push([ebp]); // Pass FOREACH loop's EBP value as a parameter.
 call([ebp+4]); // Call the success address.

```

The FOREACH loop body code looks like the following:

```

 push(ebp); // Save iterator's EBP value.
 mov([esp+8], ebp); // Fetch our EBP value pushed by the iterator.
 << loop body >>
 pop(ebp); // Restore iterator's EBP value.
 ret(4); // Resume the iterator and remove EBP value.

```

This code can be improved slightly by preserving and setting the EBP value within the iterator. Consider the following *yield* and FOREACH loop body code:

```

 push(ebp); // Save iterator's EBP value.
 mov([ebp+4], edx); // Put success address into an available register.
 mov([ebp], ebp); // Set up FOREACH loop's EBP value.
 call edx; // Call the success address.
 pop(ebp); // Restore our EBP value.

```

Here's the corresponding FOREACH loop body:

```

 << Loop Body >>

```

```
ret ();
```

These scheme isn't amazingly better than the standard resume frame approach (indeed, it is about the same). But in some situations the fact that the loop body code doesn't have to mess with the stack may be important.

## 2.4 Breaking Out of a FOREACH Loop

The BREAK, BREAKIF, CONTINUE, and CONTINUEIF statements are active within a FOREACH loop, but there are some problems you must consider if you attempt to break out of a FOREACH loop with a BREAK or BREAKIF statement. In this section we'll look at the problems of prematurely leaving a FOREACH loop.

Keep in mind that an iterator leaves some information on the stack during the execution of the FOREACH loop body. Remember, the iterator doesn't return back to the FOREACH loop in order to execute the loop body; it actually calls the FOREACH loop body. That call leaves a resume frame plus all parameters, local variables, and other information in the iterator's activation record on the stack when it calls the FOREACH loop body. If you attempt to bail out of the FOREACH loop using BREAK, BREAKIF, or (worse still) a conditional or unconditional jump, ESP does not automatically revert back to the value prior to the execution of the FOREACH statement. The HLA generated code can only clean up the stack properly if the iterator returns via the failure address.

Although HLA cannot clean up the stack for you, it is quite possible for you to clean up the stack yourself. The easiest way to do this is to store the value in ESP to a local variable immediately prior to the execution of the FOREACH statement. Then simply reload ESP from this value prior to prematurely leaving the FOREACH loop. Here's some code that demonstrates how to do this:

```
mov(esp, espSave);
foreach range(1, 10) do

 << foreach loop body >>

 if(some_condition) then

 mov(espSave, esp);
 break;

 endif;

 << more loop body code >>

endfor;
```

By restoring ESP from the *espSave* variable, this code removes all the activation record information from the stack prior to leaving the FOREACH loop body. Notice the MOV instruction immediately before the FOREACH statement that saves the stack position prior to calling the *range* iterator.

## 2.5 An Iterator Implementation of the Fibonacci Number Generator

Consider for a moment the Fibonacci number generator from the chapter on Thunks (this is the slow, non-thunk, implementation):

```
// Standard fibonacci function using the slow recursive implementation.

procedure slowfib(n:uns32); nodisplay; returns("eax");
begin slowfib;
```

```

// For n= 1,2 just return 1.

if(n <= 2) then

 mov(1, eax);

else

 // Return slowfib(n-1) + slowfib(n-2) as the function result:

 dec(n);
 slowfib(n); // compute fib(n-1)
 push(eax); // Save fib(n-1);

 dec(n); // compute fib(n-2);
 slowfib(n);

 add([esp], eax); // Compute fib(n-1) [on stack] + fib(n-2) [in eax].
 add(4, esp); // Remove old value from stack.

endif;

end slowfib;

```

---

### Program 2.1 Recursive Implementation of the Fibonacci Number Generator

---

This particular function generates the  $n^{\text{th}}$  Fibonacci number by computing the first through the  $n^{\text{th}}$  the Fibonacci number. If you wanted to generate a sequence of Fibonacci numbers, you could use a FOR loop as follows:

```

for(mov(1, ebx); ebx < n; inc(ebx)) do

 slowfib(ebx);
 stdout.put("Fib(", (type uns32 ebx), ") = ", (type uns32 eax), nl);

endfor;

```

True to its name, this implementation of *slowfib* runs quite slowly as  $n$  gets larger. The reason this function takes so much time (as pointed out in the chapter on Thunks) is that each recursive call recomputes all the previous Fibonacci numbers. Given the  $(n-1)^{\text{st}}$  and  $(n-2)^{\text{nd}}$  Fibonacci numbers, computing the  $n^{\text{th}}$  Fibonacci number is trivial and very efficient – you simply add the previous two values together. The efficiency loss occurs when the recursive implementation computes the same value over and over again. The chapter on Thunks described how to eliminate this recomputation by passing the computed values to other invocations of the functions. This allows the Fibonacci function to compute the  $n^{\text{th}}$  Fibonacci number in  $n$  units of time rather than  $2^n$  units of time, a dramatic improvement. However, since each call to the (efficient) Fibonacci generator requires  $n$  units of time to compute its result, the loop above (which repeats  $n$  times) requires approximately  $n^2$  units of time to run. This does not seem reasonable since it clearly takes only a few instructions to compute a new Fibonacci number given the previous two values; that is, we should be able to compute the  $n^{\text{th}}$  Fibonacci number in  $n$  units of time. Iterators provide a trivial way to implement a Fibonacci number generator that generates a sequence of  $n$  Fibonacci numbers in  $n$  units of time. The following program demonstrates how to do this.

---

```

program fibIter;
#include("stdlib.hhf")

```

```

// Fibonacci function using a thunk to calculate fib(n-2)
// without making a recursive call.

procedure fib(n:uns32; nm2:thunk); nodisplay; returns("eax");
var
 n2: uns32; // A recursive call to fib stores fib(n-2) here.
 t: thunk; // This thunk actually stores fib(n-2) in n2.

begin fib;

 // Special case for n = 1, 2. Just return 1 as the
 // function result and store 1 into the fib(n-2) result.

 if(n <= 2) then

 mov(1, eax); // Return as n-1 value.
 nm2(); // Store into caller as n-2 value.

 else

 // Create a thunk that will store the fib(n-2) value
 // into our local n2 variable.

 thunk t :=
 #{
 mov(eax, n2);
 }#;

 mov(n, eax);
 dec(eax);
 fib(eax, t); // Compute fib(n-1).

 // Pass back fib(n-1) as the fib(n-2) value to a previous caller.

 nm2();

 // Compute fib(n) = fib(n-1) [in eax] + fib(n-2) [in n2]:

 add(n2, eax);

 endif;

end fib;

// Standard fibonacci function using the slow recursive implementation.

procedure slowfib(n:uns32); nodisplay; returns("eax");
begin slowfib;

 // For n= 1,2 just return 1.

 if(n <= 2) then

 mov(1, eax);

 else

 // Return slowfib(n-1) + slowfib(n-2) as the function result:

```

```

 dec(n);
 slowfib(n); // compute fib(n-1)
 push(eax); // Save fib(n-1);

 dec(n); // compute fib(n-2);
 slowfib(n);

 add([esp], eax); // Compute fib(n-1) [on stack] + fib(n-2) [in eax].
 add(4, esp); // Remove old value from stack.

endif;

end slowfib;

// FibNum-
//
// Iterator that generates all the fibonacci numbers between 1 and n.

iterator FibNum(n:uns32); nodisplay;
var
 Fibn_1: uns32; // Holds Fib(n-1) for a given n.
 Fibn_2: uns32; // Holds Fib(n-2) for a given n.
 CurFib: uns32; // Current index into fib sequence.

begin FibNum;

 mov(1, Fibn_1); // Initialize these guys upon initial entry.
 mov(1, Fibn_2);
 mov(1, eax); // Fib(0) = 1
 yield();
 mov(1, eax); // Fib(1) = 1;
 yield();
 mov(2, CurFib);
 forever

 mov(CurFib, eax); // Compute sequence up to the nth #.
 breakif(eax > n);
 mov(Fibn_2, eax); // Compute this result.
 add(Fibn_1, eax);

 // Recompute the Fibn_1 and Fibn_2 values:

 mov(Fibn_1, Fibn_2);
 mov(eax, Fibn_1);

 // Return current value:

 yield();

 // Next value in sequence:

 inc(CurFib);

 endfor;

end FibNum;

var
```

```

prevTime:dword[2]; // Used to hold 64-bit result from RDTSC instr.
qw: qword; // Used to compute difference in timing.
dummy:thunk; // Used in original calls to fib.

begin fibIter;

 // "Do nothing" thunk used by the initial call to fib.
 // This thunk simply returns to its caller without doing
 // anything.

 thunk dummy := #{ }#;

 // Call the fibonacci routines to "prime" the cache:

 fib(1, dummy);
 slowfib(1);
 foreach FibNum(1) do
 endfor;

 // Okay, compute the running times for the three fibonacci routines to
 // generate a sequence of n fibonacci numbers where n ranges from
 // 1 to 32:

 for(mov(1, ebx); ebx < 32; inc(ebx)) do

 // Emit the index:

 stdout.put((type uns32 ebx):2, stdio.tab);

 // Compute the # of cycles needed to compute the Fib via iterator:

 rdtsc();
 mov(eax, prevTime);
 mov(edx, prevTime[4]);

 foreach FibNum(ebx) do

 endfor;

 rdtsc();
 sub(prevTime, eax);
 sbb(prevTime[4], edx);
 mov(eax, (type dword qw));
 mov(edx, (type dword qw[4]));

 stdout.putu64Size(qw, 4, ' ');
 stdout.putc(stdio.tab);

 // Read the time stamp counter before calling fib:

 rdtsc();
 mov(eax, prevTime);
 mov(edx, prevTime[4]);

 for(mov(1, ecx); ecx <= ebx; inc(ecx)) do

```

```

 fib(ecx, dummy);

endfor;

// Read the timestamp counter and compute the approximate running
// time of the current call to fib:

rdtsc();
sub(prevTime, eax);
sbb(prevTime[4], edx);
mov(eax, (type dword qw));
mov(edx, (type dword qw[4]));

// Display the results and timing from the call to fib:

stdout.putu64Size(qw, 10, ' ');
stdout.putc(stdio.tab);

// Okay, repeat the above for the slowfib implementation:

rdtsc();
mov(eax, prevTime);
mov(edx, prevTime[4]);

for(mov(1, ecx); ecx <= ebx; inc(ecx)) do

 slowfib(ebx);

endfor;

rdtsc();
sub(prevTime, eax);
sbb(prevTime[4], edx);
mov(eax, (type dword qw));
mov(edx, (type dword qw[4]));

stdout.putu64Size(qw, 10, ' ');
stdout.newln();

endfor;

end fibIter;

```

---

## Program 2.2 Fibonacci Iterator Example Program

---

The important concept here is that the *FibNum* iterator maintains its state across calls. In particular, it keeps track of the current iteration and the previous two Fibonacci values. Therefore, the iterator takes very little time to compute the result of each number in the sequence. This is far more efficient than either Fibonacci number generator from the chapter on Thunks, as the following table attests.

**Table 1: CPU Cycle Times for Various Fibonacci Implementations**

| n  | Iterator Implementation | Thunk Implementation | Recursive Implementation |
|----|-------------------------|----------------------|--------------------------|
| 1  | 156                     | 233                  | 98                       |
| 2  | 148                     | 98                   | 77                       |
| 3  | 178                     | 221                  | 271                      |
| 4  | 193                     | 376                  | 399                      |
| 5  | 213                     | 509                  | 879                      |
| 6  | 213                     | 712                  | 1758                     |
| 7  | 233                     | 919                  | 3493                     |
| 8  | 252                     | 1166                 | 6531                     |
| 9  | 271                     | 1460                 | 12568                    |
| 10 | 290                     | 1759                 | 22871                    |
| 11 | 308                     | 2139                 | 40727                    |
| 12 | 331                     | 2503                 | 71986                    |
| 13 | 349                     | 2938                 | 126443                   |
| 14 | 372                     | 3341                 | 220673                   |
| 15 | 380                     | 3877                 | 382364                   |
| 16 | 402                     | 4326                 | 660506                   |
| 17 | 417                     | 4977                 | 1160660                  |
| 18 | 452                     | 5528                 | 1954253                  |
| 19 | 487                     | 6222                 | 3322819                  |

## 2.6 Iterators and Recursion

It is completely possible, and sometimes very useful, to recursively call an iterator. In this section we'll explore the syntax for this and present a couple of useful recursive iterators.

Although there is nothing stopping you from manually calling an iterator with the `CALL` instruction, the only valid (high level syntax) invocation of an iterator is via the `FOREACH` statement. Therefore, to recursively call an iterator, that iterator must contain a `FOREACH` loop to recursively call itself.

Iterators are especially useful for traversing tree and graph data structures. Some of the best (and most efficient) examples of recursive iterators are those that traverse such structures. Unfortunately, this text does not assume the prerequisite knowledge of such data structures, so it cannot use such examples to demonstrate recursive iterators. Nevertheless, it's worth mentioning this fact here because if you are familiar with graph traversal algorithms (or will be learning them in the future) you should consider using iterators for this purpose.

One useful iterator that doesn't require a tremendous amount of prerequisite knowledge is the traversal of a binary search tree implemented within an array. We won't go into the details of what a binary search tree is or why you would use it here other than to describe some properties of that tree. A binary search tree, implemented as an array, is a data structure that allows one to quickly search for some value within the structure. The values are arranged in the tree such that after each comparison you can eliminate half of the possible values with a single comparison. As a result, if the array contains  $n$  items, you can locate a particular item of interest in  $\log_2 n$  units of time. To achieve this efficient search time, you have to arrange the data in the array in a particular fashion and then use a specific algorithm when searching through the tree. For the sake of our example, we'll assume that the data in the array is sorted (that is,  $a[0] < a[1] < a[2] < \dots < a[n-1]$  for some definition of "less than"). The binary search algorithm then takes the following form:

1. Set  $i = n$
2. Set  $j = i / 2$  (integer/truncating division)
3. Quit if  $i=j$  (failed to find value in the search tree).
4. Compare the *key* value (the one you're searching for) against  $a[i]$ .
5. If  $\text{key} > a[i]$  then set  $j = (i - j + 1)/2 + j$   
else set  $i = j$  and then  $j = i/2$
6. Go to step 3.

How this works and what it does is irrelevant here. What is important to this section is the arrangement of the data in the array that forms the binary search tree (specifically, the sorted nature of the data). Of course, if we wanted to generate a list of numbers in the sorted order, that would be especially trivial, all we would have to do is step through the array one element at a time. Suppose, however, that we wanted to generate a list of median values in this array. That is, the first value to generate would be the median of all the values, the second and third values would be the two median values of the array "slice" on either side of the original median. The next four values would be the medians of the array slices around the previous two medians and so on. If you're wondering what good such a sequence could be, well, were we to store this sequence into successive elements of an array, we could develop a binary search algorithm that is a little bit

faster than the algorithm above (faster by some multiplicative constant). Hence, by running this iterator over the sorted data, we can come up with a slightly faster searching algorithm.

The following is the iterator that generates this particular sequence:

---

```

program RecIter;
#include("stdlib.hhf")

const
 MaxData := 17; // # of data items to process.

type
 AryType: uns32[MaxData];

static

 // Here is the sorted data we'll process. For simplicity, we'll just
 // fill the array with 1..MaxData at indices 0..MaxData-1.

 SortedData: AryType :=
 [
 // Fill this table with the values 1..MaxData:

 ?i := 1;
 #while(i < MaxData)

 i,
 ?i := i + 1;

 #endwhile
 i
];

/*****
/*
/* MedianVal iterator-
/*
/* Given a sorted array, this iterator yields the median value,
/* then it recursively yields a list of median values for the
/* array slice consisting of the array elements whose index is
/* less than the median value. Finally, it yields the list of
/* median values for the array slice built from the array elements
/* whose indices are greater than the median element.
/*
/*
/* Inputs:
/* Ary-
/* The array whose elements we are to process.
/*
/* start-
/* Starting index for the array slice.
/*
/* last-
/* Ending index (plus one) for the array slice.
/*
/* Yields:
/* A list of median values in EAX (one median value on
/* each iteration of the corresponding FOREACH loop).
/*
/* Notes:
/* This iterator wipes out EBX.
*****/

```

```

/* */
/*****/

iterator MedianVal(var Ary: AryType; start:uns32; last:uns32); nodisplay;
var
 median: uns32;
begin MedianVal;

 mov(last, eax);
 sub(start, eax);
 if(@a) then

 shr(1, eax); // Compute half the size.
 add(start, eax); // Compute median index.
 mov(eax, median); // Save for later.

 mov(Ary, ebx); // Compute address of median element.
 mov([ebx][eax*4], eax); // Get median element.
 yield();

 // Recursively yield the medians for the elements at indices below
 // the element we just yielded. Do this by recursively calling
 // the iterator to generate the list and then yield whatever value
 // the iterator returns.

 foreach MedianVal(Ary, start, median) do

 yield();

 endfor;

 // Recursively yield the medians for the array slice whose indices
 // are greater than the current array element. Note that we don't
 // include the median value itself in this list as we already
 // returned that value above.

 mov(median, eax);
 inc(eax);
 foreach MedianVal(Ary, eax, last) do

 yield();

 endfor;

 endif;
end MedianVal;

// Main program that tests the functionality of this iterator.
begin RecIter;

 foreach MedianVal(SortedData, 0, MaxData) do

 stdout.put("Value = ", (type uns32 eax), nl);

 endfor;

```

```
end RecIter;
```

---

**Program 2.3 Recursive Iterator to Rearrange Data for a Binary Search**

---

The program above produces the following output:

```
Value = 9
Value = 5
Value = 3
Value = 2
Value = 1
Value = 4
Value = 7
Value = 6
Value = 8
Value = 14
Value = 12
Value = 11
Value = 10
Value = 13
Value = 16
Value = 15
Value = 17
```

---

**2.7 Calling Other Procedures Within an Iterator**

It is perfectly legal to call other procedures from an iterator. However, unless that procedure is nested within the iterator (see “Lexical Nesting” on page 1337), you cannot yield from that procedure using the iterator’s yield thunk unless you pass the thunk as a parameter to the other procedure. Other than the fact that you must remember that there is additional information on the stack, calling a procedure from an iterator is really no different than calling an iterator from any other procedure.

---

**2.8 Iterators Within Classes**

You can declare an iterator within a class. Iterators are called via the class’ virtual method table, just like methods. This means that you can override an iterator at run-time. See the chapter on classes for more details.

---

**2.9 Putting It Altogether**

This chapter provides a brief introduction to the low-level implementation of iterators and then discusses several different ways that you may use iterators in your programs. Although iterators are not as familiar as other program units, they are quite useful in many important situations. You should try to use iterators in your programs wherever appropriate, even if you’re not familiar with iterators from your high level language experiences.

---

# Coroutines and Generators

# Chapter Three

---

## 3.1 Chapter Overview

This chapter discusses two special types of program units known as coroutines and generators. A coroutine is similar to a procedure and a generator is similar to a function. The principle difference between these program units and procedures/functions is that the call/return mechanism is different. Coroutines are especially useful for multiplayer games and other program flow where sections of code "take turns" executing. Generators, as their name implies, are useful for generating a sequence of values; in many respects generators are quite similar to HLA's iterators without all the restrictions of the iterators (i.e., you can only use iterators within a FOREACH loop).

---

## 3.2 Coroutines

A common programming paradigm is for two sections of code to swap control of the CPU back and forth while executing. There are two ways to achieve this: preemptive and cooperative. In a preemptive system, two or more *processes* take turns executing with the *task switch* occurring independently of the executing code. A later volume in this text will consider preemptive multitasking, where the Operating System takes responsibility for interrupting one task and transferring control to some other task. In this chapter we'll take a look at coroutines that explicitly transfer control to another section of the code<sup>1</sup>

When discussing coroutines, it is instructive to review how HLA's iterators work, since there is a strong correspondence between iterators and coroutines. Like iterators, there are four types of entries and returns associated with a coroutine:

- Initial entry. During the initial entry, the coroutine's caller sets up the stack and otherwise initializes the coroutine.
- Cocal to another coroutine / coreturn to the previous coroutine.
- Coreturn from another coroutine / cocal to the current coroutine.
- Final return from the coroutine (future calls require reinitialization).

A *cocal* operation transfers control between two coroutines. A cocal is effectively a call and a return instruction all rolled into one operation. From the point of view of the process executing the cocal, the cocal operation is equivalent to a procedure call; from the point of view of the processing being called, the cocal operation is equivalent to a return operation. When the second process cocal the first, control resumes *not at the beginning of the first process*, but immediately after the cocal operation (this is similar to returning from a FOREACH loop after a YIELD operation). If two processes execute a sequence of mutual cocal, control will transfer between the two processes in the following fashion:

---

1. The term "cooperative" in this chapter doesn't not imply the use of that oxymoronic term "cooperative multitasking" that Microsoft and Apple used before they got their operating system acts together. Cooperative in this chapter means that two blocks of code explicitly pass control between one another. In a multiprogramming system (the proper technical term for "cooperative multitasking" the operating system still decides which program unit executes after some other thread of execution voluntarily gives up the CPU.

Cocall Sequence Between

**Figure 13.1 Cocall Sequence**

Cocalls are quite useful for games where the “players” take turns, following different strategies. The first player executes some code to make its first move, then cocalls the second player and allows it to make a move. After the second player makes its move, it cocalls the first process and gives the first player its second move, picking up immediately after its cocall. This transfer of control bounces back and forth until one player wins.

Note, by the way, that a program may contain more than two coroutines. If coroutine one cocalls coroutine two, and coroutine two cocalls coroutine three, and then coroutine three cocalls coroutine one, coroutine one picks up immediately after the cocall it made to coroutine two.

Cocalls Between Three 1

**Figure 13.2 Cocalls Between Three Processes**

Since a `cocall` effectively *returns* to the target coroutine, you might wonder what happens on the *first* `cocall` to any process. After all, if that process has not executed any code, there is no “return address” where you can resume execution. This is an easy problem to solve, we need only initialize the return address of such a process to the address of the first instruction to execute in that process.

A similar problem exists for the stack. When a program begins execution, the main program (coroutine one) takes control and uses the stack associated with the entire program. Since each process must have its own stack, where do the other coroutines get their stacks? There is also the question of “how much space should one reserve for each stack?” This, of course, varies with the application. If you have a simple application that doesn’t use recursion or allocate any local variables on the stack, you could get by with as little as 256 bytes of stack space for a coroutine. On the other hand, if you have recursive routines or allocate storage on the stack, you will need considerably more space. But this is getting a little ahead of ourselves, how do we create and call coroutines in the first place?

HLA does not provide a special syntax for coroutines. Instead, the HLA Standard Library provides a class with set of procedures and methods (in the `coroutines` library module) that lets you turn any procedure (or set of procedures) into a coroutine. The name of this class is `coroutine` and whenever you want to create a coroutine object, you need to declare a variable of type `coroutine` to maintain important state information about that coroutine’s thread of execution. Here are a couple of typical declarations that might appear within the VAR section of your main program:

```
var
 FirstPlayer: pointer to coroutine;
 OtherPlayer: coroutine;
```

Note that a coroutine variable is not the coroutine itself. Instead, the coroutine variable keeps track of the machine state when you switch between the declared coroutine and some other coroutine in the program (including the main program, which is a special case of a coroutine). The coroutines “body” is a procedure that you write independently of the coroutine variable and associate with that coroutine object.

The coroutine class contains a constructor that uses the conventional name `coroutine.create`. This constructor requires two parameters and has the following prototype:

```
procedure coroutine.create(stacksize:dword; body:procedure);
```

The first parameter specifies the size (in bytes) of the stack to allocate for this coroutine. The construction will allocate storage for the new coroutine in the system's heap using dynamic allocation (i.e., *malloc*). As a general rule, you should allocate at least 256 bytes of storage for the stack, more if your coroutine requires it (for local variables and return addressees). Remember, the system allocates all local variables in the coroutine (and in the procedures that the coroutine calls) on this stack; so you need to reserve sufficient space to accommodate these needs. Also note that if there are any recursive procedures in the coroutine's thread of execution, you will need some additional stack space to handle the recursive calls.

The second parameter is the address of the procedure where execution begins on the first *cocall* to this coroutine. Execution begins with the first executable statement of this procedure. If the procedure has some local variables, the procedure must build a stack frame (i.e., you shouldn't specify the *NOFRAME* procedure option). Procedures you execute via a *cocall* should never have any parameters (the calling code will not properly set up those parameters and references to the parameter list may crash the machine).

This constructor is a conventional HLA class constructor. On entry, if *ESI* contains a non-null value, the constructor assumes that it points at a coroutine class object and the constructor initializes that object. On the other hand, if *ESI* contains *NULL* upon entry into the constructor, then the constructor allocates new storage for a coroutine object on the heap, initializes that object, and returns a pointer to the object in the *ESI* register. The examples in this chapter will always assume dynamic allocation of the coroutine object (i.e., we'll use pointers).

To transfer control from one coroutine (including the main program) to another, you use the *coroutine.cocall* method. This method, which has no parameters, switches the thread of execution from the current coroutine to the coroutine object associated with the method. For example, if you're in the main program, the following two *cocalls* transfer control to the *FirstPlayer* and then the *OtherPlayer* coroutines:

```
FirstPlayer.cocall();
OtherPlayer.cocall();
```

There are two important things to note here. First, the syntax is not quite the same as a procedure call. You don't use *cocall* along with some operand that specifies which coroutine to transfer to (as you would if this were a *CALL* instruction); instead, you specify the coroutine object and invoke the *cocall* method for that object. The second thing to keep in mind is that these are coroutine transfers, not subroutine calls; therefore, the *FirstPlayer* coroutine doesn't necessarily return back to this code sequence. *FirstPlayer* could transfer control directly to *OtherPlayer* or some other coroutine once it finishes whatever tasks it's working on. Some coroutine has to explicitly transfer control to the thread of execution above in order for it to (directly) transfer control to *OtherPlayer*.

Although coroutines are more general than procedures and don't have to use the call/return semantics, it is perfectly possible to simulate and call and return exchange between two coroutines. If one coroutine calls another and that second coroutine *cocalls* the first, you get semantics that are very similar to a call/return (of course, on the next call to the second coroutine control resumes after the *cocall*, not at the start of the coroutine, but we will ignore that difference here). The only problem with this approach is that it is not general: both coroutines have to be aware of the other. Consider a cooperating pair of coroutines, *master* and *slave*. The *master* coroutine corresponds to the main program and the *slave* coroutine corresponds to a procedure that the main program calls. Unfortunately, *slave* is not general purpose like a standard procedure because it explicitly calls the *master* coroutine (at least, using the techniques we've seen thus far). Therefore, you cannot call it from an arbitrary coroutine and expect control to transfer back to that coroutine. If *slave* contains a *cocall* to the *master* coroutine it will transfer control there rather than back to the "calling" coroutine. Although these are the semantics we expect of coroutines, it would sometimes be nice if a coroutine could return to whomever invoked it without explicitly knowing who invoked it. While it is possible to set up some coroutine variables and pass this information between coroutines, the HLA Standard Library Coroutines Module provides a better solution: the *coret* procedure.

On each call to a coroutine, the coroutine run-time support code remembers the last coroutine that made a *cocall*. The *coret* procedure uses this information to transfer control back to the last coroutine that made a *cocall*. Therefore, the *slave* coroutine above can execute the *coret* procedure to transfer control back to whomever called it without knowing who that was.

Note that the *coret* procedure is not a member of the *coroutine* class. Therefore, you do not preface the call with "coroutine." You invoke it directly:

```
coret () ;
```

Another important issue to keep in mind with *coret* is that it only keeps track of the last *cocall*. It does not maintain a stack of coroutine "return addresses" (there are several different stacks in use by coroutines, on which one does it keep this information?). Therefore, you cannot make two *cocalls* in a row and then execute two *corets* to return control back to the original coroutine. If you need this facility, you're going to need to create and maintain your own stack of coroutine calls. Fortunately, the need for something like this is fairly rare. You generally don't use coroutines as though they were procedures and in the few instances where this is convenient, a single level of return address is usually sufficient.

By default, every HLA main program is a coroutine. Whenever you compile an HLA program (as opposed to a UNIT), the HLA compiler automatically inserts two pieces of extra code at the beginning of the main program. The first piece of extra code initializes the HLA exception handling system, the second sets up a coroutine variable for the main program. The purpose of this variable is to allow other coroutines to transfer control back to the main program; after call, if you transfer control from one coroutine to another using a statement like *VarName.cocall*, you're going to need a coroutine variable associated with the main program in order to *cocall* the main program. HLA automatically creates and initializes this variable when execution of the main program begins. So the only question is, "how do you gain access to this variable?"

The answer is simply, really. Whenever you include the "coroutines.hhf" header file (or "stdlib.hhf" which automatically includes "coroutines.hhf") HLA declares a static coroutine variable for you that is associated with the main program's coroutine object. That declaration looks something like the following<sup>2</sup>:

```
static MainPgm:coroutine; external("<<external name for MainPgm>>");
```

Therefore, to transfer control from one coroutine to the main program's coroutine, you'd use a *cocall* like the following:

```
MainPgm.cocall () ;
```

The last method of interest to us in the *coroutine* class is the *coroutine.cofree* method. This is the destructor for the *coroutine* class. Calling this method frees up the stack storage associated with the coroutine and cleans up other state information associated with that coroutine. A typical call might look like the following:

```
OtherPlayer.cofree () ;
```

**Warning:** do not call the *cofree* method from within the coroutine you are freeing up. There is no guarantee that the stack and coroutine state variables remain valid for a given coroutine after you call *cofree*. Generally, it is a good idea to call the *cofree* method in the same code that originally created the coroutine via the *coroutine.create* call. It goes without saying that you must not call a coroutine after you've destroyed it via the *cofree* method call.

Remember that the *coret* procedure call is really a special form of *cocall*. Therefore, you need to be careful about executing *coret* after calling the *cofree* method as you may wind up "returning" to the coroutine you just destroyed.

After you call the *cofree* method, it is perfectly reasonable create a new coroutine using that same coroutine variable by once again calling the *coroutine.create* procedure. However, you should always ensure that you call the *cofree* method prior to calling *coroutine.create* or the stack space allocated in the original call will be lost in the system (i.e., you'll create a memory leak).

**This is very important:** you never "return" from a coroutine using a RET instruction (e.g., by "falling off the end of the procedure) or via the HLA EXIT/EXITIF statement. The only legal ways to "return" from a coroutine are via the *cocall* and *coret* operations. If you RETURN or EXIT from a coroutine, that coroutine enters a special mode that rejects any future *cocalls* and immediately returns control back to whomever *cocalled* it in the first place. Most coroutines contain an infinite loop that transfers control back to the start of the coroutine to repeat whatever function they perform once they complete all the code in the coroutine. You will probably want to implement this functionality in your coroutines as well.

---

2. The external name doesn't appear here because it is subject to change. See the coroutines.hhf header file if you need to know the actual external name for some reason.

### 3.3 Parameters and Register Values in Coroutine Calls

As you've probably noticed, coroutine calls via `cocall` don't support generic parameters for transferring data between two coroutines. There are a couple of reasons for this. First of all, passing parameters to a coroutine is difficult because we typically use the stack to pass parameters and coroutines all use different stacks. Therefore, the parameters one coroutine passes to another won't be on the correct stack (and, therefore, inaccessible) when the second coroutine continues execution. Another problem with passing parameters between coroutines is that a typical coroutine has several entry points (immediately after each `cocall` in that coroutine). Nevertheless, it is often important to communicate information between coroutines. We will explore ways to do that in this section.

If we can pass parameters on the stack, that basically leaves registers and global memory locations<sup>3</sup>. Registers are the easy and obvious solution. However, keep in mind that you have a limited set of registers available so you can't pass much data between coroutines in the registers. On the other hand, you can pass a pointer to a block of data in a register (see "Passing Parameters via a Parameter Block" on page 1317 for details).

Another place to pass parameters between coroutines is in global memory locations. Keep in mind that coroutines each have their own stack. Therefore, one coroutine does not have access to another coroutine's automatic variables appearing in a VAR section (this is true even if those VAR objects appear in the main program). Always use `STATIC`, `STORAGE`, or `READONLY` objects when communicating data between coroutines using global variables. If you must communicate an automatic or dynamic object, pass the address of that object in a register or some static global variable.

A bigger problem than where we pass parameters to a coroutine is "How do we deal with parameters we pass to a coroutine?" Parameters work well in procedures because we always enter the procedure at the same point and the state of the procedure is usually the same upon entry (with the possible exception of static variable values). This is not true for coroutines. Consider the following code that executes as a coroutine:

```
procedure IsACoroutine; nodisplay; noframe;
begin IsACoroutine;

 /*
 << Do something upon initial entry >>

 coret(); // Invoke previous coroutine
 /*

 << Do some more stuff upon return >>

 forever

 OtherCoroutine.cocall(); // Invoke a third coroutine.

 << Do some more stuff here >>

 MainPgm.cocall(); // Transfer control back to the main program.
 /*

 << do some stuff >>

 coret(); // Return to whomever cocalled us.
 /*

 << do some more stuff >>
```

---

3. The chapter on low-level parameter implementation in this volume discusses different places you can pass parameters between procedures. Check out that chapter for more details on this subject.

```

endfor;

end IsACoroutine;

```

In this code you'll find several comments of the form `/**`. These comments mark the point at which some other coroutine can reenter this code. Note that, in general, the "calling" coroutine has no idea which entry point it will invoke and, likewise, this coroutine has no idea who invoked it at any given point. Passing in meaningful parameters and properly processing them under these conditions is difficult, at best. The only reasonable solution is to make every invocation pass exactly the same type of data in the same location and then write your coroutines to handle this data appropriately upon each entry. Even though this solution is more reasonable than the other possibilities, maintaining code like this is very difficult.

If you're really dead set on passing parameters to a coroutine, the best solution is to have a single entry point into the code so you've only got to handle the parameter data in one spot. Consider the following procedure that other threads invoke as a coroutine:

```

procedure HasAParm; nodisplay;
begin HasAParm;

 << Initialization code goes here, assume no parameter >>
 forever

 coret(); // Or cocall some other coroutine.

 << deal with parameter data passed into this coroutine >>

 endfor;

end HasAParm;

```

Note that there are two entry points into this code: the first occurs on the initial entry. The other occurs whenever the `coret()` procedure returns via a `cocall` to this coroutine. Immediately after the `coret` statement, the code above can process whatever parameter data the calling code has set up. After processing that data, this code returns to the invoking coroutine and that coroutine (directly or indirectly) can invoke this code again with more data.

---

### 3.4 Recursion, Reentrancy, and Variables

The fact that each coroutine has its own stack impacts access to variables from within coroutines. In particular, the only automatic (VAR) objects you can normally access are those declared within the coroutine itself and any procedures it calls. In a later chapter of this volume we'll take a look at nested procedures and how one could access local variables outside of the current procedure. For the most part, that discussion does not apply to procedures that are coroutines.

If you wish to share information between two or more coroutines, the best place to put such information is in a static object (STATIC, READONLY, and STORAGE variables). Such data does not appear on a stack and is accessible to multiple coroutines (and other procedures) simultaneously.

Whenever you execute a `cocall` instruction, the system suspends the current thread of execution and switches to a different coroutine, effectively by returning to that other coroutine and picking up where it left off (via a `coret` or `cocall` operation). This means that it isn't really possible to recursively `cocall` some coroutine. Consider the following (vain) attempt to achieve this:

```

procedure IsACoroutine; nodisplay;
begin IsACoroutine;

 << Do some initial stuff >>

 IAC.cocall(); // Note: IAC is initialized with the address of IsACoroutine.

```

```

 << Do some more stuff >>

end IsACoroutine;

```

This code assumes that *IAC* is a coroutine variable initialized with the address of the *IsACoroutine* procedure. The *IAC.cocall* statement, therefore, is an attempt to recursively call this coroutine. However, all that happens is that this call leaves the *IsACoroutine* code and then the coroutine system passes control to where *IAC* last left off. That just happens to be the *IAC.cocall* statement that just left the *IsACoroutine* procedure. Therefore this code immediately returns back to itself.

Although the idea of a recursive coroutine doesn't make sense, it is certainly possible to call procedures from within a coroutine and those procedures can be recursive. You can even make cocalls from those (recursive) procedures and the coroutine system will automatically return back into the recursive calls when control transfers back to the coroutine.

Although coroutines are not recursive, it is quite possible for the coroutine run-time system to reenter a procedure that is a coroutine. This situation can occur when you have two coroutine variables, initialize them both with the address of the same procedure, and then execute a cocall to each of the coroutine objects. Consider the following simple example:

```

procedure Reentered; nodisplay;
begin Reentered;

 << do some initialization or other work >>

 coret();

 << do some other stuff >>

end Reentered;
.
.
.
CV1.create(256, &Reentered); // Initialize two coroutine variables with
CV2.create(256, &Reentered); // the address of the same procedure.
CV1.cocall(); // Start the first coroutine.
CV2.cocall(); // Start the second coroutine.

<< At this point, both CV1 and CV2 are suspended within Reentered >>

```

Notice at the end of this code sequence, both the *CV1* and *CV2* coroutines are executing inside the *Reentered* procedure. That is, if you cocall either one of them, the cocalled routine will continue execution after the *coret* statement. This is not an example of a recursive coroutine call, but it certainly demonstrates that you can reenter some procedure while some other coroutine is currently executing the code within that procedure.

Reentering some code (whether you do this via a coroutine call or some other mechanism) is a perfectly reasonable thing to do. Indeed, recursion is one example of reentrancy. However, there are some special considerations you must be aware of when it is possible to reenter some code.

The principal issue is the use of variables in reentrant code. Suppose the *Reentered* procedure above had the following declarations:

```

var
 i: int32;
 j: uns32;

```

One concern you might have is that the two different coroutines executing in the same procedure would share these variables. However, keep in mind that HLA allocates automatic variables on the stack. Since each coroutine has its own stack, they're going to get their own private copies of the variables. Therefore, if *CV1* stores a value into *i* and *j*, *CV2* will not see these values. While this may seem to be a problem, this is

actually what you want. You generally don't want one coroutine's thread of execution affecting the calculation in a different thread of execution.

The discussion above applies only to automatic variables. HLA does not allocate static objects (those you declare in the `STATIC`, `READONLY`, and `STORAGE` sections) on the stack. Therefore, such variables are not associated with a specific coroutine; instead, all coroutines that are executing in the same procedure share the same variables. Therefore, you shouldn't use static variables within a procedure that serves as a coroutine (especially reentrant coroutines) unless you explicitly want to share that data among other coroutines or other procedures.

Coroutines have their own stack and maintain that stack between cocalls to other coroutines. Therefore, like iterators, coroutines maintain their state (including the value of automatic variables) across cocalls. This is true even if you leave a coroutine via some other procedure than the main procedure for the coroutine. For example, suppose coroutine *A* calls some procedure *B* and then within procedure *B* there is a cocall to some other coroutine *C*. Whenever coroutine *C* executes *coret* or some coroutine (including *C*) cocalls *A*, control transfers back into procedure *B* and procedure *B*'s state is maintained (including the values of all local variables *B* initialize prior to the cocall). When *B* executes a return instruction, it will return back to procedure *A* who originally called *B*.

In theory it's even possible to call a procedure as well as cocall that procedure (it's hard to imagine why you would want to do this and it's probably quite difficult to pull it off correctly, but it's certainly possible). This is such a bizarre situation that we won't consider it any farther here.

### 3.5 Generators

A generator is to a function what a coroutine is to a procedure. That is, the whole purpose of a generator is to return a value like a function result. As far as HLA and the Coroutines Library Module is concerned, there is absolutely no difference between a generator and a coroutine (anymore than there is a syntactical difference between a function and a procedure to HLA). Clearly, there are some semantic differences; this section will describe the semantics of a generator and propose a convention for generator implementation.

The best way to describe a generator is to begin with the discussion of a special-purpose generator object that HLA does support – the iterator. An iterator is a special form of a generator that does not require its own stack. Iterators share the same stack as the calling code (i.e., the code containing the `FOREACH` loop that invokes the iterator). Because of the semantics of the `FOREACH` loop, iterators can leave their activation records on the stack and, therefore, maintain their local state between exits to the `FOREACH` loop body. The disadvantage to this scheme is that the calling semantics of an iterator are very rigidly defined; you cannot call an iterator from an arbitrary point in a program and the iterator's state is preserved only for the execution of the `FOREACH` loop.

By using its own stack, a generator removes these restrictions. You can call a generator from any point in the program (except, of course, within the generator itself – remember, recursive coroutines are not possible). Also, the state (i.e., the activation record) of a generator is not tied to the execution of some syntactical item like a `FOREACH` loop. The generator maintains its local state from the point of its first call to the point you call *cofree* on that generator.

One major difference between iterators and generators is the fact that generators don't use the *yield* statement (think) to return results back to the calling code. To send a value back to whomever invokes the generator, the generator must cocall the original coroutine. Since one can call a generator from different points in the code, and in particular, from different coroutines, the typical way to "return" a value back to the "caller" is to use the *coret* procedure call after loading the return result into a register.

A typical generator does not use the *cocall* operation. The *cocall* method transfers control to some other (explicitly defined) coroutine. As a general rule, generators (like functions) return control to whomever called them. They do not explicitly pass control through to some other coroutine. Keep in mind that the *coret* procedure only returns control to the last coroutine. Therefore, if some generator passes control to another coroutine, there is no way to anonymously return back to whomever called the generator in the first place. That information is lost at the point of the second *cocall* operator. Since the main purpose of a generator is to return a value to whomever cocalled it, finding cocalls in a generator would be unusual indeed.

One problem with generators is that, like the coroutines upon which they are based, you cannot pass parameters to a generator via the stack. In most cases this is perfectly acceptable. As their name implies, generators typically generate an independent stream of data once they begin execution. After initialization, a generator generally doesn't require any additional information in order to generate its data sequence. Although this is the typical case, it is not the only case; sometimes you may need to write generators that need parameter data on each call. So what's the best way to handle this?

In a previous section (see "Parameters and Register Values in Coroutine Calls" on page 1298) we discussed a couple of ways to pass parameters to coroutines. While those techniques apply here as well, they are not particularly convenient (certainly not as convenient as passing parameters to a standard HLA procedure). Because of their function-like nature, it is more common to have to pass parameters to a generator (versus a generic coroutine) and you'll probably make more calls to generators that require parameters (versus similar calls to coroutines). Therefore, it would be nice if there were a "high-level" way of passing parameters to generators. Well, with a couple of tricks we can easily accomplish this<sup>4</sup>.

Remember that we cannot pass parameters to a coroutine (or generator) on the stack. The most convenient place to pass coroutine parameters is in registers or in static, global, memory locations. Unfortunately, writing a sequence of instructions to load up registers with parameter values (or, worse yet, copy the parameter data to global variables) prior to invoking a generator is a real pain. Fortunately, HLA's macros come to the rescue here; we can easily write a macro that lets us invoke a generator using a high level syntax and the macro can take care of the dirty work of loading registers (or global memory locations) with the necessary values. As an example, consider a generator, *\_MyGen*, that expects two parameters in the EAX and EBX registers. Here's a macro, *MyGen*, that sets up the registers and invokes this generator:

```
macro MyGen(ParmForEAX, ParmForEBX);

 mov(ParmForEAX, eax);
 mov(ParmForEBX, ebx);
 _MyGen.cocall();

endmacro;
.
.
.
MyGen(5, i);
```

You could, with just a tiny bit more effort, pass the parameters in global memory locations using this same technique.

In a few situations, you'll really need to pass parameters to a generator on the stack. We'll not go into the reasons or details here, but there are some rare circumstances where this is necessary. In many other circumstances, it may not be necessary but it's certainly more convenient to pass the parameters on the stack because you get to take advantage of HLA's high level parameter passing syntax when you use this scheme (i.e., you get to choose the parameter passing mechanism and HLA will automatically handle a lot of the gory details behind parameter passing for you when you use the stack). The best solution in this situation is to write a wrapper procedure. A wrapper procedure is a short procedure that reorganizes a parameter list before calling some other procedure. The macro above is a simple example of a wrapper – it takes two the (text) parameters and moves their run-time data into EAX and EBX prior to cocalling *\_MyGen*. We could have just as easily written a procedure to accomplish this same task:

```
procedure MyGen(ParmForEAX:dword; ParmForEBX:dword); nodisplay;
begin MyGen;

 mov(ParmForEAX, eax);
 mov(ParmForEBX, ebx);
 _MyGen.cocall();

end MyGen;
```

---

4. By the way, generators are coroutines, so these tricks apply to generic coroutines as well.

Beyond the obvious time/space trade-offs between macros and procedures, there is one other big difference between these two schemes: the procedure variation allows you to specify a parameter passing mechanism like pass by reference, pass by value/result, pass by name, etc<sup>5</sup>. Once HLA knows the parameter passing mechanism, it can automatically emit code to process the actual parameters for you. Suppose, for example, you needed pass by value/result semantics. Using the macro invocation, you'd have to explicitly write a lot of code to pull this off. In the procedure above, about the only change you'd need is to add some code to store any returned results back into *ParmForEAX* or *ParmForEBX* (whichever uses the pass by value/result mechanism).

Since coroutines and generators share the same memory address space as the calling coroutine, it is not correct to say that a coroutine or generator does not have access to the stack of the calling code. The stack is in the same address space as the coroutine/generator; the only problem is that the coroutine doesn't know exactly where any parameters may be sitting in that memory space. This is because procedures use the value in ESP<sup>6</sup> to indirectly reference the parameters passed on the stack and, unfortunately, the *cocall* method changes the value of the ESP register upon entry into the coroutine/generator. However, were we to pass the original value of ESP (or some other pointer into an activation record) through to a generator, then it would have direct access to those values on the stack. Consider the following modification to the *MyGen* procedure above:

```
procedure MyGen(ParmForEAX:dword; ParmForEBX:dword); nodisplay;
begin MyGen;

 mov(ebp, ebx);
 _MyGen.cocall();

end MyGen;
```

Notice that this code does not directly copy the two parameters into some locations that are directly accessible in the generator. Instead, this procedure simply copies the base address of *MyGen*'s activation record (the value in EBP) into the EBX register for use in the generator. To gain access to those parameters, the generator need only index off of EBX using appropriate offsets for the two parameters in the activation record. Perhaps the easiest way to do this is by declaring an explicit record declaration that corresponds to *MyGen*'s activation record:

```
type
 MyGenAR:
 record
 OldEBP: dword;
 RtnAdrs: dword;
 ParmForEAX: dword;
 ParmForEBX: dword;
 endrecord;
```

Now, within the *\_MyGen* generator code, you can access the parameters on the stack using code like the following:

```
mov((type MyGenAR [ebx]).ParmForEAX, eax);
mov((type MyGenAR [ebx]).ParmForEBX, edx);
```

This scheme works great for pass by value and pass by reference parameters (those we've seen up to this point). There are other parameter passing mechanisms, this scheme doesn't work as well for those other parameter passing mechanisms. Fortunately, you won't use those other parameter passing methods anywhere near as often as pass by value and pass by name.

---

5. For a discussion of pass by value/result and pass by name parameter passing mechanisms, see the chapter on low-level parameter implementation in this volume.

6. Okay, a procedure typically uses the value in EBP, but that same procedure also loads EBP with the value of ESP in the standard entry sequence.

---

## 3.6 Exceptions and Coroutines

Exceptions represent a special problem in coroutines. The HLA `TRY..ENDTRY` statement typically surrounds a block of statements one wishes to protect from errant code. The `TRY..ENDTRY` statement is a dynamic control structure insofar as this statement also protects any procedures you call from within the `TRY..ENDTRY` block. So the obvious question is "does the `TRY..ENDTRY` statement protect a coroutine you call from within such a block as well?" The short answer is "no, it does not."

Actually, in the first implementation of the HLA coroutines module, the exception handling system did pass control from one coroutine to another whenever an exception occurred. However, it became immediately obvious that this behavior causes non-intuitive results. Coroutines tend to be independent entities and to have one coroutine transfer control to another without an explicit `cocall` creates some problems. Therefore, the HLA compiler and the coroutines module now treat each coroutine as a standalone entity as far as exceptions are concerned. If an exception occurs within some coroutine and there isn't an outstanding `TRY..ENDTRY` block active for that coroutine, then the system behaves as though there were no active `TRY..ENDTRY` at all, *even if there is an active `TRY..ENDTRY` block in another coroutine*; in other words, the program aborts execution. Keep this in mind when using exception handling in your coroutines. For more details on exception handling, see the chapter on Exception Handling in this volume.

---

## 3.7 Putting It All Together

This chapter discusses a novel program unit – the coroutine. Coroutines have many special properties that make them especially valuable in certain situations. Coroutines are not built into the HLA language. Rather, HLA implements them via the HLA Coroutines Module in the HLA Standard Library. This chapter began by discussing the methods found in that library module. Next, this chapter discusses the use of variables, recursion, reentrancy and machine state in a coroutine. This chapter also discusses how to create generators using coroutines and pass parameters to a generator in a function-like fashion. Finally, this chapter briefly discussed the use of the `TRY..ENDTRY` statement in coroutines.

Coroutines and generators are like iterators insofar as they are control structures that few high level languages implement. Therefore, most programmers are unfamiliar with the concept of a coroutine. This, unfortunately, leads to the lack of consideration of coroutines in a program, even where a coroutine is the most suitable control structure to use. You should avoid this trap and learn how to use coroutines and generators properly so that you'll know when to use them when the need arises.

---

# Low-level Parameter Implementation Chapter Four

---

## 4.1 Chapter Overview

This chapter discusses advanced parameter passing techniques in assembly language. Both low-level and high-level syntax appears in this chapter. This chapter discusses the more advanced pass by value/result, pass by result, pass by name, and pass by lazy evaluation parameter passing mechanisms. This chapter also discusses how to pass parameters in a low-level manner and describes where you can pass such parameters.

---

## 4.2 Parameters

Although there is a large class of procedures that are totally self-contained, most procedures require some input data and return some data to the caller. Parameters are values that you pass to and from a procedure. There are many facets to parameters. Questions concerning parameters include:

- where is the data coming from?
- how do you pass and return data?
- what is the amount of data to pass?

Previous chapters have touched on some of these concepts (see the chapters on beginning and intermediate procedures as well as the chapter on Mixed Language Programming). This chapter will consider parameters in greater detail and describe their low-level implementation.

---

## 4.3 Where You Can Pass Parameters

Up to this point we've mainly used the 80x86 hardware stack to pass parameters. In a few examples we've used machine registers to pass parameters to a procedure. In this section we explore several different places where we can pass parameters. Common places are

- in registers,
- in FPU or MMX registers,
- in global memory locations,
- on the stack,
- in the code stream, or
- in a parameter block referenced via a pointer.

Finally, the amount of data has a direct bearing on where and how to pass it. For example, it's generally a bad idea to pass large arrays or other large data structures by value because the procedure has to copy that data onto the stack when calling the procedure (when passing parameters on the stack). This can be rather slow. Worse, you cannot pass large parameters in certain locations; for example, it is not possible to pass a 16-element int32 array in a register.

Some might argue that the only locations you need for parameters are the register and the stack. Since these are the locations that high level languages use, surely they should be sufficient for assembly language programmers. However, one advantage to assembly language programming is that you're not as constrained as a high level language; this is one of the major reasons why assembly language programs can be more efficient than compiled high level language code. Therefore, it's a good idea to explore different places where we can pass parameters in assembly language.

This section discusses six different locations where you can pass parameters. While this is a fair number of different places, undoubtedly there are many other places where one can pass parameters. So don't let this section prejudice you into thinking that this is the only way to pass parameters.

### 4.3.1 Passing Parameters in (Integer) Registers

Where you pass parameters depends, to a great extent, on the size and number of those parameters. If you are passing a small number of bytes to a procedure, then the registers are an excellent place to pass parameters. The registers are an ideal place to pass value parameters to a procedure. If you are passing a single parameter to a procedure you should use the following registers for the accompanying data types:

| Data Size    | Pass in this Register |
|--------------|-----------------------|
| Byte:        | al                    |
| Word:        | ax                    |
| Double Word: | eax                   |
| Quad Word:   | edx:eax               |

This is, by no means, a hard and fast rule. If you find it more convenient to pass 32 bit values in the ESI or EBX register, by all means do so. However, most programmers use the registers above to pass parameters.

If you are passing several parameters to a procedure in the 80x86's registers, you should probably use up the registers in the following order:

| First | Last                         |
|-------|------------------------------|
|       | eax, edx, esi, edi, ebx, ecx |

In general, you should avoid using EBP register. If you need more than six parameters, perhaps you should pass your values elsewhere.

HLA provides a special high level syntax that lets you tell HLA to pass parameters in one or more of the 80x86 integer registers. Consider the following syntax for an HLA parameter declaration:

```
varname : typename in register
```

In this example, *varname* represents the parameter's name, *typename* is the type of the parameter, and *register* is one of the 80x86's eight-, 16-, or 32-bit integer registers. The size of the data type must be the same as the size of the register (e.g., "int32" is compatible with a 32-bit register). The following is a concrete example of a procedure that passes a character value in a register:

```
procedure swapcase(chToSwap: char in al); nodisplay; noframe;
begin swapcase;

 if(chToSwap in 'a'..'z') then

 and($5f, chToSwap); // Convert lower case to upper case.

 elseif(chToSwap in 'A'..'Z') then

 or($20, chToSwap);

 endif;
 ret();

end swapcase;
```

There are a couple of important issues to note here. First, within the procedure's body, the parameter's name is an alias for the corresponding register if you pass the parameter in a register. In other words, *chToSwap* in the previous code is equivalent to "al" (indeed, within the procedure HLA actually defines *chToSwap* as a TEXT constant initialized with the string "al"). Also, since the parameter was passed in a register rather than on the stack, there is no need to build a stack frame for this procedure; hence the absence of the standard entry and exit sequences in the code above. Note that the code above is exactly equivalent to the following code:

```

// Actually, the following parameter list is irrelevant and
// you could remove it. It does, however, help document the
// fact that this procedure has a single character parameter.

procedure swapcase(chToSwap: char in al); nodisplay; noframe;
begin swapcase;

 if(al in 'a'..'z') then

 and($5f, al); // Convert lower case to upper case.

 elseif(al in 'A'..'Z') then

 or($20, al);

 endif;
 ret();

end swapcase;

```

Whenever you call the *swapcase* procedure with some actual (byte sized) parameter, HLA will generate the appropriate code to move that character value into the AL register prior to the call (assuming you don't specify AL as the parameter, in which case HLA doesn't generate any extra code at all). Consider the following calls that the corresponding code that HLA generates:

```

// swapcase('a');

 mov('a', al);
 call swapcase;

// swapcase(charVar);

 mov(charVar, al);
 call swapcase;

// swapcase((type char [ebx]));

 mov([ebx], al);
 call swapcase;

// swapcase(ah);

 mov(ah, al);
 call swapcase;

// swapcase(al);

 call swapcase; // al's value is already in al!

```

The examples above all use the pass by value parameter passing mechanism. When using pass by value to pass parameters in registers, the size of the actual parameter (and formal parameter) must be exactly the same size as the register. Therefore, you are limited to passing eight, sixteen, or thirty-two bit values in the registers by value. Furthermore, these object must be scalar objects. That is, you cannot pass composite (array or record) objects in registers even if such objects are eight, sixteen, or thirty-two bits long.

You can also pass reference parameters in registers. Since pass by reference parameters are four-byte addresses, you must always specify a thirty-two bit register for pass by reference parameters. For example, consider the following *memfill* function that copies a character parameter (passed in AL) throughout some number of memory locations (specified in ECX), at the memory location specified by the value in EDI:

```

// memfill- This procedure stores <ECX> copies of the byte in AL starting
// at the memory location specified by EDI:

```

```

procedure memfill
(
 charVal: char in al;
 count: uns32 in ecx;
 var dest: byte in edi // dest is passed by reference
);
 nodisplay; noframe;

begin memfill;

 pushfd(); // Save D flag;
 push(ecx); // Preserve other registers.
 push(edi);

 cld(); // increment EDI on string operation.
 rep.stosb(); // Store ECX copies of AL starting at EDI.

 pop(edi);
 pop(ecx);
 popfd();
 ret(); // Note that there are no parameters on the stack!

end memfill;

```

It is perfectly possible to pass some parameters in registers and other parameters on the stack to an HLA procedure. Consider the following implementation of *memfill* that passes the *dest* parameter on the stack:

```

procedure memfill
(
 charVal: char in al;
 count: uns32 in ecx;
 var dest: var
);
 nodisplay;

begin memfill;

 pushfd(); // Save D flag;
 push(ecx); // Preserve other registers.
 push(edi);

 cld(); // increment EDI on string operation.
 mov(dest, edi); // get dest address into EDI for STOSB.
 rep.stosb(); // Store ECX copies of AL starting at EDI.

 pop(edi);
 pop(ecx);
 popfd();

end memfill;

```

Of course, you don't have to use the HLA high level procedure calling syntax when passing parameters in the registers. You can manually load the values into registers prior to calling a procedure (with the CALL instruction) and you can refer directly to those values via registers within the procedure. The disadvantage to this scheme, of course, is that the code will be a little more difficult to write, read, and modify. The advantage of the scheme is that you have more control and can pass any eight, sixteen, or thirty-two bit value between the procedure and its callers (e.g., you can load a four-byte array or record into a 32-bit register and call the procedure with that value in a single register, something you cannot do when using the high level language syntax for procedure calls). Fortunately, HLA gives you the choice of whichever parameter pass-

ing scheme is most appropriate, so you can use the manual passing mechanism when it's necessary and use the high level syntax whenever it's not necessary.

There are other parameter passing mechanism beyond pass by value and pass by reference that we will explore in this chapter. We will take a look at ways of passing parameters in registers using those parameter passing mechanisms as we encounter them.

---

### 4.3.2 Passing Parameters in FPU and MMX Registers

Since the 80x86's FPU and MMX registers are also registers, it makes perfect sense to pass parameters in these locations if appropriate. Although using the FPU and MMX registers is a little bit more work than using the integer registers, it's generally more efficient than passing the parameters in memory (e.g., on the stack). In this section we'll discuss the techniques and problems associated with passing parameters in these registers.

The first thing to keep in mind is that the MMX and FPU register sets are not independent. These two register sets overlap, much like the eight, sixteen, and thirty-two bit integer registers. Therefore, you cannot pass some parameters in FPU registers and other parameters in MMX registers to a given procedure. For more details on this issue, please see the chapter on the MMX Instruction Set. Also keep in mind that you must execute the EMMS instruction after using the MMX instructions before executing any FPU instructions. Therefore, it's best to partition your code into sections that use the FPU registers and sections that use the MMX registers (or better yet, use only one register set throughout your program).

The FPU represents a fairly special case. First of all, it only makes sense to pass real values through the FPU registers. While it is technically possible to pass other values through the FPU registers, efficiency and accuracy restrictions severely limit what you can do in this regard. This text will not consider passing anything other than real values in the floating point registers, but keep in mind that it is possible to pass generic groups of bits in the FPU registers if you're really careful. Do keep in mind, though, that you need a very detailed knowledge of the FPU if you're going to attempt this (exceptions, rounding, and other issues can cause the FPU to incorrectly manipulate your data under certain circumstances). Needless to say, you can only pass objects by value through the FPU registers; pass by reference isn't applicable here.

Assuming you're willing to pass only real values through the FPU registers, some problems still remain. In particular, the FPU's register architecture does not allow you to load the FPU registers in an arbitrary fashion. Remember, the FPU register set is a stack; so you have to push values onto this stack in the reverse order you wish the values to appear in the register file. For example, if you wish to pass the real variables *r*, *s*, and *t* in FPU registers ST0, ST1, and ST2, you must execute the following code sequence (or something similar):

```
fld(t); // t -> ST0, but ultimately winds up in ST2.
fld(s); // s -> ST0, but ultimately winds up in ST1.
fld(r); // r -> ST0.
```

You cannot load some floating point value into an arbitrary FPU register without a bit of work. Furthermore, once inside the procedure that uses real parameters found on the FPU stack, you cannot easily access arbitrary values in these registers. Remember, FPU arithmetic operations automatically "renumber" the FPU registers as the operations push and pop data on the FPU stack. Therefore, some care and thought must go into the use of FPU registers as parameter locations since those locations are dynamic and change as you manipulate items on the FPU stack.

By far, the most common use of the FPU registers to pass value parameters to a function is to pass a single value parameter (or maybe a pair of parameter values) in the register so the procedure can operate directly on that parameter (those parameters) via FPU operations. A classic example might be a SIN function that expects its angle in degrees (rather than radians, and the FSIN instruction expects). The function could convert the degree to radians and then execute the FSIN instruction to complete the calculation.

Keep in mind the limited size of the FPU stack. This effectively eliminates the possibility of passing real parameter values through the FPU registers in a recursive procedure. Also keep in mind that it is rather difficult to preserve FPU register values across a procedure call, so be careful about using the FPU registers

to pass parameters since such operations could disturb the values already on the FPU stack (e.g., cause an FPU stack overflow).

The MMX register set, although it shares the same physical silicon as the FPU, does not suffer from the all same problems as the FPU register set when it comes to passing parameters. First of all, the MMX registers are true registers that are individually accessible (i.e., they do not use a stack implementation). You may pass data in any MMX register and you do not have to use the registers in a specific order. Of course, if you pass parameter data in an MMX register, the procedure you're calling must not execute any FPU instructions before you're done with the data or you will lose the value(s) in the MMX register(s).

In theory, you can pass any 64-bit data to a procedure in an MMX register. However, you'll find the use of the MMX register set most convenient if you're actually operating on the data in those registers using MMX instructions.

### 4.3.3 Passing Parameters in Global Variables

Once you run out of registers, the only other (reasonable) alternative you have is main memory. One of the easiest places to pass parameters is in global variables in the data segment. The following code provides an example:

```
// ThisProc-
//
// Global variable "Ref1Proc1" contains the address of a pass by reference
// parameter. Global variable "Value1Proc1" contains the value of some
// pass by value parameter. This procedure stores the value of the
// "Value1Proc1" parameter into the actual parameter pointed at by
// "Ref1Proc1".

procedure ThisProc; nodisplay; noframe;
begin ThisProc;

 mov(Ref1Proc1, ebx); // Get address of reference parameter.
 mov(Value1Proc, eax); // Get Value parameter.
 mov(eax, [ebx]); // Copy value to actual ref parameter.
 ret();

end ThisProc;
.
.
.

// Sample call to the procedure (includes setting up parameters)

 mov(xxx, eax); // Pass this parameter by value
 mov(eax, Value1Proc1);
 lea(eax, yyy); // Pass this parameter by reference
 mov(eax, Ref1Proc1);
 call ThisProc;
```

Passing parameters in global locations is inelegant and inefficient. Furthermore, if you use global variables in this fashion to pass parameters, the subroutines you write cannot use recursion. Fortunately, there are better parameter passing schemes for passing data in memory so you do not need to seriously consider this scheme.

### 4.3.4 Passing Parameters on the Stack

Most high level languages use the stack to pass parameters because this method is fairly efficient. Indeed, in most of the examples found in this text up to this chapter, passing parameters on the stack has

been the standard solution. To pass parameters on the stack, push them immediately before calling the subroutine. The subroutine then reads this data from the stack memory and operates on it appropriately. Consider the following HLA procedure declaration and call:

```
procedure CallProc(a:dword; b:dword; c:dword);
.
.
.

 CallProc(i,j,k+4);
```

By default, HLA pushes its parameters onto the stack in the order that they appear in the parameter list. Therefore, the 80x86 code you would typically write for this subroutine call is<sup>1</sup>

```
push(i);
push(j);
mov(k, eax);
add(4, eax);
push(eax);
call CallProc;
```

Upon entry into *CallProc*, the 80x86's stack looks like that shown in Figure 13.1

**Figure 13.1** Activation Record for *CallProc* Invocation

Since the chapter on intermediate procedures discusses how to access these parameters, we will not repeat that discussion here. Instead, this section will attempt to tie together material from the previous chapters on procedures and the chapter on Mixed Language Programming.

As noted in the chapter on intermediate procedures, the HLA compiler automatically associates some (positive) offset from EBP with each (non-register) parameter you declare in the formal parameter list. Keeping in mind that the base pointer for the activation record (EBP) points at the saved value of EBP and the return address is immediately above that, the first double word of parameter data starts at offset +8 from EBP in the activation record (see Figure 13.2 for one possible arrangement).

1. Actually, you'd probably use the HLA high level calling syntax in the typical case, but we'll assume the use of the low-level syntax for the examples appearing in this chapter.

**Figure 13.2** Offsets into *CallProc*'s Activation Record

The parameter layout in Figure 13.2 assumes that the caller (as in the previous example) pushes the parameters in the order (left to right) that they appear in the formal parameter list; that is, this arrangement assumes that the code pushes *i* first, *j* second, and *k*+4 last. Because this is convenient and easy to do, most high level languages (and HLA, by default) push their parameters in this order. The only problem with this approach is that it winds up locating the first parameter at the highest address in memory and the last parameter at the lowest address in memory. This non-intuitive organization isn't much of a problem because you normally refer to these parameters by their name, not by their offset into the activation record. Hence, whether *i* is at offset +16 or +8 is usually irrelevant to you. Of course, you could refer to these parameters using memory references like "[ebp+16]" or "[ebp+8]" but, in general, that would be exceeding poor programming style.

In some rare cases, you may actually need to refer to the parameters' values using an addressing mode of the form "[ebp+*disp*]" (where *disp* represents the offset of the parameter into the activation record). One possible reason for doing this is because you've written a macro and that macro always emits a memory operand using this addressing mode. However, even in this case you shouldn't use literal constants like "8" and "16" in the address expression. Instead, you should use the @OFFSET compile-time function to have HLA calculate this offset value for you. I.e., use an address expression of the form:

```
[ebp + @offset(a)]
```

There are two reasons you should specify the addressing mode in this fashion: (1) it's a little more readable this way, and, more importantly, (2) this way is easier to maintain. For example, suppose you decide to add a parameter to the end of the parameter list. This causes all the offsets in *CallProc* to change. If you've used address expressions like "[ebp+16]" in your code, you've got to go locate each instance and manually change it. On the other hand, if you use the @OFFSET operator to calculate the offset of the variable in the activation record, then HLA will automatically recompute the current offset of a variable each time you recompile the program; hence you can make changes to the parameter list and not worry about having to manually change the address expressions in your programs.

Although pushing the actual parameters on the stack in the order of the formal parameters' declarations is very common (and the default case that HLA uses), this is not the only order a program can use. Some high level languages (most notably, C, C++, Java, and other C-derived languages) push their parameters in the reverse order, that is, from right to left. The primary reason they do this is to allow variable parameter lists, a subject we will discuss a little later in this chapter (see "Variable Parameter Lists" on page 1331). Because it is very common for programmers to interface HLA programs with programs written in C, C++, Java, and other such languages, HLA provides a mechanism that allows it to process parameters in this order.

The CDECL and STDCALL procedure options tell HLA to reverse the order of the parameters in the activation record. Consider the previous declaration of *CallProc* using the CDECL procedure option:

```

procedure CallProc(a:dword; b:dword; c:dword); cdecl;
.
.
.
 CallProc(i,j,k+4);

```

To implement the call above you would write the following code:

```

mov(k, eax);
add(4, eax);
push(eax);
push(j);
push(i);
call CallProc;

```

Compare this with the previous version and note that we've pushed the parameter values in the opposite order. As a general rule, if you're not passing parameters between routines written in assembly and C/C++ or you're not using variable parameter lists, you should use the default parameter passing order (left-to-right). However, if it's more convenient to do so, don't be afraid of using the CDECL or STDCALL options to reverse the order of the parameters.

Note that using the CDECL or STDCALL procedure option immediately changes the offsets of all parameters in a parameter list that has two or more parameters. This is yet another reason for using the @OFFSET operator to calculate the offset of an object rather than manually calculating this. If, for some reason, you need to switch between the two parameter passing schemes, the @OFFSET operator automatically recalculates the offsets.

One common use of assembly language is to write procedures and functions that a high level language program can call. Since different high level languages support different calling mechanisms, you might initially be tempted to write separate procedures for those languages (e.g., Pascal) that push their parameters in a left-to-right order and a separate version of the procedure for those languages (e.g., C) that push their parameters in a right-to-left order. Strictly speaking, this isn't necessary. You may use HLA's conditional compilation directives to create a single procedure that you can compile for other high level language. Consider the following procedure declaration fragment:

```

procedure CallProc(a:dword; b:dword; c:dword);
#if(@defined(CLanguage))
 cdecl;
#endif

```

With this code, you can compile the procedure for the C language (and similar languages) by simply defining the constant *CLanguage* at the beginning of your code. To compile for Pascal (and similar languages) you would leave the *CLanguage* symbol undefined.

Another issue concerning the use of parameters on the stack is "who takes the responsibility for cleaning these parameters off the stack?" As you saw in the chapter on Mixed Language Programming, different languages assign this responsibility differently. For example, in languages like Pascal, it is the procedure's responsibility to clean up parameters off the stack before returning control to the caller. In languages like C/C++, it is the caller's responsibility to clean up parameters on the stack after the procedure returns. By default, HLA procedures use the Pascal calling convention, and therefore the procedures themselves take responsibility for cleaning up the stack. However, if you specify the CDECL procedure option for a given procedure, then HLA does not emit the code to remove the parameters from the stack when a procedure returns. Instead, HLA leaves it up to the caller to remove those parameters. Therefore, the call above to CallProc (the one with the CDECL option) isn't completely correct. Immediately after the call the code should remove the 12 bytes of parameters it has pushed on the stack. It could accomplish this using code like the following:

```

mov(k, eax);
add(4, eax);

```

```

push(eax);
push(j);
push(i);
call CallProc;
add(12, esp); // Remove parameters from the stack.

```

Many C compilers don't emit an ADD instruction after each call that has parameters. If there are two or more procedures in a row, and the previous contents of the stack is not needed between the calls, the C compilers may perform a slight optimization and remove the parameter only after the last call in the sequence. E.g., consider the following:

```

pushd(5);
call Proc1Parm

push(i);
push(eax);
call Proc2Parms;

add(12, esp); // Remove parameters for Proc1Parm and Proc2Parms.

```

The STDCALL procedure option is a combination of the CDECL and Pascal calling conventions. STDCALL passes its parameters in the right-to-left order (like C/C++) but requires the procedure to remove the parameters from the stack (like Pascal). This is the calling convention that Windows uses for most API functions. It's also possible to pass parameters in the left-to-right order (like Pascal) and require the caller to remove the parameters from the stack (like C), but HLA does not provide a specific syntax for this. If you want to use this calling convention, you will need to manually build and destroy the activation record, e.g.,

```

procedure CallerPopsParms(i:int32; j:uns32; r:real64); nodisplay; noframe;
begin CallerPopsParms;

 push(ebp);
 mov(esp, ebp);
 .
 .
 .
 mov(ebp, esp);
 pop(ebp);
 ret(); // Don't remove any parameters from the stack.

end CallerPopsParms;

.
.
.
pushd(5);
pushd(6);
pushd((type dword r[4])); // Assume r is an eight-byte real.
pushd((type dword r));
call CallerPopsParms;
add(16, esp); // Remove 16 bytes of parameters from stack.

```

Notice how this procedure uses the Pascal calling convention (to get parameters in the left-to-right order) but manually builds and destroys the activation record so that HLA doesn't automatically remove the parameters from the stack. Although the need to operate this way is nearly non-existent, it's interesting to note that it's still possible to do this in assembly language.

### 4.3.5 Passing Parameters in the Code Stream

The chapter on Intermediate Procedures introduced the mechanism for passing parameters in the code stream with a simple example of a *Print* subroutine. The *Print* routine is a very space-efficient way to print literal string constants to the standard output. A typical call to *Print* takes the following form:

```
call Print
byte "Hello World", 0 // Strings after Print must end with a zero!
```

As you may recall, the *Print* routine pops the return address off the stack and uses this as a pointer to a zero terminated string, printing each character it finds until it encounters a zero byte. Upon finding a zero byte, the *Print* routine pushes the address of the byte following the zero back onto the stack for use as the new return address (so control returns to the instruction following the zero byte). For more information on the *Print* subroutine, see the section on Code Stream Parameters in the chapter on Intermediate Procedures.

The *Print* example demonstrates two important concepts with code stream parameters: passing simple string constants by value and passing a variable length parameter. Contrast this call to *Print* with an equivalent call to the HLA Standard Library *stdout.puts* routine:

```
stdout.puts("Hello World");
```

It may look like the call to *stdout.puts* is simpler and more efficient. However, looks can be deceiving and they certainly are in this case. The statement above actually compiles into code similar to the following:

```
push(HWString);
call stdout.puts;
.
.
.
// In the CONSTs segment:

 dword 11 // Maximum string length
 dword 11 // Current string length
HWS byte "Hello World", 0
HWString dword HWS
```

As you can see, the *stdout.puts* version is a little larger because it has three extra DWORD declarations plus an extra push instruction. (It turns out that *stdout.puts* is faster because it prints the whole string at once rather than a character at a time, but the output operation is so slow anyway that the performance difference is not significant here.) This demonstrates that if you're attempting to save space, passing parameters in the code stream can help.

Note that the *stdout.puts* procedure is more flexible than *Print*. The *Print* procedure only prints string literal constants; you cannot use it to print string variables (as *stdout.puts* can). While it is possible to print string variables with a variant of the *Print* procedure (passing the variable's address in the code stream), this still isn't as flexible as *stdout.puts* because *stdout.puts* can easily print static and local (automatic) variables whereas this variant of *Print* cannot easily do this. This is why the HLA Standard Library uses the stack to pass the string variable rather than the code stream. Still, it's instructive to look at how you would write such a version of *Print*, so we'll do that in just a few moments.

One problem with passing parameters in the code stream is that the code stream is read-only<sup>2</sup>. Therefore, any parameter you pass in the code stream must, necessarily, be a constant. While one can easily dream up some functions to whom you always pass constant values in the parameter lists, most procedures work best if you can pass different values (through variables) on each call to a procedure. Unfortunately, this is not possible when passing parameters by value to a procedure through the code stream. Fortunately, we can also pass data by reference through the code stream.

When passing reference parameters in the code stream, we must specify the address of the parameter(s) following the CALL instruction in the source file. Since we can only pass constant data (whose value is

---

2. Technically, it is possible to make the code segment writable, but we will not consider that possibility here.

known at compile time) in the code stream, this means that HLA must know the address of the objects you pass by reference as parameters when it encounters the instruction. This, in turn, means that you will usually pass the address of static objects (STATIC, READONLY, and STORAGE) variables in the code stream. In particular, HLA does not know the address of an automatic (VAR) object at compile time, so you cannot pass the address of a VAR object in the code stream<sup>3</sup>.

To pass the address of some static object in the code stream, you would typically use the DWORD directive and list the object's name in its operand field. Consider the following code that expects three parameters by reference:

Calling sequence:

```
static
 I:uns32;
 J:uns32;
 K:uns32;
 .
 .
 .
 call AddEm;
 dword I,J,K;
```

Whenever you specify the name of a STATIC object in the operand field of the DWORD directive, HLA automatically substitutes the four-byte address of that static object for the operand. Therefore, the object code for the instruction above consists of the call to the *AddEm* procedure followed by 12 bytes containing the static addresses of *I*, *J*, and *K*. Assuming that the purpose of this code is to add the values in *J* and *K* together and store the sum into *I*, the following procedure will accomplish this task:

```
procedure AddEm; nodisplay;
begin AddEm;

 push(eax); // Preserve the registers we use.
 push(ebx);
 push(ecx);
 mov([ebp+4], ebx); // Get the return address.
 mov([ebx+4], ecx); // Get J's address.
 mov([ecx], eax); // Get J's value.
 mov([ebx+8], ecx); // Get K's address.
 add([ecx], eax); // Add in K's value.
 mov([ebx], ecx); // Get I's address.
 mov(eax, [ecx]); // Store sum into I.
 add(12, ebx); // Skip over addresses in code stream.
 mov(ebx, [ebp+4]); // Save as new return address.
 pop(ecx);
 pop(ebx);
 pop(eax);

end AddEm;
```

This subroutine adds *J* and *K* together and stores the result into *I*. Note that this code uses 32 bit constant pointers to pass the addresses of *I*, *J*, and *K* to *AddEm*. Therefore, *I*, *J*, and *K* must be in a static data segment. Note at the end of this procedure how the code advances the return address beyond these three pointers in the code stream so that the procedure returns beyond the address of *K* in the code stream.

The important thing to keep in mind when passing parameters in the code stream is that you must always advance the procedure's return address beyond any such parameters before returning from that procedure. If you fail to do this, the procedure will return into the parameter list and attempt to execute that data as machine instructions. The result is almost always catastrophic. Since HLA does not provide a high level syntax that automatically passes parameters in the code stream for you, you have to manually pass these

---

3. You may, however, pass the offset of that variable in some activation record. However, implementing the code to access such an object is an exercise that is left to the reader.

parameters in your code. This means that you need to be extra careful. For even if you've written your procedure correctly, it's quite possible to create a problem if the calls aren't correct. For example, if you leave off a parameter in the call to `AddEm` or insert an extra parameter on some particular call, the code that adjusts the return address will not be correct and the program will probably not function correctly. So take care when using this parameter passing mechanism.

### 4.3.6 Passing Parameters via a Parameter Block

Another way to pass parameters in memory is through a *parameter block*. A parameter block is a set of contiguous memory locations containing the parameters. Generally, you would use a record object to hold the parameters. To access such parameters, you would pass the subroutine a pointer to the parameter block. Consider the subroutine from the previous section that adds *J* and *K* together, storing the result in *I*; the code that passes these parameters through a parameter block might be

Calling sequence:

```

type
 AddEmParmBlock:
 record
 i: pointer to uns32;
 j: uns32;
 k: uns32;
 endrecord;

static
 a: uns32;
 ParmBlock: AddEmParmBlock := AddEmParmBlock: [&a, 2, 3];

procedure AddEm(var pb:AddEmParmBlock in esi); nodisplay;
begin AddEm;

 push(eax);
 push(ebx);
 mov((type AddEmParmBlock [esi]).j, eax);
 add((type AddEmParmBlock [esi]).k, eax);
 mov((type AddEmParmBlock [esi]).i, ebx);
 mov(eax, [ebx]);
 pop(ebx);
 pop(eax);

end AddEm;

```

This form of parameter passing works well when passing several static variables by reference or constant parameters by value, because you can directly initialize the parameter block as was done above.

Note that the pointer to the parameter block is itself a parameter. The examples in this section pass this pointer in a register. However, you can pass this pointer anywhere you would pass any other reference parameter – in registers, in global variables, on the stack, in the code stream, even in another parameter block! Such variations on the theme, however, will be left to your own imagination. As with any parameter, the best place to pass a pointer to a parameter block is in the registers. This text will generally adopt that policy.

Parameter blocks are mainly useful when you make several different calls to a procedure and in each instance you pass constant values. Parameter blocks are less useful when you pass variables to procedures, because you will need to copy the current variable's value into the parameter block before the call (this is roughly equivalent to passing the parameter in a global variable. However, if each particular call to a procedure has a fixed parameter list, and that parameter list contains constants (static addresses or constant values), then using parameter blocks can be a useful mechanism.

Also note that class fields are also an excellent place to pass parameters. Because class fields are very similar to records, we'll not create a separate category for these, but lump class fields together with parameter blocks.

---

## 4.4 How You Can Pass Parameters

There are six major mechanisms for passing data to and from a procedure, they are

- pass by value,
- pass by reference,
- pass by value/returned,
- pass by result,
- pass by name, and
- pass by lazy evaluation

Actually, it's quite easy to invent some additional ways to pass parameters beyond these six ways, but this text will concentrate on these particular mechanisms and leave other approaches to the reader to discover.

Since this text has already spent considerable time discussing pass by value and pass by reference, the following subsections will concentrate mainly on the last four ways to pass parameters.

---

### 4.4.1 Pass by Value-Result

Pass by value-result (also known as value-returned) combines features from both the pass by value and pass by reference mechanisms. You pass a value-result parameter by address, just like pass by reference parameters. However, upon entry, the procedure makes a temporary copy of this parameter and uses the copy while the procedure is executing. When the procedure finishes, it copies the temporary copy back to the original parameter.

This copy-in and copy-out process takes time and requires extra memory (for the copy of the data as well as the code that copies the data). Therefore, for simple parameter use pass by value-result may be less efficient than pass by reference. Of course, if the program semantics require pass by value-result, you have no choice but to pay the price for its use.

In some instances, pass by value-returned is more efficient than pass by reference. If a procedure only references the parameter a couple of times, copying the parameter's data is expensive. On the other hand, if the procedure uses this parameter often, the procedure amortizes the fixed cost of copying the data over many inexpensive accesses to the local copy (versus expensive indirect reference using the pointer to access the data).

HLA supports the use of value/result parameters via the VALRES keyword. If you prefix a parameter declaration with VALRES, HLA will assume you want to pass the parameter by value/result. Whenever you call the procedure, HLA treats the parameter like a pass by reference parameter and generates code to pass the address of the actual parameter to the procedure. Within the procedure, HLA emits code to copy the data referenced by this point to a local copy of the variable<sup>4</sup>. In the body of the procedure, you access the parameter as though it were a pass by value parameter. Finally, before the procedure returns, HLA emits code to copy the local data back to the actual parameter. Here's the syntax for a typical procedure that uses pass by value result:

```
procedure AddandZero(valres p1:uns32; valres p2:uns32); nodisplay;
begin AddandZero;

 mov(p2, eax);
 add(eax, p1);
 mov(0, p2);
```

---

4. This statement assumes that you're not using the NOFRAME procedure option.

```
end AddandZero;
```

A typical call to this function might look like the following:

```
AddandZero(j, k);
```

This call computes "j := j+k;" and "k := 0;" simultaneously.

Note that HLA automatically emits the code within the *AddandZero* procedure to copy the data from *p1* and *p2*'s actual parameters into the local variables associated with these parameters. Likewise, HLA emits the code, just before returning, to copy the local parameter data back to the actual parameter. HLA also allocates storage for the local copies of these parameters within the activation record. Indeed, the names *p1* and *p2* in this example are actually associated with these local variables, not the formal parameters themselves. Here's some code similar to that which HLA emits for the *AddandZero* procedure above:

```
procedure AddandZero(var p1_ref: uns32; var p2_ref:uns32); nodisplay; noframe;
var
 p1: uns32;
 p2: uns32;
begin AddandZero;

 push(ebp);
 sub(_vars_, esp); // Note: _vars_ is "8" in this example.
 push(eax);
 mov(p1_ref, eax);
 mov([eax], eax);
 mov(eax, p1);
 mov(p2_ref, eax);
 mov([eax], eax);
 mov(eax, p2);
 pop(eax);

 // Actual procedure body begins here:

 mov(p2, eax);
 add(eax, p1);
 mov(0, p2);

 // Clean up code associated with the procedure's return:

 push(eax);
 push(ebx);
 mov(p1_ref, ebx);
 mov(p1, eax);
 mov(eax, [ebx]);
 mov(p2_ref, ebx);
 mov(p2, eax);
 mov(eax, [ebx]);
 pop(ebx);
 pop(eax);
 ret(8);

end AddandZero;
```

As you can see from this example, pass by value/result has considerable overhead associated with it in order to copy the data into and out of the procedure's activation record. If efficiency is a concern to you, you should avoid using pass by value/result for parameters you don't reference numerous times within the procedure's body.

If you pass an array, record, or other large data structure via pass by value/result, HLA will emit code that uses a `MOVS` instruction to copy the data into and out of the procedure's activation record. Although

this copy operation will be slow for larger objects, you needn't worry about the compiler emitting a ton of individual MOV instructions to copy a large data structure via value/result.

If you specify the NOFRAME option when you actually declare a procedure with value/result parameters, HLA does not emit the code to automatically allocate the local storage and copy the actual parameter data into the local storage. Furthermore, since there is no local storage, the formal parameter names refer to the address passed as a parameter rather than to the local storage. For all intents and purposes, specifying NOFRAME tells HLA to treat the pass by value/result parameters as pass by reference. The calling code passes in the address and it is your responsibility to dereference that address and copy the local data into and out of the procedure. Therefore, it's quite unusual to see an HLA procedure use pass by value/result parameters along with the NOFRAME option (since using pass by reference achieves the same thing).

This is not to say that you shouldn't use NOFRAME when you want pass by value/result semantics. The code that HLA generates to copy parameters into and out of a procedure isn't always the most efficient because it always preserves all registers. By using NOFRAME with pass by value/result parameters, you can supply slightly better code in some instances; however, you could also achieve the same effect (with identical code) by using pass by reference.

When calling a procedure with pass by value/result parameters, HLA pushes the address of the actual parameter on the stack in a manner identical to that for pass by reference parameters. Indeed, when looking at the code HLA generates for a pass by reference or pass by value/result parameter, you will not be able to tell the difference. This means that if you manually want to pass a parameter by value/result to a procedure, you use the same code you would use for a pass by reference parameter; specifically, you would compute the address of the object and push that address onto the stack. Here's code equivalent to what HLA generates for the previous call to *AddandZero*<sup>5</sup>:

```
// AddandZero(k, j);

 lea(eax, k);
 push(eax);
 lea(eax, j);
 push(eax);
 call AddandZero;
```

Obviously, pass by value/result will modify the value of the actual parameter. Since pass by reference also modifies the value of the actual parameter to a procedure, you may be wondering if there are any semantic differences between these two parameter passing mechanisms. The answer is yes – in some special cases their behavior is different. Consider the following code that is similar to the Pascal code appearing in the chapter on intermediate procedures:

```
procedure uhoh(var i:int32; var j:int32); nodisplay;
begin uhoh;

 mov(i, ebx);
 mov(4, (type int32 [ebx]));
 mov(j, ecx);
 mov([ebx], eax);
 add([ecx], eax);
 stdout.put("i+j=", (type int32 eax), nl);

end uhoh;
.
.
.
var
 k: int32;
.
.
.
 mov(5, k);
```

---

5. Actually, this code is a little more efficient since it doesn't worry about preserving EAX's value.

```
uhoh(k, k);
.
.
.
```

As you may recall from the chapter on Intermediate Procedures, the call to *uhoh* above prints "8" rather than the expected value of "9". The reason is because *i* and *j* are aliases of one another when you call *uhoh* and pass the same variable in both parameter positions.

If we switch the parameter passing mechanism above to value/result, then *i* and *j* are not exactly aliases of one another so this procedure exhibits different semantics when you pass the same variable in both parameter positions. Consider the following implementation:

```
procedure uhoh(valres i:int32; valres j:int32); nodisplay;
begin uhoh;

 mov(4, i);
 mov(i, eax);
 add(j, eax);
 stdout.put("i+j=", (type int32 eax), nl);

end uhoh;
.
.
.
var
 k: int32;
.
.
.
 mov(5, k);
 uhoh(k, k);
.
.
.
```

In this particular implementation the output value is "9" as you would intuitively expect. The reason this version produces a different result is because *i* and *j* are not aliases of one another within the procedure. These names refer to separate local objects that the procedure happens to initialize with the value of the same variable upon initial entry. However, when the body of the procedure executes, *i* and *j* are distinct so storing four into *i* does not overwrite the value in *j*. Hence, when this code adds the values of *i* and *j* together, *j* still contains the value 5, so this procedure displays the value nine.

Note that there is a question of what value *k* will have when *uhoh* returns to its caller. Since pass by value/result stores the value of the formal parameter back into the actual parameter, the value of *k* could either be four or five (since *k* is the formal parameter associated with both *i* and *j*). Obviously, *k* may only contain one or the other of these values. HLA does not make any guarantees about which value *k* will hold other than it will be one or the other of these two possible values. Obviously, you can figure this out by writing a simple program, but keep in mind that future versions of HLA may not respect the current ordering; worse, it's quite possible that within the same version of HLA, for some calls it could store *i*'s value into *k* and for other calls it could store *j*'s value into *k* (not likely, but the HLA language allows this). The order by which HLA copies value/result parameters into and out of a procedure is completely implementation dependent. If you need to guarantee the copying order, then you should use the NOFRAME option (or use pass by reference) and copy the data yourself.

Of course, this ambiguity exists only if you pass the same actual parameter in two value/result parameter positions on the same call. If you pass different actual variables, this problem does not exist. Since it is very rare for a program to pass the same variable in two parameter slots, particularly two pass by value/result slots, it is unlikely you will ever encounter this problem.

HLA implements pass by value/result via pass by reference and copying. It is also possible to implement pass by value/result using pass by value and copying. When using the pass by reference mechanism to

support pass by value/result, it is the procedure's responsibility to copy the data from the actual parameter into the local copy; when using the pass by value form, it is the caller's responsibility to copy the data to and from the local object. Consider the following implementation that (manually) copies the data on the call and return from the procedure:

```

procedure DisplayAndClear(val i:int32); nodisplay; noframe;
begin DisplayAndClear;

 push(ebp); // NOFRAME, so we have to do this manually.
 mov(esp, ebp);

 stdout.put("I = ", i, nl);
 mov(0, i);

 pop(ebp);
 ret(); // Note that we don't clean up the parameters.

end DisplayAndClear;
.
.
.
push(m);
call DisplayAndClear;
pop(m);
stdout.put("m = ", m, nl);
.
.
.

```

The sequence above displays "I = 5" and "m = 0" when this code sequence runs. Note how this code passes the value in on the stack and then returns the result back on the stack (and the caller copies the data back to the actual parameter).

In the example above, the procedure used the NOFRAME option in order to prevent HLA from automatically removing the parameter data from the stack. Another way to achieve this effect is to use the CDECL procedure option (that tells HLA to use the C calling convention, which also leaves the parameters on the stack for the caller to clean up). Using this option, we could rewrite the code sequence above as follows:

```

procedure DisplayAndClear(val i:int32); nodisplay; cdecl;
begin DisplayAndClear;

 stdout.put("I = ", i, nl);
 mov(0, i);

end DisplayAndClear;
.
.
.
DisplayAndClear(m);
pop(m);
stdout.put("m = ", m, nl);
.
.
.

```

The advantage to this scheme is that HLA automatically emits the procedure's entry and exit sequences so you don't have to manually supply this information. Keep in mind, however, that the CDECL calling sequence pushes the parameters on the stack in the reverse order of the standard HLA calling sequence. Generally, this won't make a difference to your code unless you explicitly assume the order of parameters in memory. Obviously, this won't make a difference at all when you've only got a single parameter.

The examples in this section have all assumed that we've passed the value/result parameters on the stack. Indeed, HLA only supports this location if you want to use a high level calling syntax for value/result parameters. On the other hand, if you're willing to manually pass the parameters in and out of a procedure, then you may pass the value/result parameters in other locations including the registers, in the code stream, in global variables, or in parameter blocks.

Passing parameters by value/result in registers is probably the easiest way to go. All you've got to do is load an appropriate register with the desired value before calling the procedure and then leave the return value in that register upon return. When the procedure returns, it can use the register's value however it sees fit. If you prefer to pass the value/result parameter by reference rather than by value, you can always pass in the address of the actual object in a 32-bit register and do the necessary copying within the procedure's body.

Of course, there are a couple of drawbacks to passing value/result parameters in the registers; first, the registers can only hold small, scalar, objects (though you can pass the address of a large object in a register). Second, there are a limited number of registers. But if you can live these drawbacks, registers provide a very efficient place to pass value/result parameters.

It is possible to pass certain value/result parameters in the code stream. However, you'll always pass such parameters by their address (rather than by value) to the procedure since the code stream is in read-only memory (and you can't write a value back to the code stream). When passing the actual parameters via value/result, you must pass in the address of the object in the code stream, so the objects must be static variables so HLA can compute their addresses at compile-time. The actual implementation of value/result parameters in the code stream is left as an exercise for the end of this volume.

There is one advantage to value/result parameters in the HLA/assembly programming environment. You get semantics very similar to pass by reference without having to worry about constant dereferencing of the parameter throughout the code. That is, you get the ability to modify the actual parameter you pass into a procedure, yet within the procedure you get to access the parameter like a local variable or value parameter. This simplification makes it easier to write code and can be a real time saver if you're willing to (sometimes) trade off a minor amount of performance for easier to read-and-write code.

## 4.4.2 Pass by Result

Pass by result is almost identical to pass by value-result. You pass in a pointer to the desired object and the procedure uses a local copy of the variable and then stores the result through the pointer when returning. The only difference between pass by value-result and pass by result is that when passing parameters by result you do not copy the data upon entering the procedure. Pass by result parameters are for returning values, not passing data to the procedure. Therefore, pass by result is slightly more efficient than pass by value-result since you save the cost of copying the data into the local variable.

HLA supports pass by result parameters using the `RESULT` keyword prior to a formal parameter declaration. Consider the following procedure declaration:

```
procedure HasResParm(result r:uns32); nodisplay;
begin HasResParm;

 mov(5, r);

end HasResParm;
```

Like pass by value/result, modification of the pass by result parameter results (ultimately) in the modification of the actual parameter. The difference between the two parameter passing mechanisms is that pass by result parameters do not have a known initial value upon entry into the code (i.e., the HLA compiler does not emit code to copy any data into the parameter upon entry to the procedure).

Also like pass by value/result, you may pass result parameters in locations other than on the stack. HLA does not support anything other than the stack when using the high level calling syntax, but you may certainly pass result parameters manually in registers, in the code stream, in global variables, and in parameter blocks.

### 4.4.3 Pass by Name

Some high level languages, such as ALGOL-68 and Panacea, support pass by name parameters. Pass by name produces semantics that are similar (though not identical) to textual substitution (e.g., like macro parameters). However, implementing pass by name using textual substitution in a compiled language (like ALGOL-68) is very difficult and inefficient. Basically, you would have to recompile a function every time you call it. So compiled languages that support pass by name parameters generally use a different technique to pass those parameters. Consider the following Panacea procedure (Panacea's syntax is sufficiently similar to HLA's that you should be able to figure out what's going on):

```
PassByName: procedure(name item:integer; var index:integer);
begin PassByName;

 foreach index in 0..10 do

 item := 0;

 endfor;

end PassByName;
```

Assume you call this routine with the statement "PassByName(A[i], i);" where A is an array of integers having (at least) the elements  $A[0]..A[10]$ . Were you to substitute (textually) the pass by name parameter *item* you would obtain the following code:

```
begin PassByName;

 foreach index in 0..10 do

 A[I] := 0; (* Note that index and I are aliases *)

 endfor;

end PassByName;
```

This code zeros out elements 0..10 of array A.

High level languages like ALGOL-68 and Panacea compile pass by name parameters into *functions* that return the address of a given parameter. So in one respect, pass by name parameters are similar to pass by reference parameters insofar as you pass the address of an object. The major difference is that with pass by reference you compute the address of an object before calling a subroutine; with pass by name the subroutine itself calls some function to compute the address of the parameter whenever the function references that parameter.

So what difference does this make? Well, reconsider the code above. Had you passed  $A[I]$  by reference rather than by name, the calling code would compute the address of  $A[I]$  just before the call and passed in this address. Inside the *PassByName* procedure the variable *item* would have always referred to a single address, not an address that changes along with *I*. With pass by name parameters, *item* is really a function that computes the address of the parameter into which the procedure stores the value zero. Such a function might look like the following:

```
procedure ItemThunk; nodisplay; noframe;
begin ItemThunk;

 mov(i, eax);
 lea(eax, A[$eax*4$]);
 ret();

end ItemThunk;
```

The compiled code inside the *PassByName* procedure might look something like the following:

```
; item := 0;

call ItemThunk;
mov(0, (type dword [eax]));
```

*Thunk* is the historical term for these functions that compute the address of a pass by name parameter. It is worth noting that most HLLs supporting pass by name parameters do not call thunks directly (like the call above). Generally, the caller passes the address of a thunk and the subroutine calls the thunk indirectly. This allows the same sequence of instructions to call several different thunks (corresponding to different calls to the subroutine). In HLA, of course, we will use HLA thunk variables for this purpose. Indeed, when you declare a procedure with a pass by name parameter, HLA associates the thunk type with that parameter. The only difference between a parameter whose type is thunk and a pass by name parameter is that HLA requires a thunk constant for the pass by name parameter (whereas a parameter whose type is thunk can be either a thunk constant or a thunk variable). Here's a typical procedure prototype using a pass by name variable (note the use of the NAME keyword to specify pass by name):

```
procedure HasNameParm(name nameVar:uns32);
```

Since *nameVar* is a thunk, you call this object rather than treat it as data or as a pointer. Although HLA doesn't enforce this, the convention is that a pass by name parameter returns the address of the object when you invoke the thunk. The procedure then dereferences this address to access the actual data. The following code is the HLA equivalent of the Panacea procedure given earlier:

```
procedure passByName(name ary:int32; var ip:int32);
nodisplay;
const i:text := "(type int32 [ebx])";
begin passByName;

 mov(ip, ebx);
 mov(0, i);
 while(i <= 10) do

 ary(); // Get address of "ary[i]" into eax.
 mov(i, ecx);
 mov(ecx, (type int32 [eax]));
 inc(i);

 endwhile;

end passByName;
```

Notice how this code assumes that the *ary* thunk returns a pointer in the EAX register.

Whenever you call a procedure with a pass by name parameter, you must supply a thunk that computes some address and returns that address in the EAX register (or wherever you expect the address to be sitting upon return from the thunk; convention dictates the EAX register). Here is some code that demonstrates how to pass a thunk constant for a pass by name parameter to the procedure above:

```
var
 index:uns32;
 array: uns32[11]; // Has elements 0..10.
 .
 .
 .
 passByName
 (
 thunk
 #{
 push(ebx);
 mov(index, ebx);
 lea(eax, array[ebx*4]);
 pop(ebx);
```

```

 }#,
 index
);

```

The "think #{...}#" sequence specifies a literal think that HLA compiles into the code stream. For the environment pointer, HLA pushes the current value for EBP, for the procedure pointer, HLA passes in the address of the code in the " #{...}#" braces. Whenever the *passByName* procedure actually calls this think, the run-time system restores EBP with the pointer to the current procedure's activation record and executes the code in these braces. If you look carefully at the code above, you'll see that this code loads the EAX register with the address of the *array[index]* variable. Therefore, the *passByName* procedure will store the next value into this element of *array*.

Pass by name parameter passing has garnered a bad name because it is a notoriously slow mechanism. Instead of directly or indirectly accessing an object, you have to first make a procedure call (which is expensive compared to an access) and then dereference a pointer. However, because pass by name parameters defer their evaluation until you actually access an object, pass by name effectively gives you a deferred pass by reference parameter passing mechanism (deferring the calculation of the address of the parameter until you actually access that parameter). This can be very important in certain situations. As you've seen in the chapter on thinks, the proper use of deferred evaluation can actually improve program performance. Most of the complaints about pass by name are because someone misused this parameter passing mechanism when some other mechanism would have been more appropriate. There are times, however, when pass by name is the best approach.

It is possible to transmit pass by name parameters in some location other than the stack. However, we don't call them pass by name parameters anymore; they're just thinks (that happen to return an address in EAX) at that point. So if you wish to pass a pass by name parameter in some other location than the stack, simply create a think object and pass your parameter as the think.

#### 4.4.4 Pass by Lazy-Evaluation

Pass by name is similar to pass by reference insofar as the procedure accesses the parameter using the address of the parameter. The primary difference between the two is that a caller directly passes the address on the stack when passing by reference, it passes the address of a function that computes the parameter's address when passing a parameter by name. The pass by lazy evaluation mechanism shares this same relationship with pass by value parameters – the caller passes the address of a function that computes the parameter's value if the first access to that parameter is a read operation.

Pass by lazy evaluation is a useful parameter passing technique if the cost of computing the parameter value is very high and the procedure may not use the value. Consider the following HLA procedure header:

```

procedure PassByEval(lazy a:int32; lazy b:int32; lazy c:int32);

```

Consider the *PassByEval* procedure above. Suppose it takes several minutes to compute the values for the *a*, *b*, and *c* parameters (these could be, for example, three different possible paths in a Chess game). Perhaps the *PassByEval* procedure only uses the value of one of these parameters. Without pass by lazy evaluation, the calling code would have to spend the time to compute all three parameters even though the procedure will only use one of the values. With pass by lazy evaluation, however, the procedure will only spend the time computing the value of the one parameter it needs. Lazy evaluation is a common technique artificial intelligence (AI) and operating systems use to improve performance since it provides deferred parameter evaluation capability.

HLA's implementation of pass by lazy evaluation parameters is (currently) identical to the implementation of pass by name parameters. Specifically, pass by lazy evaluation parameters are thinks that you must call within the body of the procedure and that you must write whenever you call the procedure. The difference between pass by name and pass by lazy evaluation is the convention surrounding what the thinks return. By convention, pass by name parameters return a pointer in the EAX register. Pass by lazy evaluation parameters, on the other hand, return a value, not an address. Where the pass by lazy evaluation think returns its value depends upon the size of the value. However, by convention most programmers return eight, 16-, 32-, and 64-bit values in the AL, AX, EAX, and EDX:EAX registers, respectively. The excep-

tions are floating point values (the convention is to use the ST0 register) and MMX values (the convention is to use the MM0 register for MMX values).

Like pass by name, you only pass by lazy evaluation parameters on the stack. Use `thunks` if you want to pass lazy evaluation parameters in a different location.

Of course, nothing is stopping you from returning a value via a pass by name `thunk` or an address via a pass by lazy evaluation `thunk`, but to do so is exceeding poor programming style. Use these parameter pass mechanisms as they were intended.

## 4.5 Passing Parameters as Parameters to Another Procedure

When a procedure passes one of its own parameters as a parameter to another procedure, certain problems develop that do not exist when passing variables as parameters. Indeed, in some (rare) cases it is not logically possible to pass some parameter types to some other procedure. This section deals with the problems of passing one procedure's parameters to another procedure.

Pass by value parameters are essentially no different than local variables. All the techniques in the previous sections apply to pass by value parameters. The following sections deal with the cases where the calling procedure is passing a parameter passed to it by reference, value-result, result, name, and lazy evaluation.

### 4.5.1 Passing Reference Parameters to Other Procedures

Passing a reference parameter though to another procedure is where the complexity begins. Consider the following HLA procedure skeleton:

```
procedure ToProc(???? parm:dword);
begin ToProc;
.
.
.
end ToProc;

procedure HasRef(var refparm:dword);

begin HasRef;
.
.
.
 ToProc(refParm);
.
.
.
end HasRef;
```

The “????” in the *ToProc* parameter list indicates that we will fill in the appropriate parameter passing mechanism as the discussion warrants.

If *ToProc* expects a pass by value parameter (i.e., `????` is just an empty string), then *HasRef* needs to fetch the value of the *refparm* parameter and pass this value to *ToProc*. The following code accomplishes this<sup>6</sup>:

```
mov(refparm, ebx); // Fetch address of actual refparm value.
pushd([ebx]); // Pass value of refparm variable on the stack.
call ToProc;
```

6. The examples in this section all assume the use of a display. If you are using static links, be sure to adjust all the offsets and the code to allow for the static link that the caller must push immediately before a call.

To pass a reference parameter by reference, value-result, or result parameter is easy – just copy the caller's parameter as-is onto the stack. That is, if the *parm* parameter in *ToProc* above is a reference parameter, a value-result parameter, or a result parameter, you would use the following calling sequence:

```
push(refparm);
call ToProc;
```

We get away with pass the value of *refparm* on the stack because *refparm* currently contains the address of the actual object that *ToProc* will reference. Therefore, we need only copy this value (which is an address).

To pass a reference parameter by name is fairly easy. Just write a thunk that grabs the reference parameter's address and returns this value. In the example above, the call to *ToProc* might look like the following:

```
ToProc
(
 thunk
 #{
 mov(refparm, eax);
 }#
);
```

To pass a reference parameter by lazy evaluation is very similar to passing it by name. The only difference (in *ToProc*'s calling sequence) is that the thunk must return the value of the variable rather than its address. You can easily accomplish this with the following thunk:

```
ToProc
(
 thunk
 #{
 mov(refparm, eax); // Get the address of the actual parameter
 mov([eax], eax); // Get the value of the actual parameter.
 }#
);
```

Note that HLA's high level procedure calling syntax automatically handles passing reference parameters as value, reference, value/result, and result parameters. That is, when using the high level procedure call syntax and *ToProc*'s parameter is pass by value, pass by reference, pass by value/result, or pass by result, you'd use the following syntax to call *ToProc*:

```
ToProc(refparm);
```

HLA will automatically figure out what data it needs to push on the stack for this procedure call.

Unfortunately, HLA does not automatically handle the case where you pass a reference parameter to a procedure via pass by name or pass by lazy evaluation. You must explicitly write this thunk yourself.

## 4.5.2 Passing Value-Result and Result Parameters as Parameters

If you have a pass by value/result or pass by result parameter that you want to pass to another procedure, and you use the standard HLA mechanism for pass by value/result or pass by result parameters, passing those parameters on to another procedure is trivial because HLA creates local variables using the parameters' names. Therefore, there is no difference between a local variable and a pass by value/result or pass by result parameter in this particular case. Once HLA has made a local copy of the value-result or result parameter or allocates storage for it, you can treat that variable just like a value parameter or a local variable with respect to passing it on to other procedures. In particular, if you're using the HLA high level calling syntax in your code, HLA will automatically pass that procedure by value, reference, value/result, or by result to another procedure. If you're passing the parameter by name or by lazy evaluation to another procedure, you must manually write the thunk that computes the address of the variable (pass by name) or obtains the value of the variable (pass by lazy evaluation) prior to calling the other procedure.

Of course, it doesn't make sense to use the value of a result parameter until you've stored a value into that parameter's local storage. Therefore, take care when passing result parameters to other procedures that you've initialized a result parameter before using its value.

If you're manually passing pass by value/result or pass by result parameters to a procedure and then you need to pass those parameters on to another procedure, HLA cannot automatically generate the appropriate code to pass those parameters on. This is especially true if you've got the parameter sitting in a register or in some location other than a local variable. Likewise, if the procedure you're calling expects you to pass a value/result or result parameter using some mechanism other than passing the address on the stack, you will also have manually write the code to pass the parameter on through. Since such situations are specific to a given situation, the only advice this text can offer is to suggest that you carefully think through what you're doing.

### 4.5.3 Passing Name Parameters to Other Procedures

Since a pass by name parameter's thunk returns the address of a parameter, passing a name parameter to another procedure is very similar to passing a reference parameter to another procedure. The primary differences occur when passing the parameter on as a name parameter.

Unfortunately, HLA's high level calling syntax doesn't automatically deal with pass by name parameters. The reason is because HLA doesn't assume that thunks return an address in the EAX register (this is a convention, not a requirement). A programmer who writes the thunk could return the address somewhere else, or could even create a thunk that doesn't return an address at all! Therefore, it is up to you to handle passing pass by name parameters to other procedures.

When passing a name parameter as a value parameter to another procedure, you first call the thunk, dereference the address the thunk returns, and then pass the value to the new procedure. The following code demonstrates such a call when the thunk returns the variable's address in EAX:

```
CallThunk(); // Call the thunk which returns an address in EAX.
pushd([eax]); // Push the value of the object as a parameter.
call ToProc; // Call the procedure that expects a value parameter.
.
.
.
```

Passing a name parameter to another procedure by reference is very easy. All you have to do is push the address the thunk returns onto the stack. The following code, that is very similar to the code above, accomplishes this:

```
CallThunk(); // Call the thunk which returns an address in EAX.
push(eax); // Push the address of the object as a parameter.
call ToProc; // Call the procedure that expects a value parameter.
.
.
.
```

Passing a name parameter to another procedure as a pass by name parameter is very easy; all you need to do is pass the thunk on to the new procedure. The following code accomplishes this:

```
push((type dword CallThunk));
push((type dword CallThunk[4]));
call ToProc;
```

To pass a name parameter to another procedure by lazy evaluation, you need to create a thunk for the lazy-evaluation parameter that calls the pass by name parameter's thunk, dereferences the pointer, and then returns this value. The implementation is left as a programming project.

## 4.5.4 Passing Lazy Evaluation Parameters as Parameters

Lazy evaluation are very similar to name parameters except they typically return a value in EAX (or some other register) rather than an address. This means that you may only pass lazy evaluation parameters by value or by lazy evaluation to another procedure (since they don't have an address associated with them).

## 4.5.5 Parameter Passing Summary

The following table describes how to pass parameters from one procedure as parameters to another procedure. The rows specify the "input" parameter passing mechanism (how the parameter was passed into the current procedure) and the rows specify the "output" parameter passing mechanism (how the procedure passing the parameter on to another procedure as a parameter).

**Table 1: Passing Parameters as Parameters to Another Procedure**

|              | Pass as Value                                                                                | Pass as Reference                                               | Pass as Value-Result                                            | Pass as Result                                                  | Pass as Name                                                                             | Pass as Lazy Evaluation                                                                                                              |
|--------------|----------------------------------------------------------------------------------------------|-----------------------------------------------------------------|-----------------------------------------------------------------|-----------------------------------------------------------------|------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------|
| Value        | Pass the value                                                                               | Pass address of the value parameter                             | Pass address of the value parameter                             | Pass address of the value parameter                             | Create a thunk that returns the address of the value parameter                           | Create a thunk that returns the value                                                                                                |
| Reference    | Dereference parameter and pass the value it points at                                        | Pass the address (value of the reference parameter)             | Pass the address (value of the reference parameter)             | Pass the address (value of the reference parameter)             | Create a thunk that passes the address (value of the reference parameter)                | Create a thunk that dereferences the reference parameter and returns its value                                                       |
| Value-Result | Pass the local value as the value parameter                                                  | Pass the address of the local value as the parameter            | Pass the address of the local value as the parameter            | Pass the address of the local value as the parameter            | Create a thunk that returns the address of the local value of the value-result parameter | Create a thunk that returns the value in the local value of the value-result parameter                                               |
| Result       | Pass the local value as the value parameter                                                  | Pass the address of the local value as the parameter            | Pass the address of the local value as the parameter            | Pass the address of the local value as the parameter            | Create a thunk that returns the address of the local value of the result parameter       | Create a thunk that returns the value in the local value of the result parameter                                                     |
| Name         | Call the thunk, dereference the pointer, and pass the value at the address the thunk returns | Call the thunk and pass the address it returns as the parameter | Call the thunk and pass the address it returns as the parameter | Call the thunk and pass the address it returns as the parameter | Pass the address of the thunk and any other values associated with the name parameter    | Write a thunk that calls the name parameter's thunk, dereferences the address it returns, and then returns the value at that address |

**Table 1: Passing Parameters as Parameters to Another Procedure**

|                 | Pass as Value                                                                                                       | Pass as Reference                                                                 | Pass as Value-Result                                                              | Pass as Result                                                                    | Pass as Name                                                                      | Pass as Lazy Evaluation                                                                                       |
|-----------------|---------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------|
| Lazy Evaluation | If necessary, call the thunk to obtain the Lazy Eval parameter's value. Pass the local value as the value parameter | Not possible. Lazy Eval parameters return a value which does not have an address. | Not possible. Lazy Eval parameters return a value which does not have an address. | Not possible. Lazy Eval parameters return a value which does not have an address. | Not possible. Lazy Eval parameters return a value which does not have an address. | Create a thunk that calls the caller's Lazy Eval parameter. This new thunk returns that result as its result. |

---

## 4.6 Variable Parameter Lists

On occasion you may need the ability to pass a varying number of parameters to a given procedure. The *stdout.put* routine in the HLA Standard Library provides a good example of where having a variable number of parameters is useful. There are two ways to accomplish this: (1) Fake it and use a macro rather than a procedure (this is what the HLA Standard Library does, for example, with the *stdout.put* invocation – *stdout.put* is a macro not a procedure), and (2) Pass in some information to the procedure that describes how many parameters in must process and where it can find those parameters. We'll take a look at both of these mechanisms in this section.

HLA's macro facility allows a varying number of parameters by specifying an empty array parameter as the last formal parameter in the macro list, e.g.,

```
macro VariableNumOfParms(a, b, c[]);
 .
 .
 .
endmacro;
```

Whenever HLA processes a macro declaration like the one above, it associates the first two actual parameters with the formal parameters *a* and *b*; any remaining actual parameters becomes strings in the constant string array *c*. By using the @ELEMENTS compile-time function, you can determine how many additional parameters appear in the parameter list (which can be zero or more).

Of course, a macro is not a procedure. So the fact that we have a list of text constants and a string array that represents our actual parameter list does not satisfy the requirements for a varying parameter list at run-time. However, we can write some compile-time code that parses the parameter list and calls an appropriate set of procedures to handle each and every parameter passed to the macro. For example, the *stdout.put* macro splits up the parameter list and calls a sequence of routines (like *stdout.puts* and *stdout.puti32*) to handle each parameter individually.

Breaking up a macro's variable parameter list into a sequence of procedure calls with only one parameter per call may not solve a need you have for varying parameter lists. That being the case, it may still be possible to use macros to implement varying parameters for a procedure. If the number of parameters is within some range, then you can use the function overloading trick discussed in the chapter on macros to call one of several different procedures, each with a different number of parameters. Please see the chapter on macros for additional details.

Although macros provide a convenient way to implement a varying parameter list, they do suffer from some limitations that make them unsuitable for all applications. In particular, if you need to call a single procedure and pass it an indeterminate number of parameters (no limits), then the tricks with macros employed above won't work well for you. In this situation you will need to push the parameters on the stack (or pass them somewhere else) and include some information that tells the procedure how many parameters

you're passing (and, perhaps, their size). The most common way to do this is to push the parameters onto the stack and then, as the last parameter, push the parameter count (or size) onto the stack.

Most procedures that push a varying number of parameters on the stack use the C/C++ calling convention. There are two reasons for this: (1) the parameters appear in memory in a natural order (the number of parameters followed by the first parameter, followed by the second parameter, etc.), (2) the caller will need to remove the parameters from the stack since each call can have a different number of parameters and the 80x86 RET instruction can only remove a fixed (constant) number of parameter bytes.

One drawback to using the C/C++ calling convention to pass a variable number of parameters on the stack is that you must manually push the parameters and issue a CALL instruction; HLA does not provide a high-level language syntax for declaring and calling procedures with a varying number of parameters.

Consider, as an example, a simple *MaxUns32* procedure that computes the maximum of *n* uns32 values passed to it. The caller begins by pushing *n* uns32 values and then, finally, it also pushes *n*. Upon return, the caller removes the *n+1* uns32 values (including *n*) from the stack. The function, presumably, returns the maximum value in the EAX register. Here's a typical call to *MaxUns32*:

```

push(i);
push(j);
push(k);
pushd(10);

push(4); // n=4, number of parameters passed to this code.
call MaxUns32; // Compute the maximum of the above.
add(20, esp); // Remove the parameters from the stack.

```

The *MaxUns32* procedure itself must first fetch the value for *n* from a known location (in this case, it will be just above the return address on the stack). The procedure can then use this value to step through each of the other parameters found on the stack above the value for *n*. Here's some sample code that accomplishes this:

```

procedure MaxUns32; nodisplay; noframe;
const n:text := "(type uns32 [ebp+8])";
const first:text := "(type uns32 [ebp+12])";
begin MaxUns32;

 push(ebp);
 mov(esp, ebp);
 push(ebx);
 push(ecx);

 mov(n, ecx);
 if(ecx > 0) then

 lea(ebx, first);
 mov(first, eax); // Use this as the starting Max value.
 repeat

 if(eax < [ebx]) then

 mov([ebx], eax);

 endif;
 add(4, ebx);
 dec(ecx);

 until(ecx = 0);

 else

 // There were no parameter values to try, so just return zero.

```

```

 xor(eax, eax);

 endif;
 pop(ecx);
 pop(ebx);
 pop(ebp);
 ret(); // Can't remove the parameters!

end MaxUns32;

```

This code assumes that  $n$  is at location  $[ebp+8]$  (which it will be if  $n$  is the last parameter pushed onto the stack) and that  $n$  `uns32` values appear on the stack above this point. It steps through each of these values searching for the maximum, which the function returns in EAX. If  $n$  contains zero upon entry, this function simply returns zero in EAX.

Passing a single parameter count, as above, works fine if all the parameters are the same type and size. If the size and/or type of each parameter varies, you will need to pass information about each individual parameter on the stack. There are many ways to do this, a typical mechanism is to simply preface each parameter on the stack with a double word containing its size in bytes. Another solution is that employed by the *printf* function in the C standard library - pass an array of data (a string in the case of *printf*) that contains type information that the procedure can interpret at run-time to determine the type and size of the parameters. For example, the C *printf* function uses format strings like "%4d" to determine the size (and count, via the number of formatting options that appear within the string) of the parameters.

## 4.7 Function Results

Functions return a result, which is nothing more than a result parameter. In assembly language, there are very few differences between a procedure and a function. That is probably why there isn't a "function" directive. Functions and procedures are usually different in high level languages, function calls appear only in expressions, subroutine calls as statements<sup>7</sup>. Assembly language doesn't distinguish between them.

You can return function results in the same places you pass and return parameters. Typically, however, a function returns only a single value (or single data structure) as the function result. The methods and locations used to return function results is the subject of the next four sections.

### 4.7.1 Returning Function Results in a Register

Like parameters, the 80x86's registers are the best place to return function results. The *getc* routine in the HLA Standard Library is a good example of a function that returns a value in one of the CPU's registers. It reads a character from the keyboard and returns the ASCII code for that character in the AL register. By convention, most programmers return function results in the following registers:

| Use           | First                          | Last |
|---------------|--------------------------------|------|
| Bytes:        | al, ah, dl, dh, cl, ch, bl, bh |      |
| Words:        | ax, dx, cx, si, di, bx         |      |
| Double words: | eax, edx, ecx, esi, edi, ebx   |      |
| Quad words:   | edx:eax                        |      |
| Real Values:  | ST0                            |      |
| MMX Values:   | MM0                            |      |

7. "C" is an exception to this rule. C's procedures and functions are all called functions. PL/I is another exception. In PL/I, they're all called procedures.

Once again, this table represents general guidelines. If you're so inclined, you could return a double word value in (CL, DH, AL, BH). If you're returning a function result in some registers, you shouldn't save and restore those registers. Doing so would defeat the whole purpose of the function.

---

## 4.7.2 Returning Function Results on the Stack

Another good place where you can return function results is on the stack. The idea here is to push some dummy values onto the stack to create space for the function result. The function, before leaving, stores its result into this location. When the function returns to the caller, it pops everything off the stack except this function result. Many HLLs use this technique (although most HLLs on the IBM PC return function results in the registers). The following code sequences show how values can be returned on the stack:

```
procedure RtnOnStack(RtnResult: dword; parm1: uns32; parm2:uns32);
 nodisplay;
 noframe;
var
 LocalVar: uns32;
begin RtnOnStack;

 push(ebp); // The standard entry sequence
 mov(esp, ebp);
 sub(_vars_, esp);

 << code that leaves a value in RtnResult >>

 mov(ebp, esp); // Not quite standard exit sequence.
 pop(ebp);
 ret(__parms_-4); // Don't pop RtnResult off stack on return!

end RtnOnStack;
```

Calling sequence:

```
RtnOnStack(0, p1, p2); // "0" is a dummy value to reserve space.
pop(eax); // Retrieve return result from stack.
```

Although the caller pushed 12 bytes of data onto the stack, *RtnOnStack* only removes eight bytes. The first "parameter" on the stack is the function result. The function must leave this value on the stack when it returns.

---

## 4.7.3 Returning Function Results in Memory Locations

Another reasonable place to return function results is in a known memory location. You can return function values in global variables or you can return a pointer (presumably in a register or a register pair) to a parameter block. This process is virtually identical to passing parameters to a procedure or function in global variables or via a parameter block.

Returning parameters via a pointer to a parameter block is an excellent way to return large data structures as function results. If a function returns an entire array, the best way to return this array is to allocate some storage, store the data into this area, and leave it up to the calling routine to deallocate the storage. Most high level languages that allow you to return large data structures as function results use this technique.

Of course, there is very little difference between returning a function result in memory and the pass by result parameter passing mechanism. See "Pass by Result" on page 1323 for more details.

---

## 4.7.4 Returning Large Function Results

Returning small scalar values in the registers or on the stack makes a lot of sense. However, mechanism for returning function results does not scale very well to large data structures. The registers are too small to return large records or arrays and returning such data on the stack is a lot of work (not to mention that you've got to copy the data from the stack to its final resting spot upon return from the function). In this section we'll take a look at a couple of methods for returning large objects from a function.

The traditional way to return a large function result is to pass the location where one is to store the result as a pass by reference parameter. The advantage to this scheme is that it is relatively efficient (speed-wise) and doesn't require any extra space; the procedure uses the final destination location as scratch pad memory while it is building up the result. The disadvantage to this scheme is that it is very common to pass the destination variable as an input parameter (thus creating an alias). Since, in a high level language, you don't have the problems of aliases with function return results, this is a non-intuitive semantic result that can create some unexpected problems.

A second solution, though a little bit less efficient, is to use a pass by result parameter to return the function result. Pass by result parameters get their own local copy of the data that the system copies back over the destination location once the function is complete (thus avoiding the problem with aliases). The drawback to using pass by result, especially with large return values, is the fact that the program must copy the data from the local storage to the destination variable when the function completes. This data copy operation can take a significant amount of time for really large objects.

Another solution for returning large objects, that is relatively efficient, is to allocate storage for the object in the function, place whatever data you wish to return in the allocated storage, and then return a pointer to this storage. If the calling code references this data indirectly rather than copying the data to a different location upon return, this mechanism and run significantly faster than pass by result. Of course, it is not as general as using pass by result parameters, but with a little planning it is easy to arrange you code so that it works with pointers to large objects. String functions are probably the best example of this function result return mechanism in practice. It is very common for a function to allocate storage for a string result on the heap and then return a "string variable" in EAX (remember that strings in HLA are pointers).

---

## 4.8 Putting It All Together

This chapter discusses how and where you can pass parameters in an assembly language program. It continues the discussion of parameter passing that appears in earlier chapters in this text. This chapter discusses, in greater detail, several of the different places that a program can pass parameters to a procedure including registers, FPU/MMX register, on the stack, in the code stream, in global variables, and in parameters blocks. While this is not an all-inclusive list, it does cover the more common places where programs pass parameters.

In addition to where, this chapter discusses how programs can pass parameters. Possible ways include pass by value, pass by reference, pass by value/result, pass by result, pass by name, and pass by lazy evaluation. Again, these don't represent all the possible ways one could think of, but it does cover (by far) the most common ways programs pass parameters between procedures.

Another parameter-related issue this chapter discusses is how to pass parameters passed into one procedure as parameters to another procedure. Although HLA's high level calling syntax can take care of the grungy details for you, it's important to know how to pass these parameters manually since there are many instances where you will be forced to write the code that passes these parameters (not to mention, it's a good idea to know how this works, just on general principles).

This chapter also touches on passing a variable number of parameters between procedures and how to return function results from a procedure.

This chapter will not be the last word on parameters. We'll take another look at parameters in the very next chapter when discussing lexical scope.

---

# Lexical Nesting

# Chapter Five

---

## 5.1 Chapter Overview

This chapter discusses nested procedures and the issues associated with calling such procedure and accessing local variables in nested procedures. Nesting procedures offers HLA users a modicum of built-in information hiding support. Therefore, the material in this chapter is very important for those wanting to write highly structured code. This information is also important to those who want to understand how block structured high level languages like Pascal and Ada operate.

---

## 5.2 Lexical Nesting, Static Links, and Displays

In block structured languages like Pascal<sup>1</sup> it is possible to nest procedures and functions. Nesting one procedure within another limits the access to the nested procedure; you cannot access the nested procedure from outside the enclosing procedure. Likewise, variables you declare within a procedure are visible inside that procedure and to all procedures nested within that procedure<sup>2</sup>. This is the standard block structured language notion of scope that should be quite familiar to anyone who has written Pascal or Ada programs.

There is a good deal of complexity hidden behind the concept of scope, or lexical nesting, in a block structured language. While accessing a local variable in the current activation record is efficient, accessing global variables in a block structured language can be very inefficient. This section will describe how a high level language like Pascal deals with non-local identifiers and how to access global variables and call non-local procedures and functions.

---

### 5.2.1 Scope

Scope in most high level languages is a static, or compile-time concept<sup>3</sup>. Scope is the notion of when a name is visible, or accessible, within a program. This ability to hide names is useful in a program because it is often convenient to reuse certain (non-descriptive) names. The *i* variable used to control most FOR loops in high level languages is a perfect example.

The scope of a name limits its visibility within a program. That is, a program has access to a variable name only within that name's scope. Outside the scope, the program cannot access that name. Many programming languages, like Pascal and C++, allow you to reuse identifiers if the scopes of those multiple uses do not overlap. As you've seen, HLA provides scoping features for its variables. There is, however, another issue related to scope: *address binding* and *variable lifetime*. Address binding is the process of associating a memory address with a variable name. Variable lifetime is that portion of a program's execution during which a memory location is bound to a variable. Consider the following Pascal procedures:

```
procedure One(Entry:integer);
var
 i,j:integer;

 procedure Two(Parm:integer);
 var j:integer;
 begin

 for j:= 0 to 5 do writeln(i+j);
```

---

1. Note that C and C++ are not block structured languages. Other block structured languages include Algol, Ada, and Modula-2.

2. Subject, of course, to the limitation that you not reuse the identifier within the nested procedure.

3. There are languages that support dynamic, or run-time, scope; this text will not consider such languages.

```

 if Parm < 10 then One(Parm+1);
end;

begin {One}
 for i := 1 to 5 do Two(Entry);
end;

```

Figure 5.1 shows the scope of identifiers *One*, *Two*, *Entry*, *i*, *j*, and *Parm*. The local variable *j* in procedure *Two* masks the identifier *j* in procedure *One* for statement inside procedure *Two*.

**Figure 5.1 Lexical Scope for Variables in Nested Pascal Procedures**

## 5.2.2 Unit Activation, Address Binding, and Variable Lifetime

*Unit activation* is the process of calling a procedure or function. The combination of an activation record and some executing code is considered an *instance* of a routine. When unit activation occurs a routine binds machine addresses to its local variables. Address binding (for local variables) occurs when the routine adjusts the stack pointer to make room for the local variables. The lifetime of those variables is from that point until the routine destroys the activation record eliminating the local variable storage.

Although scope limits the visibility of a name to a certain section of code and does not allow duplicate names within the same scope, this does not mean that there is only one address bound to a name. It is quite possible to have several addresses bound to the same name at the same time. Consider a recursive procedure call. On each activation the procedure builds a new activation record. Since the previous instance still exists, there are now two activation records on the stack containing local variables for that procedure. As additional recursive activations occur, the system builds more activation records each with an address bound to the same name. To resolve the possible ambiguity (which address do you access when operating on the variable?), the system always manipulates the variable in the most recent activation record.

Note that procedures *One* and *Two* in the previous section are indirectly recursive. That is, they both call routines which, in turn, call themselves. Assuming the parameter to *One* is less than 10 on the initial call, this code will generate multiple activation records (and, therefore, multiple copies of the local variables) on the stack. For example, were you to issue the call *One(9)*, the stack would look like Figure 5.2 upon first encountering the end associated with the procedure *Two*.

**Figure 5.2** Activation Records for a Series of Recursive Calls of One and Two

As you can see, there are several copies of *I* and *J* on the stack at this point. Procedure *Two* (the currently executing routine) would access *J* in the most recent activation record that is at the bottom of Figure 5.2. The previous instance of *Two* will only access the variable *J* in its activation record when the current instance returns to *One* and then back to *Two*.

The lifetime of a variable's instance is from the point of activation record creation to the point of activation record destruction. Note that the first instance of *J* above (the one at the top of the diagram above) has the longest lifetime and that the lifetimes of all instances of *J* overlap.

### 5.2.3 Static Links

Pascal will allow procedure *Two* access to *I* in procedure *One*. However, when there is the possibility of recursion there may be several instances of *I* on the stack. Pascal, of course, will only let procedure *Two* access the most recent instance of *I*. In the stack diagram in Figure 5.2, this corresponds to the value of *I* in the activation record that begins with "*One*(9+1) parameter." The only problem is *how do you know where to find the activation record containing I?*

A quick, but poorly thought out answer, is to simply index backwards into the stack. After all, you can easily see in the diagram above that *I* is at offset eight from *Two*'s activation record. Unfortunately, this is not

always the case. Assume that procedure *Three* also calls procedure *Two* and the following statement appears within procedure *One*:

```
If (Entry <5) then Three(Entry*2) else Two(Entry);
```

With this statement in place, it's quite possible to have two different stack frames upon entry into procedure *Two*: one with the activation record for procedure *Three* sandwiched between *One* and *Two*'s activation records and one with the activation records for procedures *One* and *Two* adjacent to one another. Clearly a fixed offset from *Two*'s activation record will not always point at the *I* variable on *One*'s most recent activation record.

The astute reader might notice that the saved bp value in *Two*'s activation record points at the caller's activation record. You might think you could use this as a pointer to *One*'s activation record. But this scheme fails for the same reason the fixed offset technique fails. EBP's old value, the dynamic link, points at the caller's activation record. Since the caller isn't necessarily the enclosing procedure the dynamic link might not point at the enclosing procedure's activation record.

What is really needed is a pointer to the enclosing procedure's activation record. Many compilers for block structured languages create such a pointer, the *static link*. Consider the following Pascal code:

```
procedure Parent;
var i,j:integer;

 procedure Child1;
 var j:integer;
 begin

 for j := 0 to 2 do writeln(i);

 end {Child1};

 procedure Child2;
 var i:integer;
 begin

 for i := 0 to 1 do Child1;

 end {Child2};

begin {Parent}

 Child2;
 Child1;

end;
```

Just after entering *Child1* for the first time, the stack would look like Figure 5.3. When *Child1* attempts to access the variable *i* from *Parent*, it will need a pointer, the static link, to *Parent*'s activation record. Unfortunately, there is no way for *Child1*, upon entry, to figure out on its own where *Parent*'s activation record lies in memory. It will be necessary for the caller (*Child2* in this example) to pass the static link to *Child1*. In general, the callee can treat the static link as just another parameter; usually pushed on the stack immediately before executing the CALL instruction.

**Figure 5.3**      **Activation Records After Several Nested Calls**

To fully understand how to pass static links from call to call, you must first understand the concept of a lexical level. Lexical levels in Pascal correspond to the static nesting levels of procedures and functions. Most compiler writers specify lex level zero as the main program. That is, all symbols you declare in your main program exist at lex level zero. Procedure and function names appearing in your main program define lex level one, *no matter how many procedures or functions appear in the main program*. They all begin a new copy of lex level one. For each level of nesting, Pascal introduces a new lex level. Figure 5.4 shows this.

**Figure 5.4**      **Procedure Schematic Showing Lexical Levels**

During execution, a program may only access variables at a lex level less than or equal to the level of the current routine. Furthermore, only one set of values at any given lex level are accessible at any one time<sup>4</sup> and those values are always in the most recent activation record at that lex level.

Before worrying about how to access non-local variables using a static link, you need to figure out how to pass the static link as a parameter. When passing the static link as a parameter to a program unit (procedure or function), there are three types of calling sequences to worry about:

- A program unit calls a child procedure or function. If the current lex level is  $n$ , then a child procedure or function is at lex level  $n+1$  and is local to the current program unit. Note that most block structured languages do not allow calling procedures or functions at lex levels greater than  $n+1$ .
- A program unit calls a peer procedure or function. A peer procedure or function is one at the same lexical level as the current caller and a single program unit encloses both program units.
- A program unit calls an ancestor procedure or function. An ancestor unit is either the parent unit, a parent of an ancestor unit, or a peer of an ancestor unit.

Calling sequences for the first two types of calls above are very simple. For the sake of this example, assume the activation record for these procedures takes the generic form in Figure 5.5.

**Figure 5.5** Generic Activation Record

When a parent procedure or function calls a child program unit, the static link is nothing more than the value in the EBP register immediately prior to the call. Therefore, to pass the static link to the child unit, just push EBP before executing the call instruction:

```
<Push Other Parameters onto the stack>
push(ebp);
call ChildUnit;
```

Of course the child unit can process the static link off the stack just like any other parameter. In this case, that the static and dynamic links are exactly the same. In general, however, this is not true.

If a program unit calls a peer procedure or function, the current value in EBP is not the static link. It is a pointer to the caller's local variables and the peer procedure cannot access those variables. However, as peers, the caller and callee share the same parent program unit, so the caller can simply push a copy of its

---

4. There is one exception. If you have a *pointer* to a variable and the pointer remains accessible, you can access the data it points at even if the variable actually holding that data is inaccessible. Of course, in (standard) Pascal you cannot take the address of a local variable and put it into a pointer. However, certain dialects of Pascal (e.g., Turbo) and other block structured languages will allow this operation.

static link onto the stack before calling the peer procedure or function. The following code will do this assuming the current procedure's static link is on the stack immediately above the return address:

```
<Push Other Parameters onto the Stack>
 pushd([ebp+8]);
 call PeerUnit;
```

Calling an ancestor is a little more complex. If you are currently at lex level  $n$  and you wish to call an ancestor at lex level  $m$  ( $m < n$ ), you will need to traverse the list of static links to find the desired activation record. The static links form a list of activation records. By following this chain of activation records until it ends, you can step through the most recent activation records of all the enclosing procedures and functions of a particular program unit. The stack diagram in Figure 5.6 shows the static links for a sequence of procedure calls statically nested five lex levels deep.

**Figure 5.6 Static Links**

If the program unit currently executing at lex level five wishes to call a procedure at lex level three, it must push a static link to the most recently activated program unit at lex level two. In order to find this static link you will have to *traverse* the chain of static links. If you are at lex level  $n$  and you want to call a procedure at lex level  $m$  you will have to traverse  $(n-m)+1$  static links. The code to accomplish this is

```
// Current lex level is 5. This code locates the static link for,
// and then calls a procedure at lex level 2. Assume all calls are
// near:

<Push necessary parameters>

mov([ebp+8], ebx); // Traverse static link to LL 4.
mov([ebx+8], ebx); // To Lex Level 3.
mov([ebx+8], ebx); // To Lex Level 2.
pushd([ebx+8]); // Ptr to most recent LL 1 activation record.
call ProcAtLL2;
```

## 5.2.4 Accessing Non-Local Variables Using Static Links

In order to access a non-local variable, you must traverse the chain of static links until you get a pointer to the desired activation record. This operation is similar to locating the static link for a procedure call out-

lined in the previous section, except you traverse only  $n-m$  static links rather than  $(n-m)+1$  links to obtain a pointer to the appropriate activation record. Consider the following Pascal code:

```

procedure Outer;
var i:integer;

 procedure Middle;
 var j:integer;

 procedure Inner;
 var k:integer;
 begin
 k := 3;
 writeln(i+j+k);

 end;

 begin {middle}

 j := 2;
 writeln(i+j);
 Inner;

 end; {middle}

begin {Outer}

 i := 1;
 Middle;

end; {Outer}

```

The *Inner* procedure accesses global variables at lex level  $n-1$  and  $n-2$  (where  $n$  is the lex level of the *Inner* procedure). The *Middle* procedure accesses a single global variable at lex level  $m-1$  (where  $m$  is the lex level of procedure *Middle*). The following HLA code could implement these three procedures:

```

procedure Inner; nodisplay; noframe;
var
 k:int32;
begin Inner;

 push(ebp);
 mov(esp, ebp);
 sub(_vars_, esp); // Make room for k.

 mov(3, k); // Initialize k.
 mov([ebp+8], ebx); // Static link to previous lex level.
 mov([ebx-4], eax); // Get j's value.
 add(k, eax); // Add in k's value.
 mov([ebx+8], ebx); // Get static link to Outer's activation record.
 add([ebx-4], eax); // Add in i's value to sum.
 stdout.puti(eax); // Display the sum.
 stdout.newln();

 mov(ebp, esp); // Standard exit sequence.
 pop(ebp);
 ret(4); // Removes the stack link from the stack.

end Inner;

procedure Middle; nodisplay; noframe;

```

```

var
 j:int32;
begin Middle;

 push(ebp);
 mov(esp, ebp);
 sub(_vars_, esp); // Make room for j.

 mov(2, j); // Initialize j.
 mov([ebp+8], ebx); // Get the static link.
 mov([ebx-4], eax); // Get i's value.
 add(j, eax); // Compute i+j.
 stdout.put(eax, nl); // Display their sum.

 push(ebp); // Static link for inner.
 call Inner;

 mov(ebp, esp); // Standard exit sequence
 pop(ebp);
 ret(4); // Removes static link from stack.
end Middle;

procedure Outer; nodisplay; noframe;
var
 i:int32;
begin Outer;

 push(ebp);
 mov(esp, ebp);
 sub(_vars_, esp); // Make room for i.

 mov(1, i); // Give i an initial value.
 push(ebp); // Static link for middle.
 call Middle;

 mov(ebp, esp); // Remove local variables
 pop(ebp);
 ret(4); // Removes static link.

end Outer;

```

Note that as the difference between the lex levels of the activation records increases, it becomes less and less efficient to access global variables. Accessing global variables in the previous activation record requires only one additional instruction per access, at two lex levels you need two additional instructions, etc. If you analyze a large number of Pascal programs, you will find that most of them do not nest procedures and functions and in the ones where there are nested program units, they rarely access global variables. There is one major exception, however. Although Pascal procedures and functions rarely access local variables inside other procedures and functions, they frequently access global variables declared in the main program. Since such variables appear at lex level zero, access to such variables would be as inefficient as possible when using the static links. To solve this minor problem, most 80x86 based block structured languages allocate variables at lex level zero directly in the STATIC segment and access them directly.

---

## 5.2.5 Nesting Procedures in HLA

The example in the previous treats the procedures, syntactically, as non-nested procedures and relies upon the programmer to manual handle the lexical nesting. A severe drawback to this mechanism is that it forces the programmer to manual compute the offsets of non-local variables. Although HLA does not pro-

vide automatic support for static links, HLA does allow us to nest procedures and provides some compile-time functions to help us calculate offsets into non-global activation records. Furthermore, we can treat the static link as a parameter to the procedures, so we don't have to refer to the static link using address expressions like "[ebx+8]".

Like Pascal, HLA lets you nest procedures. You may insert a procedure in the declaration section of another procedure. The Inner, Middle, and Outer procedures of the previous section could have been written in a fashion like the following:

```

procedure Outer; nodisplay; noframe;
var
 i:int32;

 procedure Middle; nodisplay; noframe;
 var
 j:int32;

 procedure Inner; nodisplay; noframe;
 var
 k:int32;
 begin Inner;

 << Code for the Inner procedure >>

 end Inner;

 begin Middle;

 << code for the Middle procedure >>

 end Middle;
begin Outer;

 << code for the Outer procedure >>

end Outer;

```

There are two advantages to this scheme:

1. The identifier *Inner* is local to the *Middle* procedure and is not accessible outside *Middle* (not even to *Outer*); similarly, the identifier *Middle* is local to *Outer* and is not accessible outside *Outer*. This information hiding feature lets you prevent other code from accidentally accessing these nested procedures, just as for local variables.
2. The local identifiers *i* and *j* are accessible to the nested procedures.

Before discussing how to use this feature to access non-local variables in a more reasonable fashion using static links, let's also consider the issue of the static link itself. The static link is really nothing more than a special parameter to these functions, therefore we can declare the static link as a parameter using HLA's high level procedure declaration syntax. Since the static link must always be at a fixed offset in the activation record for all procedures, the most reasonable thing to do is always make the stack link the first parameter in the list<sup>5</sup>; this ensures that the static link is always found at offset "+8" in the activation record. Here's the declarations above with the static links added as parameters:

```

procedure Outer(outerStaticLink:dword); nodisplay; noframe;
var
 i:int32;

 procedure Middle(middleStaticLink:dword); nodisplay; noframe;

```

---

5. Assuming, of course, that you're using the default Pascal calling convention. If you were using the CDECL or STDCALL calling convention, you would always make the static link the last parameter in the parameter list.

```

var
 j:int32;

 procedure Inner(innerStaticLink:dword); nodisplay; noframe;
 var
 k:int32;
 begin Inner;

 << Code for the Inner procedure >>

 end Inner;

begin Middle;

 << code for the Middle procedure >>

end Middle;

begin Outer;

 << code for the Outer procedure >>

end Outer;

```

All that remains is to discuss how one references non-local (automatic) variables in this code. As you may recall from the chapter on Intermediate Procedures in Volume Four, HLA references local variables and parameters using an address expression of the form "[ebp±offset]" where offset represents the offset of the variable into the activation record (parameters typically have a positive offset, local variables have a negative offset). Indeed, we can use the HLA compile-time @offset function to access the variables without having to manually figure out the variable's offset in the activation record, e.g.,

```
mov([ebp+@offset(i)], eax);
```

The statement above is semantically equivalent to

```
mov(i, eax);
```

assuming, of course, that *i* is a local variable in the current procedure.

Because HLA automatically associates the EBP register with local variables, HLA will not allow you to use a non-local variable reference in a procedure. For example, if you tried to use the statement "mov( i, eax );" in procedure *Inner* in the example above, HLA would complain that you cannot access non-local in this manner. The problem is that HLA associates EBP with automatic variables and outside the procedure in which you declare the local variable, EBP does not point at the activation record holding that variable. Hence, the instruction "mov( i, eax );" inside the *Inner* procedure would actually load *k* into EAX, not *i* (because *k* is at the same offset in *Inner*'s activation record as *i* in *Outer*'s activation record).

While it's nice that HLA prevents you from making the mistake of such an illegal reference, the fact remains that there needs to be some way of referring to non-local identifiers in a procedure. HLA uses the following syntax to reference a non-local, automatic, variable:

```
reg32::identifier
```

reg<sub>32</sub> represents any of the 80x86's 32-bit general purpose registers and *identifier* is the non-local identifier you wish to access. HLA substitutes an address expression of the form "[reg<sub>32</sub>+@offset(identifier)]" for this expression. Given this syntax, we can now rewrite the *Inner*, *Middle*, and *Outer* example in a high level fashion as follows:

```

procedure Outer(outerStaticLink:dword); nodisplay;
var
 i:int32;

```

```

procedure Middle(middleStaticLink:dword); nodisplay;
var
 j:int32;

 procedure Inner(innerStaticLink:dword); nodisplay;
 var
 k:int32;
 begin Inner;

 mov(3, k); // Initialize k.
 mov(innerStaticLink, ebx); // Static link to previous lex level.
 mov(ebx::j, eax); // Get j's value.
 add(k, eax); // Add in k's value.

 // Get static link to Outer's activation record and
 // add in i's value:

 mov(ebx::outerStaticLink ebx);
 add(ebx::i, eax);

 // Display the results:

 stdout.puti(eax); // Display the sum.
 stdout.newln();

 end Inner;

begin Middle;

 mov(2, j); // Initialize j.
 mov(middleStaticLink, ebx); // Get the static link.
 mov(ebx::i, eax); // Get i's value.
 add(j, eax); // Compute i+j.
 stdout.put(eax, nl); // Display their sum.

 Inner(ebp); // Inner's static link is EBP.

end Middle;

begin Outer;

 mov(1, i); // Give i an initial value.
 Middle(ebp); // Static link for middle.

end Outer;

```

This example provides only a small indication of the work needed to access variables using static links. In particular, accessing `@ebx::i` in the *Inner* procedure was simplified by the fact that EBX already contained *Middle's* static link. In the typical case, it's going to take one instruction for each lex level the code traverses in order to access a given non-local automatic variable. While this might seem bad, in typical programs you rarely access non-local variables, so the situation doesn't arrive often enough to worry about.

HLA does not provide built-in support for static links. If you are going to use static links in your programs, then you must manually pass the static links as parameters to your procedures (i.e., HLA will not take care of this for you). While it is possible to modify HLA to automatically handle static links for you, HLA provides a different mechanism for accessing non-local variables - the display. To learn about displays, keep reading...

## 5.2.6 The Display

After reading the previous section you might get the idea that one should never use non-local variables, or limit non-local accesses to those variables declared at lex level zero. After all, it's often easy enough to put all shared variables at lex level zero. If you are designing a programming language, you can adopt the C language designer's philosophy and simply not provide block structure. Such compromises turn out to be unnecessary. There is a data structure, the *display*, that provides efficient access to any set of non-local variables.

A display is simply an array of pointers to activation records. *Display[0]* contains a pointer to the most recent activation record for lex level zero, *Display[1]* contains a pointer to the most recent activation record for lex level one, and so on. Assuming you've maintained the *Display* array in the current STATIC segment it only takes two instructions to access any non-local variable. Pictorially, the display works as shown in Figure 5.7.

**Figure 5.7** The Display

Note that the entries in the display always point at the most recent activation record for a procedure at the given lex level. If there is no active activation record for a particular lex level (e.g., lex level six above), then the entry in the display contains garbage.

The maximum lexical nesting level in your program determines how many elements there must be in the display. Most programs have only three or four nested procedures (if that many) so the display is usually quite small. Generally, you will rarely require more than 10 or so elements in the display.

Another advantage to using a display is that each individual procedure can maintain the display information itself, the caller need not get involved. When using static links the calling code has to compute and pass the appropriate static link to a procedure. Not only is this slow, but the code to do this must appear before every call. If your program uses a display, the callee, rather than the caller, maintains the display so you only need one copy of the code per procedure.

Although maintaining a single display in the STATIC segment is easy and efficient, there are a few situations where it doesn't work. In particular, when passing procedures as parameters, the single level display doesn't do the job. So for the general case, a solution other than a static array is necessary. Therefore, this chapter will not go into the details of how to maintain a static display since there are some problems with this approach.

Intel, when designing the 80286 microprocessor, studied this problem very carefully (because Pascal was popular at the time and they wanted to be able to efficiently handle Pascal constructs). They came up

with a generalized solution that works for all cases. Rather than using a single display in a static segment, Intel's designers decided to have each procedure carry around its own local copy of the display. The HLA compiler automatically builds an Intel-compatible display at the beginning of each procedure, assuming you don't use the NODISPLAY procedure option. An Intel-compatible display is part of a procedure's activation record and takes the form shown in Figure 5.8:

**Figure 5.8 Intel-Compatible Display in an Activation Record**

If we assume that the lex level of the main program is zero, then the display for a given procedure at lex level  $n$  will contain  $n+1$  double word elements. *Display[0]* is a pointer to the activation record for the main program, *Display[1]* is a pointer to the activation record of the most recently activated procedure at lex level one. Etc. *Display[n]* is a pointer to the current procedure's activation record (i.e., it contains the value found in EBP while this procedure executes). Normally, the procedure would never access element  $n$  of *Display* since the procedure can index off EBP directly; However, as you'll soon see, we'll need the *Display[n]* entry to build displays for procedures at higher lex levels.

One important fact to note about the Intel-compatible display array: its elements appear backwards in memory. Remember, the stack grows downwards from high addresses to low addresses. If you study Figure 5.8 for a moment you'll discover that *Display[0]* is at the highest memory address and *Display[n]* is at the lowest memory address, exactly the opposite for standard array organization. It turns out that we'll always access the display using a constant offset, so this reversal of the array ordering is no big deal. We'll just use negative offsets from *Display[0]* (the base address of the array) rather than the usual positive offsets.

If the NODISPLAY procedure option is not present, HLA treats the display as a predeclared local variable in the procedure and inserts the name "*\_display\_*" into the symbol table. The offset of the *\_display\_* variable in the activation record is the offset of the *Display[0]* entry in Figure 5.8. Therefore, you can easily access an element of this array at run-time using a statement like:

```
mov(_display_[-lexLevel*4], ebx);
```

The "\*4" component appears because `_display_` is an array of double words. `lexLevel` must be a constant value that specifies the lex level of the procedure whose activation record you'd like to obtain. The minus sign prefixing this expression causes HLA to index downwards in memory as appropriate for the display object.

Although it's not that difficult to figure out the lex level of a procedure manually, the HLA compile-time language provides a function that will compute the lex level of a given procedure for you – the `@lex` function. This function accepts a single parameter that must be the name of an HLA procedure (that is currently in scope). The `@lex` function returns an appropriate value for that function that you can use as an index into the `_display_` array. Note that `@lex` returns one for the main program, two for procedures you declare in the main program, three for procedures you declare in procedures you declare in the main program, etc. If you are writing a unit, all procedures you declare in that unit exist at lex level two.

The following program is a variation of the Inner/Middle/Outer example you've seen previously in this chapter. This example uses displays and the `@lex` function to access the non-local automatic variables:

---

```

program DisplayDemo;
#include("stdlib.hhf")

 macro Display(proc);

 display[-@lex(proc) * 4]

 endmacro;

procedure Outer;
var
 i:int32;

 procedure Middle;
 var
 j:int32;

 procedure Inner;
 var
 k:int32;
 begin Inner;

 mov(4, k);
 mov(Display(Middle), ebx);
 mov(ebx::j, eax); // Get j's value.
 add(k, eax); // Add in k's value.

 // Get static link to Outer's activation record and
 // add in i's value:

 mov(Display(Outer), ebx);
 add(ebx::i, eax);

 // Display the results:

 stdout.puti32(eax); // Display the sum.
 stdout.newln();

 end Inner;

 begin Middle;

```

```

 mov(2, j); // Initialize j.
 mov(Display(Outer), ebx); // Get the static link.
 mov(ebx::i, eax); // Get i's value.
 add(j, eax); // Compute i+j.
 stdout.puti32(eax); // Display their sum.
 stdout.newln();

 Inner();

 end Middle;

begin Outer;

 mov(1, i); // Give i an initial value.
 Middle(); // Static link for middle.

end Outer;

begin DisplayDemo;

 Outer();

end DisplayDemo;

```

---

### Program 5.1 Demonstration of Displays in an HLA Program

---

Assuming you do not attach the `NODISPLAY` procedure option to a procedure you write in HLA, HLA will automatically emit the code (as part of the standard entry sequence) to build a display for that procedure. Up to this chapter, none of the programs in this text have used nested procedures<sup>6</sup>, therefore there has been no need for a display. For that reason, most programs appearing in this text (since the introduction of the `NODISPLAY` option) have attached `NODISPLAY` to the procedure. It doesn't make a program incorrect to build a display if you never use it, but it does make the procedure a tiny bit slower and a tiny bit larger, hence the use of the `NODISPLAY` option up to this point.

---

## 5.2.7 The 80x86 ENTER and LEAVE Instructions

When designing the 80286, Intel's CPU designers decided to add two instructions to help maintain displays. This was done because Pascal was the popular high level language at the time and Pascal was a block structured language that could benefit from having a display. Since then, `C/C++` has replaced Pascal as the most common implementation language, so these two instructions have fallen into disuse since `C/C++` is not a block structured language. Still, you can take advantage of these instructions when writing assembly code with nested procedures.

Unfortunately, these two instructions, `ENTER` and `LEAVE`, are quite slow. The problem with these instructions is that `C/C++` became popular shortly after Intel designed these instructions, so Intel never bothered to optimize them since few high-performance compilers actually used these instructions. On today's processors, it's actually faster to execute a sequence of instructions that do the same job than it is to actually use these instructions; hence most compilers that build displays (like HLA) emit a discrete sequence of instructions to build the display. Do keep in mind that, although these two instructions are slower than their

---

6. Technically, this statement is not true. Every procedure you've written has been nested inside the main program. However, none of the sample programs to date have considered the possibility of accessing the main program's automatic (VAR) variables. Hence there has been no need for a display until now).

discrete counterparts, they are generally shorter. So if you're trying to save code space rather than write the fastest possible code, using ENTER and LEAVE can help.

The LEAVE instruction is very simple to understand. It performs the same operation as the two instructions:

```
mov(ebp, esp);
pop(ebp);
```

Therefore, you may use the instruction for the standard procedure exit code. On an 80386 or earlier processor, the LEAVE instruction is faster than the equivalent move and pop sequence. However, the LEAVE instruction is slower on 80486 and later processors.

The ENTER instruction takes two operands. The first is the number of bytes of local storage the current procedure requires, the second is the lex level of the current procedure. The enter instruction does the following:

```
// enter(Locals, LexLevel);

 push(ebp); // Save dynamic link
 mov(esp, tempreg); // Save for later.
 cmp(LexLevel, 0); // Done if this is lex level zero.
 je Lex0;
lp: dec(LexLevel);
 jz Done;
 sub(4, ebp); // Index into display in previous activation record
 pushd([ebp]); // and push the element there.
 jmp lp;

Done:
 push(tempreg); // Add entry for current lex level.
Lex0:
 mov(tempreg, ebp); // Pointer to current activation record.
 sub(_vars_, esp); // Allocate storage for local variables.
```

As you can see from this code, the ENTER instruction copies the display from activation record to activation record. This can get quite expensive if you nest the procedures to any depth. Most high level languages, if they use the ENTER instruction at all, always specify a nesting level of zero to avoid copying the display throughout the stack.

The ENTER instruction puts the value for the *\_display[n]* entry at location  $EBP-(n*4)$ . The ENTER instruction does not copy the value for *display[0]* into each stack frame. Intel assumes that you will keep the main program's global variables in the data segment. To save time and memory, they do not bother copying the *\_display[0]* entry. This is why HLA uses lex level one for the main program – in HLA the main program can have automatic variables and, therefore, requires a display entry.

The ENTER instruction is very slow, particularly on 80486 and later processors. If you really want to copy the display from activation record to activation record it is probably a better idea to push the items yourself. The following code snippets show how to do this:

```
// enter(n, 0); (n bytes of local variables, lex level zero.)

 push(ebp); // As you can see, "enter(n, 0);" corresponds to
 mov(esp, ebp); // the standard entry sequence for non-nested
 sub(n, esp); // procedures.

// enter(n, 1);

 push(ebp); // Save dynamic link (current EBP value).
 pushd([ebp-4]); // Push display[1] entry from previous act rec.
 lea(ebp, [esp-4]); // Point EBP at the base of new act rec.
 sub(n, esp); // Allocate local variables.

// enter(n, 2);
```

```

push(ebp); // Save dynamic link (current EBP value).
pushd([ebp-4]); // Push display[1] entry from previous act rec.
pushd([ebp-8]); // Push display[2] entry from previous act rec.
lea(ebp, [esp-8]); // Point EBP at the base of new act rec.
sub(n, esp); // Allocate local variables.

// enter(n, 3);

push(ebp); // Save dynamic link (current EBP value).
pushd([ebp-4]); // Push display[1] entry from previous act rec.
pushd([ebp-8]); // Push display[2] entry from previous act rec.
pushd([ebp-12]); // Push display[3] entry from previous act rec.
lea(ebp, [esp-12]); // Point EBP at the base of new act rec.
sub(n, esp); // Allocate local variables.

// enter(n, 4);

push(ebp); // Save dynamic link (current EBP value).
pushd([ebp-4]); // Push display[1] entry from previous act rec.
pushd([ebp-8]); // Push display[2] entry from previous act rec.
pushd([ebp-12]); // Push display[3] entry from previous act rec.
pushd([ebp-16]); // Push display[3] entry from previous act rec.
lea(ebp, [esp-16]); // Point EBP at the base of new act rec.
sub(n, esp); // Allocate local variables.

// etc.

```

If you are willing to believe Intel's cycle timings, you'll find that the ENTER instruction is almost never faster than a straight line sequence of instructions that accomplish the same thing. If you are interested in saving space rather than writing fast code, the ENTER instruction is generally a better alternative. The same is generally true for the LEAVE instruction as well. It is only one byte long, but it is slower than the corresponding "mov( esp, ebp );" and "pop( ebp );" instructions. The following sample program demonstrates how to access non-local variables using a display. This code does not use the @lex function in the interest of making the lex level access clear; normally you would use the @lex function rather than the literal constants appearing in this example.

---

```

program EnterLeaveDemo;
#include("stdlib.hhf")

procedure LexLevel2;

 procedure LexLevel3a;
 begin LexLevel3a;

 stdout.put(nl "LexLevel3a:" nl);
 stdout.put("esp = ", esp, " ebp = ", ebp, nl);
 mov(_display_[0], eax);
 stdout.put("display[0] = ", eax, nl);
 mov(_display_-4, eax);
 stdout.put("display[-1] = ", eax, nl);

 end LexLevel3a;

 procedure LexLevel3b; noframe;
 begin LexLevel3b;

```

```

 enter(0, 3);

 stdout.put(nl "LexLevel3b:" nl);
 stdout.put("esp = ", esp, " ebp = ", ebp, nl);
 mov(_display_[0], eax);
 stdout.put("display[0] = ", eax, nl);
 mov(_display_[-4], eax);
 stdout.put("display[-1] = ", eax, nl);

 leave;
 ret();

end LexLevel3b;

begin LexLevel2;

 stdout.put("LexLevel2: esp=", esp, " ebp = ", ebp, nl nl);
 LexLevel3a();
 LexLevel3b();

end LexLevel2;

begin EnterLeaveDemo;

 stdout.put("main: esp = ", esp, " ebp= ", ebp, nl);
 LexLevel2();

end EnterLeaveDemo;

```

---

### Program 5.2 Demonstration of Enter and Leave in HLA

---

## 5.3 Passing Variables at Different Lex Levels as Parameters.

Accessing variables at different lex levels in a block structured program introduces several complexities to a program. The previous section introduced you to the complexity of non-local variable access. This problem gets even worse when you try to pass such variables as parameters to another program unit. The following subsections discuss strategies for each of the major parameter passing mechanisms.

For the purposes of discussion, the following sections will assume that “local” refers to variables in the current activation record, “global” refers to static variables in a static segment, and “intermediate” refers to automatic variables in some activation record other than the current activation record (this includes automatic variables in the main program). These sections will pass all parameters on the stack. You can easily modify the details to pass these parameters elsewhere, should you choose.

---

### 5.3.1 Passing Parameters by Value

Passing value parameters to a program unit is no more difficult than accessing the corresponding variables; all you need do is push the value on the stack before calling the associated procedure.

To (manually) pass a global variable by value to another procedure, you could use code like the following:

```

push(GlobalVariable); // Assume "GlobalVariable" is a static object.
call proc;

```

To pass a local variable by value to another procedure, you could use the following code<sup>7</sup>:

```
push(LocalVariable);
call proc;
```

To pass an intermediate variable as a value parameter, you must first locate that intermediate variable's activation record and then push its value onto the stack. The exact mechanism you use depends on whether you are using static links or a display to keep track of the intermediate variable's activation records. If using static links, you might use code like the following to pass a variable from two lex levels up from the current procedure:

```
mov([ebp+8], ebx); // Assume static link is at offset 8 in Act Rec.
mov([ebx], ebx); // Traverse the second static link.
push(ebx::IntVar); // Push the intermediate variable's value.
call proc;
```

Passing an intermediate variable by value when you are using a display is somewhat easier. You could use code like the following to pass an intermediate variable from lex level one:

```
mov(_display_[-1*4], ebx); // Remember each _display_ entry is 4 bytes.
push(ebx::IntVar); // Pass the intermediate variable.
call proc;
```

It is possible to use the HLA high level procedure calling syntax when passing intermediate variables as parameters by value. The following code demonstrates this:

```
mov(_display_[-1*4], ebx);
proc(ebx::IntVar);
```

This example uses a display because HLA automatically builds the display for you. If you decide to use static links, you'll have to modify this code appropriately.

### 5.3.2 Passing Parameters by Reference, Result, and Value-Result

The pass by reference, result, and value-result parameter mechanisms generally pass the address of parameter on the stack<sup>8</sup>. In an earlier chapter, you've seen how to pass global and local parameters using these mechanisms. In this section we'll take a look at passing intermediate variables by reference, value/result, and by result.

To pass an intermediate variable by reference, value/result, or by result, you must first locate the activation record containing the variable so you can compute the effective address into the stack segment. When using static links, the code to pass the parameter's address might look like the following:

```
mov([ebp+8], ebx); // Assume static link is at offset 8 in Act Rec.
mov([ebx], ebx); // Traverse the second static link.
lea(eax, ebx::IntVar); // Get the intermediate variable's address.
push(eax); // Pass the address on the stack.
call proc;
```

When using a display, the calling sequence might look like the following:

```
mov(_display_[-1*4], ebx); // Remember each _display_ entry is 4 bytes.
lea(eax, ebx::IntVar); // Pass the intermediate variable.
push(eax);
call proc;
```

7. The non-global examples all assume the variable is at offset -2 in their activation record. Change this as appropriate in your code.

8. As you may recall, pass by reference, value-result, and result all use the same calling sequence. The differences lie in the procedures themselves.

It is possible to use the HLA high level procedure calling syntax when passing parameters by reference, by value/result, or by result. The following code demonstrates this:

```
mov(_display_[-1*4], ebx);
proc(ebx::IntVar);
```

The nice thing about the high level syntax is that it is identical whether you're passing parameters by value, reference, value/result, or by result.

As you may recall from the chapter on Low-Level Parameter Implementation, there is a second way to pass a parameter by value/result. You can push the value onto the stack and then, when the procedure returns, pop this value off the stack and store it back into the variable from whence it came. This is just a special case of the pass by value mechanism described in the previous section.

### 5.3.3 Passing Parameters by Name and Lazy-Evaluation in a Block Structured Language

Since you pass a thunk when passing parameters by name or by lazy-evaluation, the presence of global, intermediate, and local variables does not affect the calling sequence to the procedure. Instead, the thunk has to deal with the differing locations of these variables. Since HLA thunks already contain the pointer to the activation record for that thunk, returning a local (to the thunk) variable's address or value is especially trivial. About the only catch is what happens if you pass an intermediate variable by name or by lazy evaluation to a procedure. However, the calculation of the ultimate address (pass by name) or retrieval of the value (pass by lazy evaluation) is nearly identical to the code in the previous two sections. Hence, this code will be left as an exercise at the end of this volume.

## 5.4 Passing Procedures as Parameters

Many programming languages let you pass a procedure or function name as a parameter. This lets the caller pass along various actions to perform inside a procedure. The classic example is a plot procedure that graphs some generic math function passed as a parameter to plot.

HLA lets you pass procedures and functions by declaring them as follows:

```
procedure DoCall(x:procedure);
begin DoCall;

 x();

end DoCall;
```

The statement "DoCall(xyz);" calls *DoCall* that, in turn, calls procedure *xyz*.

Whenever you pass a procedure's address in this manner, HLA only passes the address of the procedure as the parameter value. Upon entry into procedure *x* via the *DoCall* invocation, the *x* procedure first creates its own display by copying appropriate entries from *DoCall*'s display. This gives *x* access to all intermediate variables that HLA allows *x* to access.

Keep in mind that thunks are special cases of functions that you call indirectly. However, there is a major difference between a thunk and a procedure – thunks carry around the pointer to the activation record they intend to use. Therefore, the thunk does not copy the calling procedure's display; instead, it uses the display of an existing procedure to access intermediate variables.

## 5.5 Faking Intermediate Variable Access

As you've probably noticed by now, accessing non-local (intermediate) variables is a bit less efficient than accessing local or global (static) variables. High level languages like Pascal that support intermediate

variable access hide a lot of effort from the programmer that becomes painfully visible when attempting the same thing in assembly language. When attempting to write maintainable and readable code, you may want to break up a large procedure into a sequence of smaller procedures and make those smaller procedures local to a surrounding procedure that simply calls these smaller routines. Unfortunately, if the original procedure you're breaking up contains lots of local variables that code throughout the procedure shares, short of restructuring your code you will have to leave those variables in the outside procedure and access them as intermediate variables. Using the techniques of this chapter may make this task a bit unpleasant, especially if you access those variables a large number of times. This may dissuade you from attempting to break up the procedure into smaller units. Fortunately, under certain special circumstances, you can avoid the headaches of intermediate variable access in situations like this.

Consider the following short code sequence:

```

procedure MainProc;
var
 ALocalVar: dword;

 procedure proc; nodisplay; noframe;
 begin proc;

 mov(ebp::ALocalVar, eax);
 ret();

 end proc;

begin MainProc;

 mov(5, ALocalVar);
 proc();

 // EAX now contains five...

end MainProc;

```

Notice that the *proc* procedure has the NOFRAME option, so HLA does not emit the standard entry sequence to build an activation record. This means that upon entry to *proc*, EBP still points at *MainProc*'s activation record. Therefore, this code can access the *ALocalVar* variable by using the syntax *ebp::ALocalVar*. No other code is necessary.

The drawback to this scheme is that *proc* may not contain any parameters or local variables (which would require setting EBP to point at *proc*'s activation record). However, if you can live with this limitation, then this is a useful trick for accessing local variables one lex level up from the current procedure.

## 5.6 Putting It All Together

This chapter introduces the concept of lexical nesting commonly found in block structured languages like Pascal, Ada, and Modula-2. This chapter introduces the notion of scope, static procedure nesting, binding, variable lifetime, static links, the display, intermediate variables, and passing intermediate variables as parameters. Although few assembly programs use these features, they are occasionally useful, especially when writing code that interfaces with a high level language that supports static nesting.

# Questions, Projects, and Labs

# Chapter Six

---

## 6.1 Questions

- 1) What is a *First Class Object*?
- 2) What is the difference between deferred and eager evaluation?
- 3) What is a thunk?
- 4) How does HLA implement thunk objects?
- 5) What is the purpose of the HLA THUNK statement?
- 6) What is the difference between a thunk and procedure variable?
- 7) What is the syntax for declaring a thunk as a formal parameter?
- 8) What is the syntax for passing a thunk constant as an actual parameter?
- 9) Explain how an activation record's lifetime can affect the correctness of a thunk invocation.
- 10) What is a trigger and how can you use a thunk to create a trigger?
- 11) The yield statement in an iterator isn't a true HLA statement. It's actually equivalent to something else. What is it equivalent to?
- 12) What is a resume frame?
- 13) What is the problem with breaking out of a FOREACH loop using the BREAK or BREAKIF statement?
- 14) What is the difference between a coroutine and a procedure?
- 15) What is the difference between a coroutine and a generator?
- 16) What is the purpose of the coret call in the coroutines class?
- 17) What is the limitation of a coret operation versus a standard RET instruction?
- 18) What is the lifetime of the automatic variables declared in a coroutine procedure?
- 19) Where is the easiest place to pass parameters between two coroutines?
- 20) Why is it difficult to pass parameters between coroutines on the stack?
- 21) State seven places you can pass parameters between two procedures.
- 22) State at least six different ways you can pass parameters.
- 23) Where is the most efficient place to pass parameters?
- 24) Where do most high level languages pass their parameters?
- 25) What some problems with passing parameters in global variables?
- 26) What is the difference between the Pascal/HLA and the CDECL parameter passing mechanisms?
- 27) What is the difference between the Pascal/HLA and the STDCALL parameter passing mechanisms?
- 28) What is the difference between the STDCALL and the CDECL parameter passing mechanisms?
- 29) Provide one reason why some assembly code might require the caller to remove the parameters from the stack.
- 30) What is the disadvantage of having the caller remove procedure parameters from the stack?
- 31) Explain how to pass parameters in the code stream.
- 32) Describe how you might pass a reference parameter in the code stream. What is the limitation on such reference parameters?

- 33) Explain how you might pass a “pass by value/result” or “pass by result” parameter in the code stream.
- 34) What is a parameter block?
- 35) What is the difference between pass by value/result and pass by result?
- 36) What is the difference between pass by name and pass by lazy evaluation?
- 37) What parameter passing mechanism does pass by name most closely resemble?
- 38) What parameter passing mechanism does pass by lazy evaluation most closely resemble?
- 39) When passing a parameter by name or lazy evaluation, what does HLA actually pass on the stack.
- 40) What is the difference in the calling sequence between pass by reference, pass by value/result, and pass by result (assuming the standard implementation)?
- 41) Give an example where pass by value/result produces different semantics than pass by reference.
- 42) What parameter passing mechanism(s) support(s) deferred execution?

For each of the following subquestions, assume that a parameter (in) is passed into one procedure and that procedure passes the parameter on to another procedure (out). Specify how to do this given the following in and out parameter passing mechanisms (if possible):

- 43) Parameter is passed into the first procedure by value and passed on to the second procedure by:
  - a. value
  - b. reference
  - c. result
  - d. result
  - e: name
  - f: lazy evaluation
- 44) Parameter is passed into the first procedure by reference and passed on to the second procedure by:
  - a. value
  - b. reference
  - c. result
  - d. result
  - e: name
  - f: lazy evaluation
- 45) Parameter is passed into the first procedure by value/result and passed on to the second procedure by:
  - a. value
  - b. reference
  - c. result
  - d. result
  - e: name
  - f: lazy evaluation
- 46) Parameter is passed into the first procedure by result and passed on to the second procedure by:
  - a. value

- b. reference
  - c. result
  - d. result
  - e: name
  - f: lazy evaluation
- 47) Parameter is passed into the first procedure by name and passed on to the second procedure by:
- a. value
  - b. reference
  - c. result
  - d. result
  - e: name
  - f: lazy evaluation
- 48) Parameter is passed into the first procedure by lazy evaluation and passed on to the second procedure by:
- a. value
  - b. reference
  - c. result
  - d. result
  - e: name
  - f: lazy evaluation
- 49) Describe how to pass a variable number of parameters to some procedure. Describe at least two different ways to do this.
- 50) How can you return a function's result on the stack?
- 51) What's the best way to return a really large function result?
- 52) What is a lex level?
- 53) What is a static link?
- 54) What does the term "scope" mean?
- 55) What is a "display"?
- 56) What does the term "address binding" mean?
- 57) What is the "lifetime" of a variable?
- 58) What is an intermediate variable?
- 59) How do you access intermediate variables using static links? Give an example.
- 60) How do you access intermediate variables using a display? Give an example.
- 61) How do you nest procedures in HLA?
- 62) What does the @lex function return?
- 63) What is one major difference between the *\_display\_* array and standard arrays?
- 64) What does the ENTER instruction do? Provide an algorithm that describes its operation.
- 65) What does the LEAVE instruction do? Provide an equivalent machine code sequence.

- 66) Why does HLA not emit the ENTER and LEAVE instructions in those procedures that have a display?
- 67) Provide a short code example that demonstrates how to pass an intermediate variable by value to another procedure.
- 68) Provide a short code example that demonstrates how to pass an intermediate variable by reference to another procedure.
- 69) Provide a short code example that demonstrates how to pass an intermediate variable by value/result to another procedure.
- 70) Provide a short code example that demonstrates how to pass an intermediate variable by result to another procedure.
- 71) Provide a short code example that demonstrates how to pass an intermediate variable by name to another procedure.
- 72) Provide a short code example that demonstrates how to pass an intermediate variable by lazy evaluation to another procedure.

## 6.2 Programming Problems

- 1) Rewrite Program 1.1 in Chapter One (Fibonacci number generation) to use a pass by reference parameter rather than a thunk parameter.
- 2) Write a function `ifx` that has the following prototype:

```
procedure ifx(expr:boolean; lazy trueVal:dword; lazy falseVal:dword);
```

The function should test *expr*'s value; if true, it should evaluate and return *trueVal*, else it should evaluate and return *falseVal*. Write a main program that tests the execution of this function.

- 3) Write an iterator that returns all "words" of a given length. The iterator should have the following prototype:

```
iterator wordOfLength(length:uns32); // returns("eax");
```

The iterator should allocate a string with *length* characters on the heap, initialize this string, and return a pointer to the string in the EAX register. On each call to this iterator, it should return the next string of alphabetic characters using a lexicographical ordering. E.g., for strings of length three, the iterator would return aaa, aab, aac, aad, ..., aaz, aba, abb, abc, ..., zzz. Write a main program to test this word generator. Don't forget to free the storage associated with each string in the main program when you're done with the string.

- 4) Modify the program in programming project (3) so that it only returns strings that have a maximum of two consonants in a row and a maximum of three vowels in a row.
- 5) Write a "Tic-Tac-Toe" game that uses coroutines to make each move. One coroutine should prompt the "X" player for a move, the second coroutine should prompt the "O" player for a move (note that the moves are made by players, not by the computer). The main program/coroutine should call the other two coroutines and determine if there was a win/loss/draw after each move.
- 6) Modify programming project (5) so that the computer makes the moves for the "O" player.
- 7) Write a factorial function ( $n!$ ) that passes a real80 parameter on the FPU stack and returns the real80 result on the FPU stack. (note:  $n! = 1*2*3*...*n$ ).
- 8) Write the equivalent of `cs.difference` that passes the two character sets to the function in the MMX registers MM0 / MM1 and MM2 / MM3. Return the character sets' difference in MM0 / MM1.
- 9) Write a "printstr" procedure that expects a pointer to a zero-terminated sequence of characters to follow the call to *printstr* in the code stream. This procedure should print the string to the standard output device. A typical call will look like the following:

```
static
 staticStrVar: char; nostorage;
 byte "Hello world", 0;
 .
 .
 .
 call printstr
 dword staticStrVar
```

Note that this function must work with any zero terminated string; don't assume the string is an HLA string. Write a main program that makes several calls to *printstr* and tests this function.

### 6.3 Laboratory Exercises

---

# Answers to Selected Exercises

# Appendix A

To be written.

My apologies that this isn't ready yet, but other chapters and appendices in this text have a higher priority. I will get around to this appendix eventually.

In the meantime, if you have some questions about the answers to any exercises in this text, please feel free to post a question to one of the internet newsgroups like "comp.lang.asm.x86" or "alt.lang.asm". Because of the high volume of email I receive daily, I will not answer questions sent to me via email. Note that posting the message to the net is very efficient because others get to share the solution. So please post your questions there.

# HLA Programming Style Guidelines

# Appendix C

---

## 1.1 Introduction

Most people consider assembly language programs difficult to read. While there are a multitude of reasons why people feel this way, the primary reason is that assembly language does not make it easy for programmers to write readable programs. This doesn't mean it's impossible to write readable programs, only that it takes an extra effort on the part of an assembly language programmer to produce readable code.

One of the design goals of the High Level Assembler (HLA) was to make it possible for assembly language programmers to write readable assembly language programs. Nevertheless, without discipline, pandemonium will result in any program of any decent size. Even if you adhere to a fixed set of style guidelines, others may still have trouble reading and understanding your code. Equally important to following a set of style guidelines is that you following a generally accepted set of style guidelines; guidelines that others are familiar and agree with. The purpose of this appendix, written by the designer of the HLA language, is to provide a consistent set of guidelines that HLA programmers can use consistently. Unless you can show a good reason to violate these rules, you should following them carefully when writing HLA programs; other HLA programmers will thank you for this.

---

### 1.1.1 Intended Audience

Of course, an assembly language program is going to be nearly unreadable to someone who doesn't know assembly language. This is true for almost any programming language. Other than burying a tutorial on 80x86 assembly language in a program's comments, there is no way to address this problem<sup>1</sup> other than to assume that the reader is familiar with assembly language programming and specifically HLA.

In view of the above, it makes sense to define an "intended audience" that we intend to have read our assembly language programs. Such a person should:

- Be a reasonably competent 80x86 assembly language/HLA programmer.
- Be reasonably familiar with the problem the assembly language program is attempting to solve.
- Fluently read English<sup>2</sup>.
- Have a good grasp of high level language concepts.
- Possess appropriate knowledge for someone working in the field of Computer Science (e.g., understands standard algorithms and data structures, understands basic machine architecture, and understands basic discrete mathematics).

---

### 1.1.2 Readability Metrics

One has to ask "What is it that makes one program more readable than another?" In other words, how do we measure the "readability" of a program? The usual metric, "I know a well-written program when I see one" is inappropriate; for most people, this translates to "If your programs look like my better programs then they are readable, otherwise they are not." Obviously, such a metric is of little value since it changes with every person.

To develop a metric for measuring the readability of an assembly language program, the first thing we must ask is "Why is readability important?" This question has a simple (though somewhat flippant) answer:

- 
1. Doing so (inserting an 80x86 tutorial into your comments) would wind up making the program *less* readable to those who already know assembly language since, at the very least, they'd have to skip over this material; at the worst they'd have to read it (wasting their time).
  2. Or whatever other natural language is in use at the site(s) where you develop, maintain, and use the software.

Readability is important because programs are *read* (furthermore, a line of code is typically read ten times more often than it is written). To expand on this, consider the fact that most programs are read and maintained by other programmers (Steve McConnell claims that up to ten generations of maintenance programmers work on a typical real world program before it is rewritten from scratch; furthermore, they spend up to 60% of their effort on that code simply figuring out how it works). The more readable your programs are, the less time these other people will have to spend figuring out what your program does. Instead, they can concentrate on adding features or correcting defects in the code.

For the purposes of this document, we will define a "readable" program as one that has the following trait:

- A "readable" program is one that a competent programmer (one who is familiar with the problem the program is attempting to solve) can pick up, without ever having seen the program before, and fully comprehend the entire program in a minimal amount of time.

That's a tall order! This definition doesn't sound very difficult to achieve, but few non-trivial programs ever really achieve this status. This definition suggests that an appropriate programmer (i.e., one who is familiar with the problem the program is trying to solve) can pick up a program, read it at their normal reading pace (just once), and fully comprehend the program. Anything less is not a "readable" program.

Of course, in practice, this definition is unusable since very few programs reach this goal. Part of the problem is that programs tend to be quite long and few human beings are capable of managing a large number of details in their head at one time. Furthermore, no matter how well-written a program may be, "a competent programmer" does not suggest that the programmer's IQ is so high they can read a statement a fully comprehend its meaning without expending much thought. Therefore, we must define readability, not as a boolean entity, but as a scale. Although truly unreadable programs exist, there are many "readable" programs that are less readable than other programs. Therefore, perhaps the following definition is more realistic:

- A readable program is one that consists of one or more *modules*. A competent program should be able to pick a given module in that program and achieve an 80% comprehension level by expending no more than an average of one minute for each statement in the program.

An 80% comprehension level means that the programmer can correct bugs in the program and add new features to the program without making mistakes due to a misunderstanding of the code at hand.

---

### 1.1.3 How to Achieve Readability

The "I'll know one when I see one" metric for readable programs provides a big hint concerning how one should write programs that are readable. As pointed out early, the "I'll know it when I see it" metric suggests that an individual will consider a program to be readable if it is very similar to (good) programs that this particular person has written. This suggests an important trait that readable programs must possess: consistency. If all programmers were to write programs using a consistent style, they'd find programs written by others to be similar to their own, and, therefore, easier to read. This single goal is the primary purpose of this appendix - to suggest a consistent standard that everyone will follow.

Of course, consistency by itself is not good enough. Consistently bad programs are not particularly easy to read. Therefore, one must carefully consider the guidelines to use when defining an all-encompassing standard. The purpose of this paper is to create such a standard. However, don't get the impression that the material appearing in this document appears simply because it sounded good at the time or because of some personal preferences. The material in this paper comes from several software engineering texts on the subject (including *Elements of Programming Style*, *Code Complete*, and *Writing Solid Code*), nearly 20 years of personal assembly language programming experience, and research that led to the development of a set of generic programming guidelines for industrial use.

This document assumes consistent usage by its readers. Therefore, it concentrates on a lot of mechanical and psychological issues that affect the readability of a program. For example, uppercase letters are harder to read than lower case letters (this is a well-known result from psychology research). It takes longer

for a human being to recognize uppercase characters, therefore, an average human being will take more time to read text written all in upper case. Hence, this document suggests that one should avoid the use of uppercase sequences in a program. Many of the other issues appearing in this document are in a similar vein; they suggest minor changes to the way you might write your programs that make it easier for someone to recognize some pattern in your code, thus aiding in comprehension.

---

### 1.1.4 How This Document is Organized

This document follows a top-down discussion of readability. It starts with the concept of a program. Then it discusses modules. From there it works its way down to procedures. Then it talks about individual statements. Beyond that, it talks about components that make up statements (e.g., instructions, names, and operators). Finally, this paper concludes by discussing some orthogonal issues.

Section Two discusses programs in general. It primarily discusses documentation that must accompany a program and the organization of source files. It also discusses, briefly, configuration management and source code control issues. Keep in mind that figuring out how to build a program (make, assemble, link, test, debug, etc.) is important. If your reader fully understands the "heapsort" algorithm you are using, but cannot build an executable module to run, they still do not fully understand your program.

Section Three discusses how to organize modules in your program in a logical fashion. This makes it easier for others to locate sections of code and organizes related sections of code together so someone can easily find important code and ignore unimportant or unrelated code while attempting to understand what your program does.

Section Four discusses the use of procedures within a program. This is a continuation of the theme in Section Three, although at a lower, more detailed, level.

Section Five discusses the program at the level of the statement. This (large) section provides the meat of this proposal. Most of the rules this paper presents appear in this section.

Section Six discusses comments and other documentation appearing within the source code.

Section Seven discusses those items that make up a statement (labels, names, instructions, operands, operators, etc.) This is another large section that presents a large number of rules one should follow when writing readable programs. This section discusses naming conventions, appropriateness of operators, and so on.

Section Eight discusses data types and other related topics.

---

### 1.1.5 Guidelines, Rules, Enforced Rules, and Exceptions

Not all rules are equally important. For example, a rule that you check the spelling of all the words in your comments is probably less important than suggesting that the comments all be in English<sup>3</sup>. Therefore, this paper uses three designations to keep things straight: Guidelines, Rules, and Enforced Rules.

A Guideline is a suggestion. It is a rule you should follow unless you can verbally defend why you should break the rule. As long as there is a good, defensible, reason, you should feel no apprehension violated a guideline. Guidelines exist in order to encourage consistency in areas where there are no good reasons for choosing one methodology over another. You shouldn't violate a Guideline just because you don't like it -- doing so will make your programs inconsistent with respect to other programs that do follow the Guideline (and, therefore, harder to read), however, you shouldn't lose any sleep because you violated a Guideline.

Rules are much stronger than Guidelines. You should never break a rule unless there is some external reason for doing so (e.g., making a call to a library routine forces you to use a bad naming convention). Whenever you feel you must violate a rule, you should verify that it is reasonable to do so in a peer review with at least two peers. Furthermore, you should explain in the program's comments why it was necessary

---

3. You may substitute the local language in your area if it is not English.

to violate the rule. Rules are just that -- rules to be followed. However, there are certain situations where it may be necessary to violate the rule in order to satisfy external requirements or even make the program more readable.

Enforced Rules are the toughest of the lot. You should *never* violate an enforced rule. If there is ever a true need to do this, then you should consider demoting the Enforced Rule to a simple Rule rather than treating the violation as a reasonable alternative.

An Exception is exactly that, a known example where one would commonly violate a Guideline, Rule, or (very rarely) Enforced Rule. Although exceptions are rare, the old adage "Every rule has its exceptions..." certainly applies to this document. The Exceptions point out some of the common violations one might expect.

Of course, the categorization of Guidelines, Rules, Enforced Rules, and Exceptions herein is one man's opinion. At some organizations, this categorization may require reworking depending on the needs of that organization.

### 1.1.6 Source Language Concerns

This document will assume that the entire program is written in 80x86 assembly language using the HLA assembler/compiler. Although this organization is rare in commercial applications, this assumption will, in no way, invalidate these guidelines. Other guidelines exist for various high level languages (including a set written by this paper's author). You should adopt a reasonable set of guidelines for the other languages you use and apply these guidelines to the 80x86 assembly language modules in the program.

## 1.2 Program Organization

A source program generally consists of one or more source, object, and library files. As a project gets larger and the number of files increases, it becomes difficult to keep track of the files in a project. This is especially true if a number of different projects share a common set of source modules. This section will address these concerns.

### 1.2.1 Library Functions

A library, by its very nature, suggests stability. Ignoring the possibility of software defects, one would rarely expect the number or function of routines in a library to vary from project to project. A good example is the "HLA Standard Library." One would expect "stdout.put" to behave identically in two different programs that use the Standard Library. Contrast this against two programs, each of which implement their own version of *stdout.put*. One could not reasonably assume both programs have identical implementations<sup>4</sup>. This leads to the following rule:

- |            |                                                                                                                                                                                                                                                         |
|------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Rule:      | Library functions are those routines intended for common reuse in many different assembly language programs. All assembly language (callable) libraries on a system should exist as ".lib" files and should appear in a "lib" or "hlalib" subdirectory. |
| Guideline: | "hlalib" is probably a better choice if you're using multiple languages since those other languages may need to put files in a "lib" directory.                                                                                                         |
| Exception: | It's probably reasonable to leave the HLA Standard Library's "hlalib.lib" file in the "hlahlalib" directory since most people expect it there.                                                                                                          |

The rule above ensures that the library files are all in one location so they are easy to find, modify, and review. By putting all your library modules into a single directory, you avoid configuration management

4. In fact, just the opposite is true. One should get concerned if both implementations *are* identical. This would suggest poor planning on the part of the program's author(s) since the same routine must now be maintained in two different programs.

problems such as having outdated versions of a library linking with one program and up-to-date versions linking with other programs.

---

## 1.2.2 Common Object Modules

This document defines a *library* as a collection of object modules that have wide application in many different programs. The HLA Standard Library is a typical example of a library. Some object modules are not so general purpose, but still find application in two or more different programs. Two major configuration management problems exist in this situation: (1) making sure the ".obj" file is up-to-date when linking it with a program; (2) Knowing which modules use the module so one can verify that changes to the module won't break existing code.

The following rules take care of case one:

- Rule:** If two different programs share an object module, then the associated source, object, and make-files for that module should appear in a subdirectory that is specific to that module (i.e., no other files in the subdirectory). The subdirectory name should be the same as the module name. If possible, you should create a set of link/alias/shortcuts to this subdirectory and place these links in the main directory of each of the projects that utilize the module. If links are not possible, you should place the module's subdirectory in a "\common" subdirectory.
- Enforced Rule:** Every subdirectory containing one or more modules should have a make file that will automatically generate the appropriate, up-to-date, ".obj" files. An individual, a batch file, or another make file should be able to automatically generate new object modules (if necessary) by simply executing the make program.
- Guideline:** Use Microsoft's nmake program. At the very least, use nmake acceptable syntax in your make-files.

The other problem, noting which projects use a given module is much more difficult. The obvious solution, commenting the source code associated with the module to tell the reader which programs use the module, is impractical. Maintaining these comments is too error-prone and the comments will quickly get out of phase and be worse than useless -- they would be incorrect. A better solution is to create alias and place this alias in the main subdirectory of each program that links the module.

- Guideline:** If a project uses a module that is not local to the project's subdirectory, create an alias to the file in the project's subdirectory. This makes locating the file very easy.

---

## 1.2.3 Local Modules

Local modules are those that a single program/project uses. Typically, the source and object code for each module appears in the same directory as the other files associated with the project. This is a reasonable arrangement until the number of files increases to the point that it is difficult to find a file in a directory listing. At that point, most programmers begin reorganizing their directory by creating subdirectories to hold many of these source modules. However, the placement, name, and contents of these new subdirectories can have a big impact on the overall readability of the program. This section will address these issues.

The first issue to consider is the contents of these new subdirectories. Since programmers rummaging through this project in the future will need to easily locate source files in a project, it is important that you organize these new subdirectories so that it is easy to find the source files you are moving into them. The best organization is to put each source module (or a small group of *strongly related* modules) into its own subdirectory. The subdirectory should bear the name of the source module minus its suffix (or the main module if there is more than one present in the subdirectory). If you place two or more source files in the same directory, ensure this set of source files forms a *cohesive* set (meaning the source files contain code that solve a single problem). A discussion of cohesiveness appears later in this document.

- Rule:** If a project directory contains too many files, try to move some of the modules to subdirectories within the project directory; give the subdirectory the same name as the source file with-

out the suffix. This will nearly reduce the number of files in half. If this reduction is insufficient, try categorizing the source modules (e.g., FileIO, Graphics, Rendering, and Sound) and move these modules to a subdirectory bearing the name of the category.

**Enforced Rule:** Each new subdirectory you create should have its own make file that will automatically assemble all source modules within that subdirectory, as appropriate.

**Enforced Rule:** Any new subdirectories you create for these source modules should appear within the directory containing the project. The only exceptions are those modules that are, or you anticipate, sharing with other projects. See “Common Object Modules” on page 1375 for more details.

Stand-alone assembly language programs generally contain a "main" procedure – the first program unit that executes when the operating system loads the program into memory. For any programmer new to a project, this procedure is the *anchor* where one first begins reading the code and the point where the reader will continually refer. Therefore, the reader should be able to easily locate this source file. The following rule helps ensure this is the case:

**Rule:** The source module containing the *main program* should have the same name as the executable (obviously the suffix will be different). For example, if the "Simulate 886" program's executable name is "Sim886.exe" then you should find the main program in the "Sim886.hla" source file.

Finding the source file that contains the main program is one thing. Finding the main program itself can be almost as hard. Assembly language lets you give the main program any name you want. However, to make the main procedure easy to find (both in the source code and at the O/S level), you should actually name this program "main". See “Module Organization” on page 1377 for more details about the placement of the main program. An alternative is to give the main program's source file the name of the project.

**Guideline:** The name of the main procedure in an assembly language program should be "main" or the name of the entire project.

## 1.2.4 Program Make Files

Every project, even if it contains only a single source module, should have an associated make file. If someone wants to assemble your program, they should not have to worry about what program (e.g., HLA) to use to compile the program, what command line options to use, what library modules to use, etc. They should be able to type "nmake"<sup>5</sup> and wind up with an executable program. Even if assembling the program consists of nothing more than typing the name of the assembler and the source file, you should still have a make file. Someone else may not realize that's all that is necessary.

**Enforced Rule:** The main project directory should contain a make file that will automatically generate an executable (or other expected object module) in response to a simple make/nmake command.

**Rule:** If your project uses object modules that are not in the same subdirectory as the main program's module, you should test the ".obj" files for those modules and execute the corresponding make files in their directories if the object code is out of date. You can assume that library files are up to date.

**Guideline:** Avoid using fancy "make" features. Most programmers only learn the basics about make and will not be able to understand what your make file is doing if you fully exploit the make language. Especially avoid the use of default rules since this can create havoc if someone arbitrarily adds or removes files from the directory containing the make file.

5. Or whatever make program you normally use.

---

## 1.3 Module Organization

A module is a collection of objects that are logically related. Those objects may include constants, data types, variables, and program units (e.g., functions, procedures, etc.). Note that objects in a module need not be *physically* related. For example, it is quite possible to construct a module using several different source files. Likewise, it is quite possible to have several different modules in the same source file. However, the best modules are physically related as well as logically related; that is, all the objects associated with a module exist in a single source file (or directory if the source file would be too large) and nothing else is present.

Modules contain several different objects including constants, types, variables, and program units (routines). Modules shares many of the attributes with routines (program units); this is not surprising since routines are the major component of a typical module. However, modules have some additional attributes of their own. The following sections describe the attributes of a well-written module.

Note: *Unit* and *package* are both synonyms for the term *module*.

---

### 1.3.1 Module Attributes

A module is a generic term that describes a set of program related objects (program units as well as data and type objects) that are somehow coupled. Good modules share many of the same attributes as good program units as well as the ability to hide certain details from code outside the module.

---

#### 1.3.1.1 Module Cohesion

Modules exhibit the following different kinds of *cohesion* (listed from good to bad):

- Functional or logical cohesion exists if the module accomplishes exactly one (simple) task.
- Sequential or *pipelined* cohesion exists when a module does several sequential operations that must be performed in a certain order with the data from one operation being fed to the next in a “filter-like” fashion.
- Global or *communicational* cohesion exists when a module performs a set of operations that make use of a common set of data, but are otherwise unrelated.
- Temporal cohesion exists when a module performs a set of operations that need to be done at the same time (though not necessarily in the same order). A typical initialization module is an example of such code.
- Procedural cohesion exists when a module performs a sequence of operations in a specific order, but the only thing that binds them together is the order in which they must be done. Unlike sequential cohesion, the operations do not share data.
- State cohesion occurs when several different (unrelated) operations appear in the same module and a state variable (e.g., a parameter) selects the operation to execute. Typically such modules contain a case (switch) or **if..elseif..elseif...** statement.
- No cohesion exists if the operations in a module have no apparent relationship with one another.

The first three forms of cohesion above are generally acceptable in a program. The fourth (temporal) is probably okay, but you should rarely use it. The last three forms should almost never appear in a program. For some reasonable examples of module cohesion, you should consult “Code Complete”.

Guideline: Design good modules! *Good modules exhibit strong cohesion*. That is, a module should offer a (small) group of services that are logically related. For example, a “printer” module might provide all the services one would expect from a printer. The individual routines within the module would provide the individual services.

### 1.3.1.2 Module Coupling

Coupling refers to the way that two modules communicate with one another. There are several criteria that define the level of coupling between two modules:

- Cardinality- the number of objects communicated between two modules. The fewer objects the better (i.e., fewer parameters).
- Intimacy- how “private” is the communication? Parameter lists are the most private form; private data fields in a class or object are next level; public data fields in a class or object are next, global variables are even less intimate, and passing data in a file or database is the least intimate connection. Well-written modules exhibit a high degree of intimacy.
- Visibility- this is somewhat related to intimacy above. This refers to how visible the data is to the entire system that you pass between two modules. For example, passing data in a parameter list is direct and very visible (you always see the data the caller is passing in the call to the routine); passing data in global variables makes the transfer less visible (you could have set up the global variable long before the call to the routine). Another example is passing simple (scalar) variables rather than loading up a bunch of values into a structure/record and passing that structure/record to the callee.
- Flexibility- This refers to how easy it is to make the connection between two routines that may not have been originally intended to call one another. For example, suppose you pass a structure containing three fields into a function. If you want to call that function but you only have three data objects, not the structure, you would have to create a dummy structure, copy the three values into the field of that structure, and then call the function. On the other hand, had you simply passed the three values as separate parameters, you could still pass in structures (by specifying each field) as well as call the function with separate values. The module containing this later function is more flexible.

A module is *loosely coupled* if its functions exhibit low cardinality, high intimacy, high visibility, and high flexibility. Often, these features are in conflict with one another (e.g., increasing the flexibility by breaking out the fields from a structures [a good thing] will also increase the cardinality [a bad thing]). It is the traditional goal of any engineer to choose the appropriate compromises for each individual circumstance; therefore, you will need to carefully balance each of the four attributes above.

A module that uses loose coupling generally contains fewer errors per KLOC (thousands of lines of code). Furthermore, modules that exhibit loose coupling are easier to reuse (both in the current and future projects). For more information on coupling, see the appropriate chapter in “Code Complete”.

Guideline: Design good modules! *Good modules exhibit loose coupling.* That is, there are only a few, well-defined (visible) interfaces between the module and the outside world. Most data is private, accessible only through accessor functions (see information hiding below). Furthermore, the interface should be flexible.

Guideline: Design good modules! *Good modules exhibit information hiding.* Code outside the module should only have access to the module through a small set of public routines. All data should be private to that module. A module should implement an *abstract data type*. All interface to the module should be through a well-defined set of operations.

### 1.3.1.3 Physical Organization of Modules

Many languages provide direct support for modules (e.g., units in HLA, packages in Ada, modules in Modula-2, and units in Delphi/Pascal). Some languages provide only indirect support for modules (e.g., a source file in C/C++). Others, like BASIC, don’t really support modules, so you would have to simulate them by physically grouping objects together and exercising some discipline. The primary mechanism in HLA for hiding names from other modules is to implement a module as an individual source file and publish only those names that are part of the module’s interface to the outside world (i.e., EXTERNAL directives in a header file).

Rule: Each module should completely reside in a single source file. If size considerations prevent

this, then all the source files for a given module should reside in a subdirectory specifically designated for that module.

Some people have the crazy idea that modularization means putting each function in a separate source file. Such *physical modularization* generally impairs the readability of a program more than it helps. Strive instead for *logical modularization*, that is, defining a module by its actions rather than by source code syntax (e.g., separating out functions).

This document does not address the decomposition of a problem into its modular components. Presumably, you can already handle that part of the task. There are a wide variety of texts on this subject if you feel weak in this area.

### 1.3.1.4 Module Interface

In any language system that supports modules, there are two primary components of a module: the interface component that publicizes the module visible names and the implementation component that contains the actual code, data, and private objects. HLA (like most assemblers) uses a scheme that is very similar to the one C/C++ uses. There are directives that let you import and export names. Like C/C++, you could place these directives directly in the related source modules. However, such code is difficult to maintain (since you need to change the directives in every file whenever you modify a public name). The solution, as adopted in the HLA programming language, is to use *header files*. Header files contain all the public definitions and exports (as well as common data type definitions and constant definitions). The header file provides the *interface* to the other modules that want to use the code present in the implementation module.

The HLA EXTERNAL attribute is perfect for creating interface/header files. When you use EXTERNAL within a source module that defines a symbol, EXTERNAL behaves like a *public* directive, exporting the name to other modules. When you use EXTERNAL within a source modules that refers to an external name, EXTERNAL declares the object to be supplied in a different module. This lets you place an EXTERNAL declaration of an object in a single header file and include this file into both the modules that import and export the public names.

- Rule: Keep all module interface directives (EXTERNAL) in a single header file for a given module. Place any other common data type definitions and constant definitions in this header file as well.
- Guideline: There should only be a single header file associated with any one module (even if the module has multiple source files associated with it). If, for some reason, you feel it is necessary to have multiple header files associated with a module, you should create a single file that includes all of the other interface files. That way a program that wants to use all the header files need only include the single file.

When designing header files, make sure you can include a file more than once without ill effects (e.g., duplicate symbol errors). The traditional way to do this is to put a #IF statement like the following around all the statements in a header file:

```
; Module: MyHeader.hhf

#if(@defined(MyHeader_hhf))
?MyHeader_hhf:=true; // Actual type and value doesn't really matter.
 .
 . ;Statements in this header file.
 .
#endif
```

The first time a source file includes "MyHeader.hhf" the symbol "MyHeader\_hhf" is undefined. Therefore, the assembler will process all the statements in the header file. In successive include operations (during the same assembly) the symbol "MyHeader\_hhf" is already defined, so the assembler ignores the body of the include file.

My would you ever include a file twice? Easy. Some header files may include other header files. By including the file "YourHeader.hhf" a module might also be including "MyHeader.hhf" (assuming "Your-

Header.hhf" contains the appropriate include directive). Your main program, that includes "YourHeader.hhf" might also need "MyHeader.hhf" so it explicitly includes this file not realizing "YourHeader.hhf" has already processed "MyHeader.hhf" thereby causing symbol redefinitions.

- Rule: Always put an appropriate #IF statement around all the definitions in a header file to allow multiple inclusion of the header file without ill effect.
- Guideline: Use the ".hhf" suffix for HLA header/interface files.
- Rule: Include files for library functions on a system should exist as ".hhf" files and should appear in the "\include" or "\hla\include" subdirectory.
- Guideline: "\hla\include" is probably a better choice if you're using multiple languages since those other languages may need to put files in a "\include" directory.
- Exception: It's probably reasonable to leave the HLA Standard Library's "stdlib.hhf" file in the "\hla\include" directory since most people expect it there.

You can also prevent multiple inclusion of a file by using the #INCLUDEONCE directive. However, it's safer to use the #IF.#ENDIF approach since that doesn't rely on the user of your include file to use the right directive.

## 1.4 Program Unit Organization

A program unit is any procedure, function, coroutine, iterator, subroutine, subprogram, routine, or other term that describes a section of code that abstracts a set of common operations on the computer. This text will simply use the term *procedure* or *routine* to describe these concepts.

Routines are closely related to modules, since they tend to be the major component of a module (along with data, constants, and types). Hence, many of the attributes that apply to a module also apply to routines. The following paragraphs, at the expense of being redundant, repeat the earlier definitions so you don't have to flip back to the previous sections.

### 1.4.1 Routine Cohesion

Routines exhibit the following kinds of *cohesion* (listed from good to bad and are mostly identical to the kinds of cohesion that modules exhibit):

- Functional or logical cohesion exists if the routine accomplishes exactly one (simple) task.
- Sequential or *pipelined* cohesion exists when a routine does several sequential operations that must be performed in a certain order with the data from one operation being fed to the next in a "filter-like" fashion.
- Global or *communicational* cohesion exists when a routine performs a set of operations that make use of a common set of data, but are otherwise unrelated.
- Temporal cohesion exists when a routine performs a set of operations that need to be done at the same time (though not necessarily in the same order). A typical initialization routine is an example of such code.
- Procedural cohesion exists when a routine performs a sequence of operations in a specific order, but the only thing that binds them together is the order in which they must be done. Unlike sequential cohesion, the operations do not share data.
- State cohesion occurs when several different (unrelated) operations appear in the same routine and a state variable (e.g., a parameter) selects the operation to execute. Typically such routines contain a case (switch) or **if..elseif..elseif...** statement.
- No cohesion exists if the operations in a routine have no apparent relationship with one another.

The first three forms of cohesion above are generally acceptable in a program. The fourth (temporal) is probably okay, but you should rarely use it. The last three forms should almost never appear in a program. For some reasonable examples of routine cohesion, you should consult "Code Complete".

Guideline: All routines should exhibit good cohesiveness. Functional cohesiveness is best, followed by sequential and global cohesiveness. Temporal cohesiveness is okay on occasion. You should avoid the other forms.

## 1.4.2 Routine Coupling

Coupling refers to the way that two routines communicate with one another. There are several criteria that define the level of coupling between two routines; again these are identical to the types of coupling that modules exhibit:

- Cardinality- the number of objects communicated between two routines. The fewer objects the better (i.e., fewer parameters).
- Intimacy- how “private” is the communication? Parameter lists are the most private form; private data fields in a class or object are next level; public data fields in a class or object are next, global variables are even less intimate, and passing data in a file or database is the least intimate connection. Well-written routines exhibit a high degree of intimacy.
- Visibility- this is somewhat related to intimacy above. This refers to how visible the data is to the entire system that you pass between two routines. For example, passing data in a parameter list is direct and very visible (you always see the data the caller is passing in the call to the routine); passing data in global variables makes the transfer less visible (you could have set up the global variable long before the call to the routine). Another example is passing simple (scalar) variables rather than loading up a bunch of values into a structure/record and passing that structure/record to the callee.
- Flexibility- This refers to how easy it is to make the connection between two routines that may not have been originally intended to call one another. For example, suppose you pass a structure containing three fields into a function. If you want to call that function but you only have three data objects, not the structure, you would have to create a dummy structure, copy the three values into the field of that structure, and then call the routine. On the other hand, had you simply passed the three values as separate parameters, you could still pass in structures (by specifying each field) as well as call the routine with separate values.

A function is *loosely coupled* if it exhibits low cardinality, high intimacy, high visibility, and high flexibility. Often, these features are in conflict with one another (e.g., increasing the flexibility by breaking out the fields from a structures [a good thing] will also increase the cardinality [a bad thing]). It is the traditional goal of any engineer to choose the appropriate compromises for each individual circumstance; therefore, you will need to carefully balance each of the four attributes above.

A program that uses loose coupling generally contains fewer errors per KLOC (thousands of lines of code). Furthermore, routines that exhibit loose coupling are easier to reuse (both in the current and future projects). For more information on coupling, see the appropriate chapter in “Code Complete”.

Guideline: Coupling between routines in source code should be loose.

## 1.4.3 Routine Size

Sometime in the 1960’s, someone decided that programmers could only look at one page in a listing at a time, therefore routines should be a maximum of one page long (66 lines, at the time). In the 1970’s, when interactive computing became popular, this was adjusted to 24 lines -- the size of a terminal screen. In fact, there is very little empirical evidence to suggest that small routine size is a good attribute. In fact, several studies on code containing artificial constraints on routine size indicate just the opposite -- shorter routines often contain more bugs per KLOC<sup>6</sup>.

6. This happens because shorter functions invariably have stronger coupling, leading to integration errors.

A routine that exhibits functional cohesiveness is the right size, almost regardless of the number of lines of code it contains. You shouldn't artificially break up a routine into two or more subroutines (e.g., sub\_partI and sub\_partII) just because you feel a routine is getting to be too long. First, verify that your routine exhibits strong cohesion and loose coupling. If this is the case, the routine is not too long. Do keep in mind, however, that a long routine is probably a good indication that it is performing several actions and, therefore, does not exhibit strong cohesion.

Of course, you can take this too far. Most studies on the subject indicate that routines in excess of 150-200 lines of code tend to contain more bugs and are more costly to fix than shorter routines. Note, by the way, that you do not count blank lines or lines containing only comments when counting the lines of code in a program.

Also note that most studies involving routine size deal with HLLs. A comparable HLA routine will contain more lines of code than the corresponding HLL routine. Therefore, you can expect your routines in assembly language to be a little longer.

- Guideline: Do not let artificial constraints affect the size of your routines. If a routine exceeds about 200-250 lines of code, make sure the routine exhibits functional or sequential cohesion. Also look to see if there aren't some generic subsequences in your code that you can turn into stand alone routines.
- Rule: Never shorten a routine by dividing it into  $n$  parts that you would always call in the appropriate sequence as a way of shortening the original routine.

## 1.5 Statement Organization

In an assembly language program, the author must work extra hard to make a program readable. By following a large number of rules, you can produce a program that is readable. However, by breaking a single rule *no matter how many other rules you've followed*, you can render a program unreadable. Nowhere is this more true than how you organize the statements within your program.

### 1.5.1 Writing "Pure" Assembly Code

Consider the following example taken from "The Art of Assembly Language Programming/DOS Edition" and converted to HLA:

The Microsoft Macro Assembler is a free form assembler. The various fields of an assembly language statement may appear in any column (as long as they appear in the proper order). Any number of spaces or tabs can separate the various fields in the statement. To the assembler, the following two code sequences are identical:

```

mov(0, ax);
mov(ax, bx);
add(dx, ax);
mov(ax, cx);

```

---

```

mov(0, ax);
 mov(ax, bx);
add(ad, ax);
 mov(ax, cx);

```

The first code sequence is much easier to read than the second (if you don't think so, perhaps you should go see a doctor!). With respect to readability, the judicious use of spacing within your program can make all the difference in the world.

While this is an extreme example, do note that it only takes a few mistakes to have a large impact on the readability of a program.

HLA is a free-form assembler insofar as it does not place stringent formatting requirements on its statements. For example, you can put multiple statements on a single line as well as spread a single statement across multiple lines. However, the freedom to arrange these statements in any manner is one of the primary contributors to hard to read assembly language programs. Although HLA lets you enter your programs in free-form, there is absolutely no reason you cannot adopt a fixed format. Doing so generally helps make an assembly language program much easier to read. Here are the rules you should use:

- Guideline: Only place one statement per source line.
- Rule: Within a given block of code, all mnemonics should start in the same column.
- Exception: See the indentation rules appearing later in this documentation.
- Guideline: Try to always start the comment fields on adjacent source lines in the same column (note that it is impractical to always start the comment field in the same column throughout a program).

Most people learn a high level language prior to learning assembly language. They have been firmly taught that readable (HLL) programs have their control structures properly indented to show the structure of the program. Indentation works great when you have a *block structured* language. In old-fashioned assembly language this scheme doesn't work; one of the principle benefits to HLA is that it lets you continue to use the indentation schemes you're familiar with in HLLs like C/C++ and Pascal. However, this assumes that you're using the HLA high level control structures. If you choose to work in "pure" assembly language, then these rules don't apply. The following discussion assumes the use of "pure" assembly language code; we'll address HLA's high level control statements later.

If you need to set off a sequence of statements from surrounding code, the best thing you can do is use blank lines in your source code. For a small amount of detachment, to separate one computation from another for example, a single blank line is sufficient. To really show that one section of code is special, use two, three, or even four blank lines to separate one block of statements from the surrounding code. To separate two totally unrelated sections of code, you might use several blank lines and a row of dashes or asterisks to separate the statements. E.g.,

```

mov(FileSpec, eax);
mov(0, cl);
call MyFunction;
jc Error;

//*****

mov(&fileRecords, edi);
mov(&files, ebx);
sub(2, ebx);

```

- Guideline: Use blank lines to separate special blocks of code from the surrounding code. Use an aesthetic looking row of asterisks or dashes if you need a stronger separation between two blocks of code (do not overdo this, however).

If two sequences of assembly language statements correspond to roughly two HLL statements, it's generally a good idea to put a blank line between the two sequences. This helps clarify the two segments of code in the reader's mind. Of course, it is easy to get carried away and insert too much white space in a program, so use some common sense here.

- Guideline: If two sequences of code in assembly language correspond to two adjacent statements in a HLL, then use a blank line to separate those two assembly sequences (assuming the sequences are real short).

A common problem in any language (not just assembly language) is a line containing a comment that is adjacent to one or two lines containing code. Such a program is very difficult read because it is hard to

determine where the code ends and the comment begins (or vice-versa). This is especially true when the comments contain sample code. It is often quite difficult to determine if what you're looking at is code or comments; hence the following enforced rule:

**Enforced Rule:** Always put at least one blank line between code and comments (assuming, of course, the comment is sitting only a line by itself; that is, it is not an endline comment<sup>7</sup>).

## 1.5.2 Using HLA's High Level Control Statements

Since HLA's high level control statements are so similar to high level language control statements, it's not surprising to discover that you'll use the same formatting for HLA's statements as you would with those other HLLs. Most of these statements compile to very efficient machine code (usually matching what you'd write yourself if you were writing "pure" assembly code). Since their use can make your programs more readable, you should use them whenever practical.

**Guideline:** Use the HLA high level control structures when they are appropriate in your programs.

There are two problems advanced assembly programmers have with high level control structures: (1) the compiler for such statements (e.g., HLA) doesn't always generate the best code, and (2) the use of such statements encourages inefficient coding on the programmer's part.

HLA's control structures are relatively limited, so point (1) above isn't as big a problem as you might expect. Nevertheless, there will certainly be situations where HLA does not generate the same exact instruction sequence you would for a given control construct. Therefore, it's a good idea to become familiar with the low-level code that HLA emits for each of the control structures so that you can intelligently choose whether to use a high level or low level control structure in a given situation. A later appendix explains how HLA generates code for the high level control structures; you should study this material. Also note that HLA emits MASM compatible assembly code, so you can certainly study HLA's output if you've got any questions about the code HLA generates.

Point (2) above is something that HLA has no control over. It is quite true that if you write "C code with MOV instructions" in HLA, the code probably isn't going to be as efficient as pure assembly code. However, with a little discipline you can prevent this problem from occurring.

One of the benefits to using the high level control structures HLA provides is that you can now use indentation of your statements to better show the structure of the program. Since HLA's high level control structures are very similar to those found in traditional high level languages, you can use well-established programming conventions when indenting statements in your HLA programs. Here are some suggestions:

**Rule:** Indent statements within a high-level control block four space. The ENDxxxx clause that matches the statement should begin in the same column as the statement that starts a block.

```
// Example of nesting an IF..THEN..ENDIF statement:

 if(eax = 0) then
 << Indent these statements four spaces >>
 endif; // endif should be at the same level as the if statement.
```

**Guideline:** Avoid putting multiple statements on the same line.

The HLA programming language contains eight flow-of-control statements: two conditional selection statements (IF.THEN.ELSEIF.ELSE and SWITCH.CASE.DEFAULT.ENDSWITCH), five loops (WHILE.ENDWHILE, REPEAT.UNTIL, FOR.ENDFOR, FOREACH.ENDFOR, and FOREVER.ENDFOR), a program unit invocation (i.e., procedure call), and the statement sequence.

7. See the next section concerning comments for more information.

**Rule:** If your code contains a chain of `if..elseif..elseif.....elseif.....` statements, do not use the final `else` clause to handle a remaining case. Only use the final `else` to catch an error condition. If you need to test for some value in an `if..elseif..elseif....` chain, always test the value in an `if` or `elseif` statement.

The HLA Standard Library implements the multi-way selection statements (SWITCH) using a jump table. This means that the order of the cases within the selection statement is usually irrelevant. Placing the statements in a particular order rarely improves performance. Since the order is usually irrelevant to the compiler, you should organize the cases so that they are easy to read. There are two common organizations that make sense: sorted (numerically or alphabetically) or by frequency (the most common cases first). Either organization is readable; one drawback to this approach is that it is often difficult to predict which cases the program will execute most often.

**Guideline:** When using multi-way selection statements (`case/switch`) sort the cases numerically (alphabetically) or by frequency of expected occurrence.

There are three general categories of looping constructs available in common high-level languages—loops that test for termination at the beginning of the loop (e.g., `WHILE`), loops that test for loop termination at the bottom of the loop (e.g., `REPEAT..UNTIL`), and those that test for loop termination in the middle of the loop (e.g., `FOREVER..ENDFOR`). It is possible simulate any one of these loops using any of the others. This is particularly trivial with the `FOREVER..ENDFOR` construct:

```
/* Test for loop termination at beginning of FOREVER..ENDFOR */
```

```

forever
 breakif(ax = y);
 .
 .
 .
endfor;
```

```
/* Test for loop termination in the middle of FOREVER..ENDFOR */
```

```

forever
 .
 .
 .
 breakif(ax = y);
 .
 .
 .
endfor;
```

```
/* Test for loop termination at the end of FOREVER..ENDFOR */
```

```

forever
 .
 .
 .
 breakif(x = y);
endfor;
```

Given the flexibility of the `FOREVER..ENDFOR` control structure, you might question why one would even burden a compiler with the other loop statements. However, using the appropriate looping structure makes a program far more readable, therefore, you should never use one type of loop when the situation demands another. If someone reading your code sees a `FOREVER..ENDFOR` construct, they may think it's okay to insert statements before or after the exit statement in the loop. If your algorithm truly depends on `WHILE..ENDWHILE` or `REPEAT..UNTIL` semantics, the program may now malfunction.

**Rule:** Always use the most appropriate type of loop (categorized by termination test position). Never force one type of loop to behave like another.

Many languages provide a special case of the while loop that executes some number of times specified upon first encountering the loop (a *definite* loop rather than an *indefinite* loop). This is the “for” loop in most languages. The vast majority of the time a for loop sequences through a fixed range of value incrementing or decrementing the loop control variable by one. Therefore, most programmers automatically assume this is the way a for loop will operate until they take a closer look at the code. Since most programmers immediately expect this behavior, it makes sense to limit FOR loops to these semantics. If some other looping mechanism is desirable, you should use a WHILE loop to implement it (since the for loop is just a special case of the while loop). There are other reasons behind this decision as well.

**Rule:** “FOR” loops should always use an ordinal loop control variable (e.g., integer, char, boolean, enumerated type) and should always increment or decrement the loop control variable by one.

Most people expect the execution of a loop to begin with the first statement at the top of the loop, therefore,

**Rule:** All loops should have one entry point. The program should enter the loop with the instruction at the top of the loop.

Likewise, most people expect a loop to have a single exit point, especially if it’s a WHILE or REPEAT..UNTIL loop. They will rarely look closely inside a loop body to determine if there are “break” statements within the loop once they find one exit point. Therefore,

**Guideline:** Loops with a single exit point are more easily understood.

Whenever a programmer sees an empty loop, the first thought is that something is missing. Therefore,

**Guideline:** Avoid empty loops. If testing the loop termination condition produces some side effect that is the whole purpose of the loop, move that side effect into the body of the loop. If a loop truly has an empty body, place a comment like `/* nothing */` within your code.

Even if the loop body is not empty, you should avoid side effects in a loop termination expression. When someone else reads your code and sees a loop body, they may skim right over the loop termination expression and start reading the code in the body of the loop. If the (correct) execution of the loop body depends upon the side effect, the reader may become confused since s/he did not notice the side effect earlier. The presence of side effects (that is, having the loop termination expression compute some other value beyond whether the loop should terminate or repeat) indicates that you’re probably using the wrong control structure. Consider the following WHILE loop in HLA that is easily corrected:

```
while(mov(stdin.geti32(), ecx) != 0) do
 << statements >>
endwhile;
```

A better implementation of this code fragment would be to use a FOREVER..ENDFOR construct:

```
forever
 stdin.geti32();
 mov(eax, ecx);
 breakif(eax = 0);
 .
 .
 .
```

```
endfor;
```

**Rule:** Avoid side-effects in the computation of the loop termination expression (others may not be expecting such side effects). Also see the guideline about empty loops.

Like functions, loops should exhibit functional cohesion. That is, the loop should accomplish exactly one thing. It's very tempting to initialize two separate arrays in the same loop. You have to ask yourself, though, "what do you really accomplish by this?" You save about four machine instructions on each loop iteration, that's what. That rarely accounts for much. Furthermore, now the operations on those two arrays are tied together, you cannot change the size of one without changing the size of the other. Finally, someone reading your code has to remember two things the loop is doing rather than one.

**Guideline:** Make each loop perform only one function.

Programs are much easier to read if you read them from left to right, top to bottom (beginning to end). Programs that jump around quite a bit are much harder to read. Of course, the *jmp (goto)* statement is well-known for its ability to scramble the logical flow of a program, but you can produce equally hard to read code using other, structured, statements in a language. For example, a deeply nested set of if statements, some with and some without ELSE clauses, can be very difficult to follow because of the number of possible places the code can transfer depending upon the result of several different boolean expressions.

**Rule:** Code, as much as possible, should read from top to bottom.

**Rule:** Related statements should be grouped together and separated from unrelated statements with whitespace or comments.

In theory, a line of source code can be arbitrarily long. In practice, there are several practical limitations on source code lines. Paramount is the amount of text that will fit on a given terminal display device (we don't all have 21" high resolution monitors!) and what can be printed on a typical sheet of paper. Even with small fonts and wide carriage printers, keep in mind that many people like to print listings two-up or three-up in order to save paper. If this isn't enough to suggest an 80 character limit on source lines, McConnell suggests that longer lines are harder to read (remember, people tend to look at only the left side of the page while skimming through a listing).

**Enforced Rule:** Source code lines will not exceed 80 characters in length.

If a statement approaches the maximum limit of 80 characters, it should be broken up at a reasonable point and split across two lines. If the line is a control statement that involves a particularly long logical expression, the expression should be broken up at a logical point (e.g., at the point of a low-precedence operator outside any parentheses) and the remainder of the expression placed underneath the first part of the expression. E.g., (note that the following involves constant expressions, run-time expressions generally aren't very long):

```
#if
(
 ((x + y * z) < (ComputeProfits(1980,1990) / 1.0775))
 && (ValueOfStock[ThisYear] >= ValueOfStock[LastYear])
)

 << statements >>

#endif
```

Many statements (e.g., IF, WHILE, FOR, and function or procedure calls) contain a keyword followed by a parenthesis. If the expression appearing between the parentheses is too long to fit on one line, consider putting the opening and closing parentheses in the same column as the first character of the start of the statement and indenting the remaining expression elements. The example above demonstrates this for the "IF" statement. The following examples demonstrate this technique for other statements:

```
while
(
 SomeFunctionReturningAValueInEAX(with, lots, of, parameters)
 <= AFunctionReturningAValueInEBX(also, has, lots, of, parameters)
) do

 << Statements to execute >>

endwhile;

fileio.put
(
 outputFileHandle,
 "Error in module ",
 ModuleName,
 " at line #",
 LineNumber,
 ", encountered illegal value",
 nl
);
```

**Guideline:** For statements that are too long to fit on one physical 80-column line, you should break the statement into two (or more) lines at points in the statement that will have the least impact on the readability of the statement. This situation usually occurs immediately after low-precedence operators or after commas.

If a procedure, function, or other program unit has a particularly long actual or formal parameter list, each parameter should be placed on a separate line. The following examples demonstrate a procedure declaration and call using this technique:

```
procedure MyFunction
(
 NumberOfDataPoints: int32,
 X1Root: real32,
 X2Root: real32,
 var YIntercept: real32
);

MyFunction
(
 GetNumberOfPoints(RootArray), // Assume "RETURNS" value is EAX.
 RootArray[EBX*4],
 RootArray[ECX*4],
 Solution
);
```

**Rule:** If an actual or formal parameter list is too long to fit a function call or definition on a single line, then place each parameter on a separate line and align them so they are easy to read.

**Guideline:** If a boolean expression exceeds the length of the source line (usually 80 characters), then break the source line into pieces and align the parentheses associated with the statement underneath

the start of the statement.

This usually isn't a problem in HLA since expressions are very limited. However, if you call a function with a long parameter list you could run into this problem. One area where this problem does occur is when you're using HLA's hybrid control structures. For such sequences you should always place the statements associated with the boolean expression on separate lines and align the braces with the high level control structure, e.g.,

```

if
{
 cmp(ax, bx);;
 jne true;
 cmp(ax, 5);
 jl false;
 cmp(bx, 0);
 je false;
}

<< statements to execute on TRUE >>

endif;

```

**Rule:** Always put a blank line between a high level control statement and the nested statements associated with that statement. Likewise, put a blank line between the end of the nested statements and the corresponding ENDxxx clause of the statement. E.g.,

```

if(ax = 0) then
 <-- Blank line.
 << Nested Statements >>
 <-- Blank line.
endif;

```

HLA provides special symbols like “@c” and “@s” to denote flag bits within boolean expressions. Using statements like “if( @c ) then ... endif;” is semantically equivalent to using a conditional jump (JNC in this case) to jump around the THEN code. Not only is this statement semantically equivalent, it is exactly equivalent since it simply generates the JNC (or whatever) instruction to transfer control to the statement following the ENDIF. The difference between the two, from a readability point of view, is that JNC requires a statement label. As it turns out, the large number of statement labels that appear in an assembly language program contribute to the lack of readability. Hence, anything you can do to legitimately reduce the number of statement labels will improve the readability of your program. So,

**Guideline:** Try to use statements like “if(@c) then...endif;” rather than “jnc label; ... label:” in your programs to reduce the number of statement labels in the code. Combined with indentation, this will make your programs easier to read since the user doesn't have to search for a specific label associated with the branch (searching for the end of indentation is a much easier task).

---

## 1.6 Comments

Comments in an assembly language program generally come in two forms: *endline* comments and *standalone* comments<sup>8</sup>. As their names suggest, endline lines comments always occur at the end of a source statement and standalone comments sit on a line by themselves<sup>9</sup>. These two types of comments have distinct purposes, this section will explore their use and describe the attributes of a well-commented program.

---

8. This document will simply use the term *comments* when referring to standalone comments.

9. Since the label, mnemonic, and operand fields are all optional, it is legal to have a comment on a line by itself.

## 1.6.1 What is a Bad Comment?

It is amazing how many programmers claim their code is well-commented. Were you to count characters between (or after) the comment delimiters, they might have a point. Consider, however, the following comment:

```
mov(0, ax); //Set AX to zero.
```

Quite frankly, this comment is worse than no comment at all. It doesn't tell the reader anything the instruction itself doesn't tell and it requires the reader to take some of his or her precious time to figure out that the comment is worthless. If someone cannot tell that this instruction is setting AX to zero, they have no business reading an assembly language program. This brings up the first guideline of this section:

**Guideline:** Choose an intended audience for your source code and write the comments to that audience. For HLA source code, you can usually assume that the target audience are those who know a reasonable amount of HLA and assembly language.

Don't explain the actions of an assembly language instruction in your code unless that instruction is doing something that isn't obvious (and most of the time you should consider changing the code sequence if it isn't obvious what is going on). Instead, explain how that instruction is helping to solve the problem at hand. The following is a much better comment for the instruction above:

```
mov(0, ax); //AX is the resulting sum. Initialize it.
```

Note that the comment does not say "Initialize it to zero." Although there would be nothing intrinsically wrong with saying this, the phrase "Initialize it" remains true no matter what value you assign to AX. This makes maintaining the code (and comment) much easier since you don't have to change the comment whenever you change the constant associated with the instruction.

**Guideline:** Write your comments in such a way that minor changes to the instruction do not require that you change the corresponding comment.

**Note:** Although a trivial comment is bad (indeed, worse than no comment at all), the worst comment a program can have is one that is wrong. Consider the following statement:

```
mov(1, ax); //Set AX to zero.
```

It is amazing how long a typical person will look at this code trying to figure out how on earth the program sets AX to zero when it's obvious it does not do this. *People will always believe comments over code.* If there is some ambiguity between the comments and the code, they will assume that the code is tricky and that the comments are correct. Only after exhausting all possible options is the average person likely to concede that the comment must be incorrect.

**Enforced Rule:** Never allow incorrect comments in your program.

This is another reason not to put trivial comments like "Set AX to zero" in your code. As you modify the program, these are the comments most likely to become incorrect as you change the code and fail to keep the comments in sync. However, even some non-trivial comments can become incorrect via changes to the code. Therefore, always follow this rule:

**Enforced Rule:** Always update *all* comments affected by a code change immediately after making the code change.

Undoubtedly you've heard the phrase "make sure you comment your code as though someone else wrote it for you; otherwise in six months you'll wish you had." This statement encompasses two concepts. First, don't ever think that your understanding of the current code will last. While working on a given section of a program you're probably investing considerable thought and study to figure out what's going on. Six months down the road, however, you will have forgotten much of what you figured out and the comments can go a long way to getting you back up to speed quickly. The second point this code makes is the implication that others read and write code too. You will have to read someone else's code, they will have to read yours. If you write the comments the way you would expect others to write it for you, chances are pretty good that your comments will work for them as well.

**Rule:** Never use racist, sexist, obscene, or other exceptionally politically incorrect language in your comments. Undoubtedly such language in your comments will come back to embarrass you in the future. Furthermore, it's doubtful that such language would help someone better understand the program.

It's much easier to give examples of bad comments than it is to discuss good comments. The following list describes some of the worst possible comments you can put in a program (from worst up to barely tolerable):

- The absolute worst comment you can put into a program is an incorrect comment. Consider the following assembly statement:  

```
mov(10, ax); // Set AX to 11
```

 It is amazing how many programmers will automatically assume the comment is correct and try to figure out how this code manages to set the variable "A" to the value 11 when the code so obviously sets it to 10.
- The second worst comment you can place in a program is a comment that explains what a statement is doing. The typical example is something like "mov( 10, ax ); // Set 'A' to 10". Unlike the previous example, this comment is correct. But it is still worse than no comment at all because it is redundant and forces the reader to spend additional time reading the code (reading time is directly proportional to reading difficulty). This also makes it harder to maintain since slight changes to the code (e.g., "mov( 9, ax );") requires modifications to the comment that would not otherwise be required.
- The third worst comment in a program is an irrelevant one. Telling a joke, for example, may seem cute, but it does little to improve the readability of a program; indeed, it offers a distraction that breaks concentration.
- The fourth worst comment is no comment at all.
- The fifth worst comment is a comment that is obsolete or out of date (though not incorrect). For example, comments at the beginning of the file may describe the current version of a module and who last worked on it. If the last programmer to modify the file did not update the comments, the comments are now out of date.

---

## 1.6.2 What is a Good Comment?

Steve McConnell provides a long list of suggestions for high-quality code. These suggestions include:

- **Use commenting styles that don't break down or discourage modification.** Essentially, he's saying pick a commenting style that isn't so much work people refuse to use it. He gives an example of a block of comments surrounded by asterisks as being hard to maintain. This is a poor example since modern text editors will automatically "outline" the comments for you. Nevertheless, the basic idea is sound.
- **Comment as you go along.** If you put commenting off until the last moment, then it seems like another task in the software development process always comes along and management is likely to discourage the completion of the commenting task in hopes of meeting new deadlines.
- **Avoid self-indulgent comments.** Also, you should avoid sexist, profane, or other insulting remarks in your comments. Always remember, someone else will eventually read your code.
- **Avoid putting comments on the same physical line as the statement they describe.** Such comments are very hard to maintain since there is very little room. McConnell suggests that endline comments are okay for variable declarations. For some this might be true but many variable declarations may require considerable explanation that simply won't fit at the end of a line. One exception to this rule is "maintenance notes." Comments that refer to a defect tracking entry in the defect database are okay (note that the CodeWright text editor provides a much better solution for this -- buttons that can bring up an external file). Of course, endline comments are marginally more useful in assembly language than in the HLLs that McConnell addresses, but the basic idea is sound.

- **Write comments that describe blocks of statements rather than individual statements.** Comments covering single statements tend to discuss the mechanics of that statement rather than discussing what the program is doing.
- **Focus paragraph comments on the *why* rather than the *how*.** Code should explain what the program is doing and why the programmer chose to do it that way rather than explain what each individual statement is doing.
- **Use comments to prepare the reader for what is to follow.** Someone reading the comments should be able to have a good idea of what the following code does without actually looking at the code. Note that this rule also suggests that comments should always precede the code to which they apply.
- **Make every comment count.** If the reader wastes time reading a comment of little value, the program is harder to read; period.
- **Document surprises and tricky code.** Of course, the best solution is not to have any tricky code. In practice, you can't always achieve this goal. When you do need to restore to some tricky code, make sure you fully document what you've done.
- **Avoid abbreviations.** While there may be an argument for abbreviating identifiers that appear in a program, no way does this apply to comments.
- **Keep comments close to the code they describe.** The prologue to a program unit should give its name, describe the parameters, and provide a short description of the program. It should not go into details about the operation of the module itself. Internal comments should to that.
- **Comments should explain the parameters to a function,** assertions about these parameters, whether they are input, output, or in/out parameters.
- **Comments should describe a routine's limitations, assumptions, and any side effects.**

Rule: All comments will be high-quality comments that describe the actions of the surrounding code in a concise manner

---

### 1.6.3 Endline vs. Standalone Comments

Guideline: Adjacent lines of comments should not have any interspersed blank lines. At least lead off the comment with the HLA comment character sequence (e.g., "//").

The guideline above suggests that your code should look like this:

```
// This is a comment with a blank line between it and the next comment.
//
// This is another line with a comment on it.
```

Rather than like this:

```
// This is a comment with a blank line between it and the next comment.

// This is another line with a comment on it.
```

The "//" appearing between the two statements suggest continuity that is not present when you remove the "//". If two blocks of comments are truly separate and whitespace between them is appropriate, you should consider separating them by a large number of blank lines to completely eliminate any possible association between the two.

Standalone comments are great for describing the actions of the code that immediately follows. So what are endline comments useful for? Endline comments can explain how a sequence of instructions are implementing the algorithm described in a previous set of standalone comments. Consider the following code:

```
// Compute the transpose of a matrix using the algorithm:
//
// for i := 0 to 3 do
// for j := 0 to 3 do
```

```
// swap(a[i][j], b[j][i]);

for(mov(0, i); i < 3; inc(i)) do

 for(mov(0, j); j < 3; inc(j)) do

 mov(i, ebx); // Compute address of a[i][j] using
 shl(2, ebx); // row major ordering (i*4 + j)*4.
 add(j, ebx);
 lea(ebx, a[ebx*4]);
 push(ebx); // Push address of a[i][j] onto stack.

 mov(j, ebx); // Compute address of b[j][i] using
 shl(2, ebx); // row major ordering (j*4 + i)*4.
 add(i, ebx);
 lea(ebx, b[ebx*4]);
 push(ebx); // Push address of b[j][i] onto stack.
 call swap; // Swap objects pointed at by [esp] and [esp+4].

 endfor;

endfor;
```

Note that the block comments before this sequence explain, in high level terms, what the code is doing. The endline comments explain how the statement sequence implements the general algorithm. Note, however, that the endline comments do not explain what each statement is doing (at least at the machine level). Rather than claiming "lea( ebx, b[ebx\*4] )" also multiplies the quantity in EBX by four, this code assumes the reader can figure that out for themselves (any reasonable assembly programmer would know this). Once again, keep in mind your audience and write your comments for them.

---

## 1.6.4 Unfinished Code

Often it is the case that a programmer will write a section of code that (partially) accomplishes some task but needs further work to complete a feature set, make it more robust, or remove some known defect in the code. It is common for such programmers to place comments into the code like "This needs more work," "Kludge ahead," etc. The problem with these comments is that they are often forgotten. It isn't until the code fails in the field that the section of code associated with these comments is found and their problems corrected.

Ideally, one should never have to put such code into a program. Of course, ideally, programs never have any defects in them, either. Since such code inevitably finds its way into a program, it's best to have a policy in place to deal with it, hence this section.

Unfinished code comes in five general categories: non-functional code, partially functioning code, suspect code, code in need of enhancement, and code documentation. Non-functional code might be a stub or driver that needs to be replaced in the future with actual code or some code that has severe enough defects that it is useless except for some small special cases. This code is really bad, fortunately its severity prevents you from ignoring it. It is unlikely anyone would miss such a poorly constructed piece of code in early testing prior to release.

Partially functioning code is, perhaps, the biggest problem. This code works well enough to pass some simple tests yet contains serious defects that should be corrected. Moreover, these defects are known. Software often contains a large number of unknown defects; it's a shame to let some (prior) known defects ship with the product simply because a programmer forgot about a defect or couldn't find the defect later.

Suspect code is exactly that- code that is suspicious. The programmer may not be aware of a quantifiable problem but may suspect that a problem exists. Such code will need a later review in order to verify whether it is correct.

The fourth category, code in need of enhancement, is the least serious. For example, to expedite a release, a programmer might choose to use a simple algorithm rather than a complex, faster algorithm. S/he could make a comment in the code like "This linear search should be replaced by a hash table lookup in a future version of the software." Although it might not be absolutely necessary to correct such a problem, it would be nice to know about such problems so they can be dealt with in the future.

The fifth category, documentation, refers to changes made to software that will affect the corresponding documentation (user guide, design document, etc.). The documentation department can search for these defects to bring existing documentation in line with the current code.

This standard defines a mechanism for dealing with these five classes of problems. Any occurrence of unfinished code will be preceded by a comment that takes one of the following forms (where "\_" denotes a single space):

```
//_#defect#severe_//
//_#defect#functional_//
//_#defect#suspect_//
//_#defect#enhancement_//
//_#defect#documentation_//
```

It is important to use all lower case and verify the correct spelling so it is easy to find these comments using a text editor search or a tool like grep. Obviously, a separate comment explaining the situation must follow these comments in the source code.

Examples:

```
// #defect#suspect //
// #defect#enhancement //
// #defect#documentation //
```

Notice the use of comment delimiters (the "//") on both sides even though HLA doesn't require them.

**Enforced Rule:** If a module contains some defects that cannot be immediately removed because of time or other constraints, the program will insert a standardized comment before the code so that it is easy to locate such problems in the future. The five standardized comments are "`//_#defect#severe_//`", "`//_#defect#functional_//`", "`//_#defect#suspect_//`", "`//_#defect#enhancement_//`", and "`//_#defect#documentation_//`" where "\_" denotes a single space. The spelling and spacing should be exact so it is easy to search for these strings in the source tree.

---

## 1.6.5 Cross References in Code to Other Documents

In many instances a section of code might be intrinsically tied to some other document. For example, you might refer the reader to the user document or the design document within your comments in a program. This document proposes a standard way to do this so that it is relatively easy to locate cross references appearing in source code. The technique is similar to that for defect reporting, except the comments take the form:

```
// text #link#location text //
```

"Text" is optional and represents arbitrary text (although it is really intended for embedding html commands to provide hyperlinks to the specified document). "Location" describes the document and section where the associated information can be found.

Examples:

```
// #link#User's Guide Section 3.1 //
// #link#Program Design Document, Page 5 //
// #link#Funcs.pas module, "xyz" function //
```

```
// #link#xyzfunc //
```

**Guideline:** If a module contains some cross references to other documents, there should be a comment that takes the form `"// text #link#location text //` that provides the reference to that other document. In this comment `"text"` represents some optional text (typically reserved for html tags) and `"location"` is some descriptive text that describes the document (and a position in that document) related to the current section of code in the program.

## 1.7 Names, Instructions, Operators, and Operands

Although program features like good comments, proper spacing of statements, and good modularization can help yield programs that are more readable; ultimately, a programmer must read the instructions in a program to understand what it does. Therefore, do not underestimate the importance of making your statements as readable as possible. This section deals with this issue.

### 1.7.1 Names

According to studies done at IBM, the use of high-quality identifiers in a program contributes more to the readability of that program than any other single factor, including high-quality comments. The quality of your identifiers can make or break your program; program with high-quality identifiers can be very easy to read, programs with poor quality identifiers will be very difficult to read. There are very few “tricks” to developing high-quality names; most of the rules are nothing more than plain old-fashion common sense. Unfortunately, programmers (especially C/C++ programmers) have developed many arcane naming conventions that ignore common sense. The biggest obstacle most programmers have to learning how to create good names is an unwillingness to abandon existing conventions. Yet their only defense when quizzed on why they adhere to (existing) bad conventions seems to be “because that’s the way I’ve always done it and that’s the way everybody else does it.”

The aforementioned researchers at IBM developed several programs with the following set of attributes:

- Bad comments, bad names
- Bad comments, good names
- Good comments, bad names
- Good comments, good names

As should be obvious, the programs that had bad comments and names were the hardest to read; likewise, those programs with good comments and names were the easiest to read. The surprising results concerned the other two cases. Most people assume good comments are more important than good names in a program. Not only did IBM find this to be false, they found it to be *really* false.

As it turns out, good names are even more important than good comments in a program. This is not to say that comments are unimportant, they are extremely important; however, it is worth pointing out that if you spend the time to write good comments and then choose poor names for your program’s identifiers, you’ve damaged the readability of your program despite the work you’ve put into your comments. Quickly read over the following code:

```
mov(SignedValue, ax);
cwd();
add(-1, ax);
rcl(1, dx);
mov(dx, AbsoluteValue);
```

**Question:** What does this code compute and store in the AbsoluteValue variable?

- The sign extension of SignedValue.
- The negation of SignedValue.
- The absolute value of SignedValue.
- A boolean value indicating that the result is positive or negative.
- Signum(SignedValue) (-1, 0, +1 if neg, zero, pos).
- Ceil(SignedValue)
- Floor(SignedValue)

The obvious answer is the absolute value of SignedValue. This is also incorrect. The correct answer is signum:

```

mov(SignedValue, ax); // Get value to check.
cwd(); // DX = FFFF if neg, 0000 otherwise.
add($ffff, ax); // Carry=0 if ax is zero, one otherwise.
rcl(1, dx); // DX = FFFF if AX is neg, 0 if ax=0,
mov(dx, Signum); // 1 if ax>0.

```

Granted, this is a tricky piece of code<sup>10</sup>. Nonetheless, even without the comments you can probably figure out what the code sequence does even if you can't figure out how it does it:

```

mov(SignedValue, ax);
cwd();
add($ffff, ax);
rcl(1, dx);
mov(dx, Signum);

```

Based on the names alone you can probably figure out that this code computes the signum function (even if understanding *how* it does it remains a mystery). This is the "understanding 80% of the code" referred to earlier. Note that you don't need misleading names to make this code unfathomable. Consider the following code that doesn't trick you by using misleading names:

```

mov(x, ax);
cwd();
add($ffff, ax);
rcl(1, dx);
mov(dx, y);

```

This is a very simple example. Now imagine a large program that has many names. As the number of names increase in a program, it becomes harder to keep track of them all. If the names themselves do not provide a good clue to the meaning of the name, understanding the program becomes very difficult.

**Enforced Rule:** All identifiers appearing in an assembly language program must be descriptive names whose meaning and use are clear.

Since labels (i.e., identifiers) are the target of jump and call instructions, a typical assembly language program may have a large number of identifiers, especially if you write in "pure" assembly and forego the HLA high level control structures. Therefore, it is tempting to begin using names like "label1, label2, label3, ..." Avoid this temptation! There is always a reason you are jumping to some spot in your code. Try to describe that reason and use that description for your label name.

**Rule:** Never use names like "Lbl0, Lbl1, Lbl2, ..." in your program. Always use meaningful names!

---

10. It could be worse, you should see what the "superoptimizer" outputs for the signum function. It's even shorter and harder to understand than this code.

---

### 1.7.1.1 Naming Conventions

Naming conventions represent one area in Computer Science where there are far too many divergent views (program layout is the other principle area). The primary purpose of an object's name in a programming language is to describe the use and/or contents of that object. A secondary consideration may be to describe the type of the object. Programmers use different mechanisms to handle these objectives. Unfortunately, there are far too many "conventions" in place, it would be asking too much to expect any one programmer to follow several different standards. Therefore, this standard will apply across all languages as much as possible.

The vast majority of programmers know only one language - English. Some programmers know English as a second language and may not be familiar with a common non-English phrase that is not in their own language (e.g., rendezvous). Since English is the common language of most programmers, all identifiers should use easily recognizable English words and phrases.

Rule: All identifiers that represent words or phrases must be English words or phrases.

---

### 1.7.1.2 Alphabetic Case Considerations

A case-neutral identifier will work properly whether you compile it with a compiler that has case sensitive identifiers or case insensitive identifiers. In practice, this means that all uses of the identifiers must be spelled exactly the same way (including case) *and* that no other identifier exists whose only difference is the case of the letters in the identifier. For example, if you declare an identifier "ProfitsThisYear" in Pascal (a case-insensitive language), you could legally refer to this variable as "profitsThisYear" and "PROFITSTHISYEAR". However, this is not a case-neutral usage since a case sensitive language would treat these three identifiers as different names. Conversely, in case-sensitive languages like C/C++, it is possible to create two different identifiers with names like "PROFITS" and "profits" in the program. This is not case-neutral since attempting to use these two identifiers in a case insensitive language (like Pascal) would produce an error since the case-insensitive language would think they were the same name.

Enforced Rule: All identifiers must be "case-neutral."

Fortunately, HLA enforces case neutrality in its identifiers; so HLA doesn't allow you to violate this rule. However, if you are linking assembly and high level language code together, it's a good idea to follow this rule in the HLL code to prevent problems when linking with the HLA code.

Different programmers (especially in different languages) use alphabetic case to denote different objects. For example, a common C/C++ coding convention is to use all upper case to denote a constant, macro, or type definition and to use all lower case to denote variable names or reserved words. Prolog programmers use an initial lower case alphabetic to denote a variable. Other comparable coding conventions exist. Unfortunately, there are so many different conventions that make use of alphabetic case, they are nearly worthless, hence the following rule:

Rule: You should never use alphabetic case to denote the type, classification, or any other program-related attribute of an identifier.

There are going to be some obvious exceptions to the above rule, this document will cover those exceptions a little later. Alphabetic case does have one very useful purpose in identifiers - it is useful for separating words in a multi-word identifier; more on that subject in a moment.

To produce readable identifiers often requires a multi-word phrase. Natural languages typically use spaces to separate words; we can not, however, use this technique in identifiers.

Unfortunately writing multiword identifiers makes them almost impossible to read if you do not do something to distinguish the individual words (Unfortunately writing multiword identifiers makes them almost impossible to read if you do not do something to distinguish the individual words).

There are a couple of good conventions in place to solve this problem. This standard's convention is to capitalize the first alphabetic character of each word in the middle of an identifier.

**Rule:** Capitalize the first letter of interior words in all multi-word identifiers.

Note that the rule above does not specify whether the first letter of an identifier is upper or lower case. Subject to the other rules governing case, you can elect to use upper or lower case for the first symbol, although you should be consistent throughout your program. The second convention is to use an underscore to separate words in a multi-word document. This is also acceptable, though the capitalization rule probably produces identifiers that are to read and write.

Lower case characters are easier to read than upper case. Identifiers written completely in upper case take almost twice as long to recognize and, therefore, impair the readability of a program. Yes, all upper case does make an identifier stand out. Such emphasis is rarely necessary in real programs. Yes, common C/C++ coding conventions dictate the use of all upper case identifiers. Forget them. They not only make your programs harder to read, they also violate the first rule above.

**Rule:** Avoid using all upper case characters in an identifier.

Some programmers prefer to begin all identifiers with a lower case letter. Others prefer to begin them with an upper case alphabetic character. Either scheme is fine as long as you apply it consistently throughout your program. Under no circumstances should you use the presence of an upper or lower case character to denote different things in your code (see the earlier rule about this).

### 1.7.1.3 Abbreviations

The primary purpose of an identifier is to describe the use of, or value associated with, that identifier. The best way to create an identifier for an object is to describe that object in English and then create a variable name from that description. Variable names should be meaningful, concise, and non-ambiguous to an average programmer fluent in the English language. Avoid short names. Some research has shown that programs using identifiers whose average length is 10-20 characters are generally easier to debug than programs with substantially shorter or longer identifiers.

Avoid abbreviations as much as possible. What may seem like a perfectly reasonable abbreviation to you may totally confound someone else. Consider the following variable names that have actually appeared in commercial software:

NoEmployees, NoAccounts, pend

The “NoEmployees” and “NoAccounts” variables seem to be boolean variables indicating the presence or absence of employees and accounts. In fact, this particular programmer was using the (perfectly reasonable in the real world) abbreviation of “number” to indicate the number of employees and the number of accounts. The “pend” name referred to a procedure's end rather than any pending operation.

Programmers often use abbreviations in two situations: they're poor typists and they want to reduce the typing effort, or a good descriptive name for an object is simply too long. The former case is an unacceptable reason for using abbreviations. The second case, especially if care is taken, may warrant the occasional use of an abbreviation.

**Guideline:** Avoid all identifier abbreviations in your programs. When necessary, use standardized abbreviations or ask someone to review your abbreviations. Whenever you use abbreviations in your programs, create a “data dictionary” in the comments near the names' definition that provides a full name and description for your abbreviation.

The variable names you create should be pronounceable. “NumFiles” is a much better identifier than “NmFls”. The first can be spoken, the second you must generally spell out. Avoid homonyms and long names that are identical except for a few syllables. If you choose good names for your identifiers, you should be able to read a program listing over the telephone to a peer without overly confusing that person.

**Rule:** All identifiers should be pronounceable (in English) without having to spell out more than one letter.

---

### 1.7.1.4 The Position of Components Within an Identifier

When scanning through a listing, most programmers only read the first few characters of an identifier. It is important, therefore, to place the most important information (that defines and makes this identifier unique) in the first few characters of the identifier. So, you should avoid creating several identifiers that all begin with the same phrase or sequence of characters since this will force the programmer to mentally process additional characters in the identifier while reading the listing. Since this slows the reader down, it makes the program harder to read.

Guideline: Try to make most identifiers unique in the first few character positions of the identifier. This makes the program easier to read.

Corollary: Never use a numeric suffix to differentiate two names.

Many C/C++ Programmers, especially Microsoft Windows programmers, have adopted a formal naming convention known as “Hungarian Notation.” To quote Steve McConnell from Code Complete: “The term ‘Hungarian’ refers both to the fact that names that follow the convention look like words in a foreign language and to the fact that the creator of the convention, Charles Simonyi, is originally from Hungary.” One of the first rules given concerning identifiers stated that all identifiers are to be English names. Do we really want to create “artificially foreign” identifiers? Hungarian notation actually violates another rule as well: names using the Hungarian notation generally have very common prefixes, thus making them harder to read.

Hungarian notation does have a few minor advantages, but the disadvantages far outweigh the advantages. The following list from Code Complete and other sources describes what’s *wrong* with Hungarian notation:

- Hungarian notation generally defines objects in terms of basic machine types rather than in terms of abstract data types.
- Hungarian notation combines *meaning* with *representation*. One of the primary purposes of high level language is to abstract representation away. For example, if you declare a variable to be of type *integer*, you shouldn’t have to change the variable’s name just because you changed its type to *real*.
- Hungarian notation encourages lazy, uninformative variable names. Indeed, it is common to find variable names in Windows programs that contain *only* type prefix characters, without an descriptive name attached.
- Hungarian notation prefixes the descriptive name with some type information, thus making it harder for the programming to find the descriptive portion of the name.

Guideline: Avoid using Hungarian notation and any other formal naming convention that attaches low-level type information to the identifier.

Although attaching *machine* type information to an identifier is generally a bad idea, a well thought-out name can successfully associate some high-level type information with the identifier, especially if the name implies the type or the type information appears as a suffix. For example, names like “PencilCount” and “BytesAvailable” suggest integer values. Likewise, names like “IsReady” and “Busy” indicate boolean values. “KeyCode” and “MiddleInitial” suggest character variables. A name like “StopWatchTime” probably indicates a real value. Likewise, “CustomerName” is probably a string variable. Unfortunately, it isn’t always possible to choose a great name that describes both the content and type of an object; this is particularly true when the object is an instance (or definition of) some abstract data type. In such instances, some additional text can improve the identifier. Hungarian notation is a raw attempt at this that, unfortunately, fails for a variety of reasons.

A better solution is to use a *suffix phrase* to denote the type or class of an identifier. A common UNIX/C

convention, for example, is to apply a “\_t” suffix to denote a type name (e.g., size\_t, key\_t, etc.). This convention succeeds over Hungarian notation for several reasons including (1) the “type phrase” is a suffix and doesn’t interfere with reading the name, (2) this particular convention specifies the *class* of the object (const, var, type, function, etc.) rather than a low level *type*, and (3) It certainly makes sense to change the identifier if it’s classification changes.

**Guideline:** If you *want* to differentiate identifiers that are constants, type definitions, and variable names, use the suffixes “\_c”, “\_t”, and “\_v”, respectively (generally, the lack of a suffix denotes a variable).

**Rule:** The classification suffix should not be the only component that differentiates two identifiers.

Can we apply this suffix idea to variables and avoid the pitfalls? Sometimes. Consider a high level data type “button” corresponding to a button on a Visual BASIC or Delphi form. A variable name like “CancelButton” makes perfect sense. Likewise, labels appearing on a form could use names like “ETWWLabel” and “EditPageLabel”. Note that these suffixes still suffer from the fact that a change in type will require that you change the variable’s name. However, changes in high level types are far less common than changes in low-level types, so this shouldn’t present a big problem.

HLA provides a special operator, “`” (grave accent) that separates an identifier name from an attached comment. For example, the legal HLA identifier “Hello`world” is really just “Hello”. The characters following the grave accent (to the end of the identifier) are treated as a comment by the compiler. So if you want to attach a comment concerning the variable’s type or use to the identifier, you can use this feature in HLA.

**Guideline:** If you must attach low level type information to an identifier, use the HLA identifier comment (“`”, grave accent) and append the information to the end of the identifier.

### 1.7.1.5 Names to Avoid

Avoid using symbols in an identifier that are easily mistaken for other symbols. This includes the sets {"1" (one), "I" (upper case "I"), and "l" (lower case "L")}, {"0" (zero) and "O" (upper case "O")}, {"2" (two) and "Z" (upper case "Z")}, {"5" (five) and "S" (upper case "S")}, and {"6" (six) and "G" (upper case "G")}.

**Guideline:** Avoid using symbols in identifiers that are easily mistaken for other symbols (see the list above).

Avoid misleading abbreviations and names. For example, FALSE shouldn’t be an identifier that stands for “Failed As a Legitimate Software Engineer.” Likewise, you shouldn’t compute the amount of free memory available to a program and stuff it into the variable “Profits”.

**Rule:** Avoid misleading abbreviations and names.

You should avoid names with similar meanings. For example, if you have two variables “InputLine” and “InputLn” that you use for two separate purposes, you will undoubtedly confuse the two when writing or reading the code. If you can swap the names of the two objects and the program still makes sense, you should rename those identifiers. Note that the names do not have to be similar, only their meanings. “Input-Line” and “LineBuffer” are obviously different but you can still easily confuse them in a program.

**Rule:** Do not use names with similar meanings for different objects in your programs.

In a similar vein, you should avoid using two or more variables that have different meanings but similar names. For example, if you are writing a teacher’s grading program you probably wouldn’t want to use the name “NumStudents” to indicate the number of students in the class along with the variable “StudentNum” to hold an individual student’s ID number. “NumStudents” and “StudentNum” are too similar.

**Rule:** Do not use similar names that have different meanings.

Avoid names that sound similar when read aloud, especially out of context. This would include names like “hard” and “heart”, “Knew” and “new”, etc. Remember the discussion in the section above on abbreviations, you should be able to discuss your problem listing over the telephone with a peer. Names that sound alike make such discussions difficult.

**Guideline:** Avoid homonyms in identifiers.

Avoid misspelled words in names and avoid names that are commonly misspelled. Most programmers are notoriously bad spellers (look at some of the comments in our own code!). Spelling words correctly is hard enough, remembering how to spell an identifier *incorrectly* is even more difficult. Likewise, if a word is often spelled incorrectly, requiring a programmer to spell it correctly on each use is probably asking too much.

**Guideline:** Avoid misspelled words and names that are often misspelled in identifiers.

If you redefine the name of some library routine in your code, another program will surely confuse your name with the library’s version. This is especially true when dealing with standard library routines and APIs.

**Enforced Rule:** Do not reuse existing standard library routine names in your program unless you are specifically replacing that routine with one that has similar semantics (i.e., don’t reuse the name for a different purpose).

**Corollary:** Use Namespaces to prevent name space pollution!

### 1.7.1.6 Special Identifiers

By convention, HLA programmers use certain identifiers for special purposes. Any identifier beginning with an underscore falls into this category. HLA defines five such conventions. The HLA compiler does not enforce these conventions, but if you violate them you may run into problems. The following paragraphs describe each of these conventions.

HLA reserves for its own use (and the use of the HLA Standard Library) all identifiers that begin and end with a single underscore. You should never define any identifiers in your programs that take this form since your identifiers may conflict with HLA’s use. These reservation effectively reserves an “HLA namespace” of identifiers that the compiler and Standard Library can draw from without fear of breaking any existing code (that follows this convention).

Identifiers that begin and end with two underscores are reserved for use as local symbols in user-defined macros. To avoid conflicts with such symbols (especially in context-free/multi-part macros) you should never use symbols that begin and end with two underscores outside of a macro. Within a macro, you should use the convention for all symbols that are local to that macro.

By convention, HLA programmers reserve all identifiers beginning with two underscores for defining private data in classes, records, and other declaration sections. If you’re using a class (or other structure) and some of its identifiers begin with two underscores, this is your hint that these fields are private to that class and subject to change. You should never directly access such fields. When you’re defining your own classes, you should employ this convention to warn others when you’re defining private data to that class.

Identifiers that begin with a single underscore have two uses. First, some languages and calling conventions (most notably, C) prepend an underscore to all external names. Therefore, it is common to use reserve symbols that begin with a single underscore for external linkage. The second use is closely related to the first – HLA programmers conventionally use identifiers beginning with a single underscore as a *shadow name*. Consider the following linkage to an external procedure written in C:

```
procedure _externalCFunc(parm2:int32; parm1:int32); external;
```

```
macro externalCFunc(p1, p2);
 _externalCFunc(p2, p1);
endmacro;
```

The C compiler exports the name “\_externalCFunc” for the C function that is actually named “externalCFunc” inside the C code. Of course, inside our HLA code we would like to use the C name, not the exported name. We could easily achieve this using the following external definition:

```
procedure externalCFunc(parm2:int32; parm1:int32); external(“_externalCFunc”);
```

The only catch is that we’d have to always remember to put the parameters in the reverse order (to match C’s calling convention). Savvy HLA programmers use a macro to swap the parameters as in the previous example. They use the exported C name as a shadow name of the function and then write the macro that swaps the function’s parameters as the real name.

You can use shadow names for all sorts of different purposes, not just for linkage to C functions. For example, the chapter on macros in this text has given examples of function overloading that uses a macro with the overloaded function name and shadow names for the actual functions that implement each of the overloaded calls. The convention is to use a leading underscore on all the shadow function (and other object) names.

## 1.7.2 Instructions, Directives, and Pseudo-Opcodes

Your choice of assembly language sequences, the instructions themselves, and your choice of directives and pseudo-opcodes can have a big impact on the readability of your programs. The following subsections discuss these problems.

### 1.7.2.1 Choosing the Best Instruction Sequence

Like any language, you can solve a given problem using a wide variety of solutions involving different instruction sequences. As a continuing example, consider (again) the following code sequence:

```
mov(SignedValue, ax); // Get value to check.
cwd(); // DX = FFFF if neg, 0000 otherwise.
add($ffff, ax); // Carry=0 if ax is zero, one otherwise.
rcl(1, dx); // DX = FFFF if AX is neg, 0 if ax=0,
mov(dx, Signum); // 1 if ax>0.
```

Now consider the following code sequence that also computes the signum function:

```
mov(SignedValue, ax); // Get value to check.
cmp(ax, 0); // Check the sign.
je GotSignum; // We’re done if it’s zero
mov(1, ax); // Assume it’s positive.
jns GotSignum; // We’re done if it was positive.
neg(ax); // 1 -> -1, we’ve got a negative value.
GotSignum: mov(ax, Signum);
```

Yes, the second version is longer and slower. However, an average person can read the instruction sequence and figure out what it’s doing; hence the second version is much easier to read than the first. Which sequence is best? Unless speed or space is an extremely critical factor and you can show that this routine is in the critical execution path, then the second version is obviously better. There is a time and a place for tricky assembly code; however, it’s rare that you would need to pull tricks like this throughout your code.

So how does one choose appropriate instruction sequences when there are many possible ways to accomplish the same task? The best way is to ensure that you have a choice. Although there are many different ways to accomplish an operation, few people bother to consider any instruction sequence other than the first one that comes to their mind. Unfortunately, the "best" instruction sequence is rarely the first instruction sequence that comes to most people's minds<sup>11</sup>. In order to make a choice, you have to have a choice to make. That means you should create at least two different code sequences for a given operation if there is ever a question concerning the readability of your code. Once you have at least two versions, you can choose between them based on your needs at hand. While it is impractical to "write your program twice" so that you'll have a choice for every sequence of instructions in the program, you should apply this technique to particularly bothersome code sequences.

Guideline: For particularly difficult to understand sections of code, try solving the problem several different ways. Then choose the most easily understood solution for actual incorporation into your program.

One problem with the above suggestion is that you're often too close to your own work to make decisions like "this code isn't too hard to understand, I don't have to worry about it." It is often a good idea to have someone else review your code and point out those sections they find hard to understand<sup>12</sup>.

Guideline: Take advantage of reviews to determine those sections of code in your program that may need to be rewritten to make them easier to understand.

### 1.7.2.2 Control Structures

Ralph Griswold<sup>13</sup> once said (roughly) the following about C, Pascal, and Icon: "C makes it easy to write hard to read programs<sup>14</sup>, Pascal makes it hard to write hard to read programs, and Icon makes it easy to write easy to read programs." Assembly language can be summed up like this: "Assembly language makes it hard to write easy to read programs and easy to write hard to read programs." It takes considerable discipline to write readable assembly language programs; *but it can be done*. Sadly, most assembly code you find today is extremely poorly written. Indeed, that state of affairs is the whole reason for this document. Once you get past issues like comments and naming conventions, issues like program control flow and data structure design have among the largest impacts on program readability. One need look no farther than the public domain code on the Internet, or at Microsoft's sample code for that matter<sup>15</sup>, to see abundant examples of poorly written assembly language code.

Fortunately, with a little discipline it is possible to write readable assembly language programs. Particularly in HLA which was designed from the beginning to allow the easy creation of readable code. How you design your control structures can have a big impact on the readability of your programs. The best way to do this can be summed up in two words: avoid spaghetti.

*Spaghetti code* is the name given to a program that has a large number of intertwined branches and branch targets within a code sequence. Consider the following example:

```

 jmp L1;
L1: mov(0, ax);
 jmp L2;
L3: mov(1, ax);
 jmp L2;
L4: mov(-1, ax);
 jmp L2;
L0: mov(x, ax);
 cmp(ax, 0);

```

11. This is true regardless of what metric you use to determine the "best" code sequence.

12. Of course, if the program is a *class assignment*, you may want to check your instructor's cheating policy before showing your work to your classmates!

13. The designer of the SNOBOL4 and Icon programming languages.

14. Note that this does not infer that it is hard to write easy to read C programs. Only that if one is sloppy, one can easily write something that is near impossible to understand.

15. Okay, this is a cheap shot. In fact, most of the assembly code on this planet is poorly written.

```

 je L1;
 jns L3;
 jmp L4;
L2: mov(ax, y);

```

This code sequence, by the way, is our good friend the Signum function. It takes a few moments to figure this out because as you manually trace through the code you find yourself spending more time following jumps around than you do looking at code that computes useful results. Now this is a rather extreme example, but it is also fairly short. A longer code sequence code become just as obfuscated with even fewer branches all over the place.

Spaghetti code is given this name because it resembles a bowl of spaghetti. That is, if we consider a control path in the program a spaghetti noodle, spaghetti code contains lots of intertwined branches into and out of different sections of the program. Needless to say, most spaghetti programs are difficult to understand, generally contain lots of bugs, and are often inefficient (don't forget that branches are among the slowest executing instructions on most modern processors).

So how to we resolve this? Easy by physically adopting structured programming techniques in assembly language code. Of course, "pure" 80x86 assembly language doesn't provide IF..THEN..ELSE..ENDIF, WHILE..ENDWHILE, REPEAT..UNTIL, and other such statements, but we can certainly simulate them if you insist on writing "pure" assembly code<sup>16</sup>. Consider the following high level sequence:

```

if(expression) then
 << statements to execute if expression is true >>
else
 << statements to execute if expression is false >>
endif;

```

Almost any high level language programmer can figure out what this type of statement will do. Assembly language programmers should leverage this knowledge by attempting to organize their code so it takes this same form. Specifically, the assembly language version should look something like the following:

```

<< Assembly code to compute value of expression >>

JNxx ElsePart ;xx is the opposite condition we want to check.

<< Assembly code corresponding to the then portion >>

jmp AroundElsePart

ElsePart:
 << Assembly code corresponding to the else portion >>

AroundElsePart:

```

For an concrete example, consider the following:

```

if(ax = y) then
 write('ax = y');
else
 write('ax <> y');

```

---

16. We'll consider the HLA high level control statements elsewhere in this appendix.

```

endif;

; Corresponding Assembly Code:

mov(x, ax);
cmp(ax, y);
jne ElsePart;

stdout.put("x = y",nl);
jmp IfDone;

ElsePart: stdout.put("x<>y",nl);
IfDone:

```

While this may seem like the obvious way to organize an IF.THEN.ELSE..ENDIF statement, it is surprising how many people would naturally assume they've got to place the ELSE part somewhere else in the program as follows:

```

mov(x, ax);
cmp(ax, y);
jne ElsePart;

stdout.put("x = y", nl);

IfDone:
.
.
.
ElsePart: stdout.put("x <> y", nl);
jmp IfDone;

```

This code organization makes the program more difficult to follow. Most programmers have a HLL background and despite a current assignment, they still work mostly in HLLs. Assembly language programs will be more readable if they mimic the HLL control constructs<sup>17</sup>.

For similar reasons, you should attempt to organize your assembly code that simulates WHILE loops, REPEAT..UNTIL loops, FOR loops, etc., so that the code resembles the HLL code (for example, a WHILE loop should physically test the condition at the beginning of the loop with a jump at the bottom of the loop).

**Rule:** Attempt to design your programs using HLL control structures. The organization of the assembly code that you write should physically resemble the organization of some corresponding HLL program.

Assembly language offers you the flexibility to design arbitrary control structures. This flexibility is one of the reasons good assembly language programmers can write better code than that produced by a compiler (that can only work with high level control structures). However, keep in mind that a fast program doesn't have to contain the tightest possible code in every sequence. Execution speed is nearly irrelevant in most parts of the program. Sacrificing readability for speed isn't a big win in most of the program.

**Guideline:** Avoid control structures that don't easily map to well-known high level language control structures in your assembly language programs. Deviant control structures should only appear in small sections of code when efficiency demands their use.

---

### 1.7.2.3 Instruction Synonyms

HLA defines several synonyms for common instructions. This is especially true for the conditional jump and "set on condition code" instructions. For example, JA and JNBE are synonyms for one another.

---

17. Sometimes, for performance reasons, the code sequence above is justified since straight-line code executes faster than code with jumps. If the program rarely executes the ELSE portion of an if statement, always having to jump over it could be a waste of time. But if you're optimizing for speed, you will often need to sacrifice readability.

Logically, one could use either instruction in the same context. However, the choice of synonym can have an impact on the readability of a code sequence. To see why, consider the following:

```

 if(x <= y) then
 << true statements>>
 else
 << false statements>>
 endif

// Assembly code:

 mov(x, ax);
 cmp(ax, y);
 ja ElsePart;

 << true code >>

 jmp IfDone;

ElsePart: << false code >>
IfDone:

```

When someone reads this program, the "JA" statement skips over the true portion. Unfortunately, the "JA" instruction gives the illusion we're checking to see if something is greater than something else; in actuality, we're testing to see if some condition is less than or equal, not greater than. As such, this code sequence hides some of the original intent of high level algorithm. One solution is to swap the false and true portions of the code:

```

 mov(x, ax);
 cmp(ax, y);
 jbe ThenPart;

 << false code >>

 jmp IfDone;

ThenPart: << true code >>
IfDone:

```

This code sequence uses the conditional jump that matches the high level algorithm's test (less than or equal). However, this code is now organized in a non-standard fashion (it's an IF..ELSE..THEN..ENDIF statement). This hurts the readability more than using the proper jump helped it. Now consider the following solution:

```

 mov(x, ax);
 cmp(ax, y);
 jnbe ElsePart;

 << true code >>

 jmp IfDone;

ElsePart: << false code >>
IfDone:

```

This code is organized in the traditional IF..THEN..ELSE..ENDIF fashion. Instead of using JA to skip over the then portion, it uses JNBE to do so. This helps indicate, in a more readable fashion, that the code falls through on below or equal and branches if it is not below or equal. Since the instruction (JNBE) is easier to relate to the original test ( $\leq$ ) than JA, this makes this section of code a little more readable.

**Rule:** When skipping over some code because some condition has failed (e.g., you fall into the code because the condition is successful), always use a conditional jump of the form "JNxx" to skip

over the code section. For example, to fall through to a section of code if one value is less than another, use the JNL or JNB instruction to skip over the code. Of course, if you are testing a negative condition (e.g., testing for equality) then use an instruction of the form Jx to skip over the code.

---

## 1.8 Data Types

Prior to the arrival of MASM from Microsoft for the 80x86, most assemblers provided very little capability for declaring and allocating complex data types. Generally, you could allocate bytes, words, and other primitive machine structures. You could also set aside a block of bytes. As high level languages improved their ability to declare and use abstract data types, assembly language fell farther and farther behind. Then MASM came along and changed all that<sup>18</sup>. HLA expands the ability to declare abstract data types even farther than MASM. Unfortunately, many new assembly language programmers don't bother learning and using these data typing facilities because they're already overwhelmed by assembly language and want to minimize the number of things they've got to learn. This is really a shame because HLA's data typing is one of the biggest improvements to assembly language since using mnemonics rather than binary opcodes for machine level programming.

Note that HLA is a "high-level" assembler. It does things assemblers for other chips won't do like checking the types of operands and reporting errors if there are mismatches. Some people, who are used to assemblers on other machines find this annoying. However, it's a great idea in assembly language for the same reason it's a great idea in HLLs<sup>19</sup>. These features have one other beneficial side-effect: they help other understand what you're trying to do in your programs. It should come as no surprise, then, that this style guide will encourage the use of these features in your assembly language programs.

---

### 1.8.1 Declaring Structures in Assembly Language

HLA provides an excellent facility for declaring and using records and unions; for some reason, many assembly language programmers ignore them and manually compute offsets to fields within structures in their code. Not only does this produce hard to read code, the result is nearly unmaintainable as well.

**Rule:** When a structure data type is appropriate in an assembly language program, declare the corresponding structure in the program and use it. Do not compute the offsets to fields in the structure manually, use the standard structure "dot-notation" to access fields of the structure.

One problem with using structures occurs when you access structure fields indirectly (i.e., through a pointer). Indirect access always occurs through a register. Once you load a pointer value into a register, the program doesn't readily indicate what pointer you are using. This is especially true if you use the indirect access several times in a section of code without reloading the register(s). One solution is to use a text constant to create a special symbol that expands as appropriate. Consider the following code:

```
type
 s: record
 a: int32;
 b: int32;
 endrecord;
 .
 .
 .
static
 r: s;
```

---

18. Okay, MASM wasn't the first, but such techniques were not popularized until MASM appeared.

19. Of course, MASM gives you the ability to override this behavior when necessary. Therefore, the complaints from "old-hand" assembly language programmers that this is insane are groundless.

```

ptr2r: pointer to s;
.
.
.
mov(ptr2r, edi);
mov((type s [edi]).a, eax); // No indication this is ptr2r!
.
.
.
mov(ebx, (type s [edi]).b); // Still no indication.

```

Now consider the following:

```

type
s:record

 a: int32;
 b: int32;

endrecord;

sptr : pointer to s;
.
.
.
static
r: s;
ptr2r: sptr := q;
?_r:text := (type s [edi])";
.
.
.
mov(ptr2r, edi);
mov(_r.a, eax); // Now it's a lot more clear that we're using r.
.
.
.
mov(ebx, _r.b); // It's still clear that we're using r!

```

Note that the "\_" symbol is a legal identifier character to HLA, hence "\_r" is just another symbol. Of course, you must always make sure to load the pointer into EDI when using the text constant above. If you use several different registers to access the data that "r" points at, this trick may not make the code anymore readable since you will need several text constants that all mean the same thing.

# The 80x86 Instruction Set

# Appendix D

The following three tables discuss the integer/control, floating point, and MMX instruction sets. This document uses the following abbreviations:

|                |                                                                                                       |
|----------------|-------------------------------------------------------------------------------------------------------|
| imm-           | A constant value, must be appropriate for the operand size.                                           |
| imm8-          | An eight-bit immediate constant. Some instructions limit the range of this value to less than 0..255. |
| immL-          | A 16- or 32-bit immediate constant.                                                                   |
| immH-          | A 16- or 32-bit immediate constant.                                                                   |
| reg-           | A general purpose integer register.                                                                   |
| reg8-          | A general purpose eight-bit register                                                                  |
| reg16-         | A general purpose 16-bit register.                                                                    |
| reg32-         | A general purpose 32-bit register.                                                                    |
| mem-           | An arbitrary memory location using any of the available addressing modes.                             |
| mem16-         | A word variable using any legal addressing mode.                                                      |
| mem32-         | A dword variable using any legal addressing mode.                                                     |
| mem64-         | A qword variable using any legal addressing mode.                                                     |
| label-         | A statement label in the program.                                                                     |
| ProcedureName- | The name of a procedure in the program.                                                               |

Instructions that have two source operands typically use the first operand as a source operand and the second operand as a destination operand. For exceptions and other formats, please see the description for the individual instruction.

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                               | Description                                                                                                                                                                |
|--------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| aaa()                                                                                            | ASCII Adjust after Addition. Adjusts value in AL after a decimal addition operation.                                                                                       |
| aad()                                                                                            | ASCII Adjust before Division. Adjusts two unpacked values in AX prior to a decimal division.                                                                               |
| aam()                                                                                            | ASCII Adjust AX after Multiplication. Adjusts the result in AX for a decimal multiply.                                                                                     |
| aas()                                                                                            | ASCII Adjust AL after Subtraction. Adjusts the result in AL for a decimal subtraction.                                                                                     |
| adc( imm, reg );<br>adc( imm, mem );<br>adc( reg, reg );<br>adc( reg, mem );<br>adc( mem, reg ); | Add with carry. Adds the source operand plus the carry flag to the destination operand.                                                                                    |
| add( imm, reg );<br>add( imm, mem );<br>add( reg, reg );<br>add( reg, mem );<br>add( mem, reg ); | Add. Adds the source operand to the destination operand.                                                                                                                   |
| and( imm, reg );<br>and( imm, mem );<br>and( reg, reg );<br>and( reg, mem );<br>and( mem, reg ); | Bitwise AND. Logically ANDs the source operand into the destination operand. Clears the carry and overflow flags and sets the sign and zero flags according to the result. |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|--------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| bound( reg, mem );<br>bound( reg, immL, immH );                                | <p>Bounds check. Reg and memory operands must be the same size and they must be 16 or 32-bit values. This instruction compares the register operand against the value at the specified memory location and raises an exception if the register's value is less than the value in the memory location. If greater or equal, then this instruction compares the register to the next word or dword in memory and raises an exception if the register's value is greater.</p> <p>The second form of this instruction is an HLA extended syntax instruction. HLA encodes the constants as two memory locations and then emits the first form of this instruction using these newly created memory locations.</p> <p>For the second form, the constant values must not exceed the 16-bit or 32-bit register size.</p> |
| bsf( reg, reg );<br>bsr( mem, reg );                                           | <p>Bit Scan Forward. The two operands must be the same size and they must be 16-bit or 32-bit operands. This instruction locates the first set bit in the source operand and stores the bit number into the destination operand and clears the zero flag. If the source operand does not have any set bits, then this instruction sets the zero flag and the dest register value is undefined.</p>                                                                                                                                                                                                                                                                                                                                                                                                               |
| bsr( reg, reg );<br>bsr( mem, reg );                                           | <p>Bit Scan Reverse. The two operands must be the same size and they must be 16-bit or 32-bit operands. This instruction locates the last set bit in the source operand and stores the bit number into the destination operand and clears the zero flag. If the source operand does not have any set bits, then this instruction sets the zero flag and the dest register value is undefined.</p>                                                                                                                                                                                                                                                                                                                                                                                                                |
| bswap( reg32 );                                                                | <p>Byte Swap. This instruction reverses the order of the bytes in a 32-bit register. It swaps bytes zero and three and it swaps bytes one and two. This effectively converts data between the little endian (used by Intel) and big endian (used by some other CPUs) formats.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| bt( reg, mem );<br>bt( reg, reg );<br>bt( imm8, reg );<br>bt( imm8, mem );     | <p>Register and memory operands must be 16- or 32-bit values. Eight bit immediate values must be in the range 0..15 for 16-bit registers, 0..31 for 32-bit registers, and 0..255 for memory operands. Source register must be in the range 0..15 or 0..31 for registers. Any value is legal for the source register if the destination operand is a memory location. This instruction copies the bit in the second operand, whose bit position the first operand specifies, into the carry flag.</p>                                                                                                                                                                                                                                                                                                             |
| btc( reg, mem );<br>btc( reg, reg );<br>btc( imm8, reg );<br>btc( imm8, mem ); | <p>Bit test and complement. As above, except this instruction also complements the value of the specified bit in the second operand. Note that this instruction first copies the bit to the carry flag, then complements it. To support atomic operations, the memory-based forms of this instruction are always "memory locked" and they always directly access main memory; the CPU does not use the cache for this result. Hence, this instruction always operates at memory speeds (i.e., slow).</p>                                                                                                                                                                                                                                                                                                         |
| btr( reg, mem );<br>btr( reg, reg );<br>btr( imm8, reg );<br>btr( imm8, mem ); | <p>Bit test and reset. Same as BTC except this instruction tests and resets (clears) the bit.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| bts( reg, mem );<br>bts( reg, reg );<br>bts( imm8, reg );<br>bts( imm8, mem ); | <p>Bit test and set. Same as BTC except this instructions tests and sets the bit.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| call label;<br>call( label );<br>call( reg32 );<br>call( mem32 );              | <p>Pushes a return address onto the stack and calls the subroutine at the address specified. Note that the first two forms are the same instruction. The other two forms provide indirect calls via a register or a pointer in memory.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

| cmp( imm, reg );<br>cmp( imm, mem );<br>cmp( reg, reg );<br>cmp( reg, mem );<br>cmp( mem, reg ); | Compare. Compares the first operand against the second operand. The two operands must be the same size. This instruction sets the condition code flags as appropriate for the condition jump and set instructions. This instruction does not change the value of either operand.                                                                                                                                                                                                                                                                                             |
| cmpsb();<br>repe.cmpsb();<br>repne.cmpsb();                                                      | Compare string of bytes. Compares the byte pointed at by ESI with the byte pointed at by EDI and then adjusts ESI and EDI by $\pm 1$ depending on the value of the direction flag. Sets the flags according to the result. With the REPNE (repeat while not equal) flag, this instruction compares up to ECX bytes until all the first byte it finds in the two string that are equal. With the REPE (repeat while equal) prefix, this instruction compares two strings up to the first byte that is different. See the chapter on the String Instructions for more details. |
| cmpsw()<br>repe.cmpsw();<br>repne.cmpsw();                                                       | Compare a string of words. Like cmpsb except this instruction compares words rather than bytes and adjusts ESI/EDI by $\pm 2$ .                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| cmpsd()<br>repe.cmpsd();<br>repne.cmpsd();                                                       | Compare a string of double words. Like cmpsb except this instruction compares double words rather than bytes and adjusts ESI/EDI by $\pm 4$ .                                                                                                                                                                                                                                                                                                                                                                                                                                |
| cmpxchg( reg, mem );<br>cmpxchg( reg, reg );                                                     | Reg and mem must be the same size. They can be eight, 16, or 32 bit objects. This instruction compares the value in the accumulator (al, ax, or eax) against the second operand. If the two values are equal, this instruction copies the source (first) operand to the destination (second) operand. Otherwise, this instruction copies the second operand into the accumulator.                                                                                                                                                                                            |
| cmpxchg8b( mem64 );                                                                              | Compares the 64-bit value in EDX:EAX with the memory operand. If the values are equal, then this instruction stores the 64-bit value in ECX:EBX into the memory operand and sets the zero flag. Otherwise, this instruction copies the 64-bit memory operand into the EDX:EAX registers and clears the zero flag.                                                                                                                                                                                                                                                            |
| cpuid();                                                                                         | CPU Identification. This instruction identifies various features found on the different Pentium processors. See the Intel documentation on this instruction for more details.                                                                                                                                                                                                                                                                                                                                                                                                |
| cwd();                                                                                           | Convert Word to Double. Sign extends AX to DX:AX.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| cwde();                                                                                          | Convert Word to Double Word Extended. Sign extends AX to EAX.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| daa();                                                                                           | Decimal Adjust after Addition. Adjusts value in AL after a decimal addition.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                                                                                                                                                                                      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| das( );                                                                                                                                                                                                                                                 | Decimal Adjust after Subtraction. Adjusts value in AL after a decimal subtraction.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| dec( reg );<br>dec( mem );                                                                                                                                                                                                                              | Decrement. Subtracts one from the destination memory location or register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| div( reg );<br>div( reg8, ax );<br>div( reg16, dx:ax );<br>div( reg32, edx:eax );<br>div( mem );<br>div( mem8, ax );<br>div( mem16, dx:ax );<br>div( mem32, edx:eax );<br>div( imm8, ax );<br>div( imm16, dx:ax );<br>div( imm32, edx:eax );            | <p>Divides accumulator or extended accumulator (dx:ax or edx:eax) by the source operand. Note that the instructions involving an immediate operand are HLA extensions. HLA creates a memory object holding these constants and then divides the accumulator or extended accumulator by the contents of this memory location. Note that the accumulator operand is twice the size of the source (divisor) operand. This instruction computes the quotient and places it in AL, AX, or EAX and it computes the remainder and places it in AH, DX, or EDX (depending on the divisor's size). This instruction raises an exception if you attempt to divide by zero or if the quotient doesn't fit in the destination register (AL, AX, or EAX).</p> <p>This instruction performs an unsigned division.</p>                                                                      |
| enter( imm16, imm8 );                                                                                                                                                                                                                                   | Enter a procedure. Creates an activation record for a procedure. The first constant specifies the number of bytes of local variables. The second parameter (in the range 0..31) specifies the static nesting level (lex level) of the procedure.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| idiv( reg );<br>idiv( reg8, ax );<br>idiv( reg16, dx:ax );<br>idiv( reg32, edx:eax );<br>idiv( mem );<br>idiv( mem8, ax );<br>idiv( mem16, dx:ax );<br>idiv( mem32, edx:eax );<br>idiv( imm8, ax );<br>idiv( imm16, dx:ax );<br>idiv( imm32, edx:eax ); | <p>Divides accumulator or extended accumulator (dx:ax or edx:eax) by the source operand. Note that the instructions involving an immediate operand are HLA extensions. HLA creates a memory object holding these constants and then divides the accumulator or extended accumulator by the contents of this memory location. Note that the accumulator operand is twice the size of the source (divisor) operand. This instruction computes the quotient and places it in AL, AX, or EAX and it computes the remainder and places it in AH, DX, or EDX (depending on the divisor's size). This instruction raises an exception if you attempt to divide by zero or if the quotient doesn't fit in the destination register (AL, AX, or EAX).</p> <p>This instruction performs a signed division. The condition code bits are undefined after executing this instruction.</p> |
| imul( reg );<br>imul( reg8, al );<br>imul( reg16, ax );<br>imul( reg32, eax );<br>imul( mem );<br>imul( mem8, al );<br>imul( mem16, ax );<br>imul( mem32, eax );<br>imul( imm8, al );<br>imul( imm16, ax );<br>imul( imm32, eax );                      | <p>Multiplies the accumulator (AL, AX, or EAX) by the source operand. The source operand will be the same size as the accumulator. The product produces an operand that is twice the size of the two operands with the product winding up in AX, DX:AX, or EDX:EAX. Note that the instructions involving an immediate operand are HLA extensions. HLA creates a memory object holding these constants and then multiplies the accumulator by the contents of this memory location.</p> <p>This instruction performs a signed multiplication. Also see INTMUL.</p> <p>This instruction sets the carry and overflow flag if the H.O. portion of the result (AH, DX, EDX) is not a sign extension of the L.O. portion of the product. The sign and zero flags are undefined after the execution of this instruction.</p>                                                        |
| in( imm8, al );<br>in( imm8, ax );<br>in( imm8, eax );<br>in( dx, al );<br>in( dx, ax );<br>in( dx, eax );                                                                                                                                              | Input data from a port. These instructions read a byte, word, or double word from an input port and place the input data into the accumulator register. Immediate port constants must be in the range 0..255. For all other port addresses you must use the DX register to hold the 16-bit port number. Note that this is a privileged instruction that will raise an exception in many Win32 Operating Systems.                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| inc( reg );<br>inc( mem );                                                                                                                                                                                                                              | Increment. Adds one to the specified memory or register operand. Does not affect the carry flag. Sets the overflow flag if there was signed overflow. Sets the zero and sign flags according to the result. Note that Z=1 indicates an unsigned overflow.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                                                                                                                         | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>int( imm8 );</code>                                                                                                                                                                  | Call an interrupt service routine specified by the immediate operand. Note that Windows does not use this instruction for system calls, so you will probably never use this instruction under Windows. Note that <code>INT(3)</code> ; is the user breakpoint instruction (that raises an appropriate exception). <code>INT(0)</code> is the divide error exception. <code>INT(4)</code> is the overflow exception. However, it's better to use the HLA <code>RAISE</code> statement than to use this instruction for these exceptions.                                        |
| <code>intmul( imm, reg );</code><br><code>intmul( imm, reg, reg );</code><br><code>intmul( imm, mem, reg );</code><br><code>intmul( reg, reg );</code><br><code>intmul( mem, reg );</code> | <p>Integer multiply. Multiplies the destination (last) operand by the source operand (if there are only two operands; or it multiplies the two source operands together and stores the result in the destination operand (if there are three operands). The operands must all be 16 or 32-bit operands and they must all be the same size.</p> <p>This instruction computes a signed product. This instruction sets the overflow and carry flags if there was a signed arithmetic overflow; the zero and sign flags are undefined after the execution of this instruction.</p> |
| <code>into();</code>                                                                                                                                                                       | Raises an exception if the overflow flag is set. Note: the HLA pseudo-variable “@into” controls the code generation for this instruction. If @into is false, HLA ignores this instruction; if @into is true (default), then HLA emits the object code for this instruction. Note that if the overflow flag is set, this instruction behaves like the “ <code>INT(4)</code> ,” instruction.                                                                                                                                                                                     |
| <code>iret();</code>                                                                                                                                                                       | Return from an interrupt. This instruction is not generally usable from an application program. It is for use in interrupt service routines only.                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>ja label;</code>                                                                                                                                                                     | Conditional jump if (unsigned) above. You would generally use this instruction immediately after a <code>CMP</code> instruction to test to see if one operand is greater than another using an unsigned comparison. Control transfers to the specified label if this condition is true, control falls through to the next instruction if the condition is false.                                                                                                                                                                                                               |
| <code>jae label;</code>                                                                                                                                                                    | Conditional jump if (unsigned) above or equal. See <code>JA</code> above for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <code>jb label;</code>                                                                                                                                                                     | Conditional jump if (unsigned) below. See <code>JA</code> above for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| <code>jbe label;</code>                                                                                                                                                                    | Conditional jump if (unsigned) below or equal. See <code>JA</code> above for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| <code>jc label;</code>                                                                                                                                                                     | Conditional jump if carry is one. See <code>JA</code> above for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>je label;</code>                                                                                                                                                                     | Conditional jump if equal. See <code>JA</code> above for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| <code>jg label;</code>                                                                                                                                                                     | Conditional jump if (signed) greater. See JA above for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| <code>jcxz label;</code>                                                                                                                             | Conditional jump if CX is zero. See JA above for details. Note: the range of this branch is limited to $\pm 128$ bytes around the instruction. HLA does not check for this (MASM reports the error when it assembles HLA's output). Since this instruction is slower than comparing CX to zero and using JZ, you probably shouldn't even use this instruction. If you do, be sure that the target label is nearby in your code.                                                                                                                                                                                                                                                                                                                                          |
| <code>jecxz label;</code>                                                                                                                            | Conditional jump if ECX is zero. See JA above for details. Note: the range of this branch is limited to $\pm 128$ bytes around the instruction. HLA does not check for this (MASM reports the error when it assembles HLA's output). Since this instruction is slower than comparing ECX to zero and using JZ, you probably shouldn't even use this instruction. If you do, be sure that the target label is nearby in your code.                                                                                                                                                                                                                                                                                                                                        |
| <code>jmp label;</code><br><code>jmp( label );</code><br><code>jmp ProcedureName;</code><br><code>jmp( mem32 );</code><br><code>jmp( reg32 );</code> | <p>Jump Instruction. This instruction unconditionally transfers control to the specified destination operand. If the operand is a 32-bit register or memory location, the JMP instruction transfers control to the instruction whose address appears in the register or the memory location.</p> <p>Note: you should exercise great care when jumping to a procedure label. The JMP instruction does not push a return address or any other data associated with a procedure's activation record. Hence, when the procedure attempts to return it will use data on the stack that was pushed prior to the execution of the JMP instruction; it is your responsibility to ensure such data is present on the stack when using JMP to transfer control to a procedure.</p> |
| <code>lahf();</code>                                                                                                                                 | Load AH from FLAGS. This instruction loads the AH register with the L.O. eight bits of the FLAGS register. See SAHF for the flag layout.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| <code>lea( reg32, mem );</code><br><code>lea( mem, reg32 );</code>                                                                                   | Load Effective Address. These instructions, which are both semantically identical, load the 32-bit register with the address of the specified memory location. The memory location does not need to be a double word object. Note that there is never any ambiguity in this instruction since the register is always the destination operand and the memory location is always the source.                                                                                                                                                                                                                                                                                                                                                                               |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

| leave();              | Leave procedure. This instruction cleans up the activation record for a procedure prior to returning from the procedure. You would normally use this instruction to clean up the activation record created by the ENTER instruction.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| lock prefix           | <p>The lock prefix asserts a special pin on the processor during the execution of the following instruction. In a multiprocessor environment, this ensures that the processor has exclusive use of a shared memory object while the instruction executes. The lock prefix may only precede one of the following instructions:<br/>           ADD, ADC, AND, BTC, BTR, BTS, CMPXCHG, DEC, INC, NEG, NOT, OR, SBB, SUB, XOR, XADD, and XCHG. Furthermore, this prefix is only valid for the forms that have a memory operand as their destination operand. Any other instruction or addressing mode will raise an undefined opcode exception.</p> <p>HLA does not directly support the LOCK prefix on these instructions (if it did, you would normally write instructions like “lock.add(;)” and “lock.bts(;)” However, you can easily add this instruction to HLA’s instruction set through the use of the following macro:</p> <pre>macro lock;   byte \$F0; // \$F0 is the opcode for the lock prefix. endmacro;</pre> <p>To use this macro, simply precede the instruction you wish to lock with an invocation of the macro, e.g.,</p> <pre>lock add( al, mem );</pre> <p>Note that a LOCK prefix will dramatically slow an instruction down since it must access main memory (i.e., no cache) and it must negotiate for the use of that memory location with other processors in a multiprocessor system. The LOCK prefix has very little value in single processor systems.</p> |
| lodsrb();             | Load String Byte. Loads AL with the byte whose address appears in ESI. Then it increments or decrements ESI by one depending on the value of the direction flag. See the chapter on string instructions for more details. Note: HLA does not allow the use of any repeat prefix with this instruction.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| lodsw();              | Load String Word. Loads AX from [ESI] and adds ±2 to ESI. See LODSRB for more details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| loadsd();             | Load String Double Word. Loads EAX from [ESI] and adds ±4 to ESI. See LODSRB for more details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| loop <i>label</i> ;   | Decrements ECX and jumps to the target label if ECX is not zero. See JA for more details. Like JECX, this instruction is limited to a range of ±128 bytes around the instruction and only MASM will catch the range error. Since this instruction is actually slower than a DEC/JNZ pair, you should probably avoid using this instruction.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

| mov( imm, reg );<br>mov( imm, mem );<br>mov( reg, reg );<br>mov( reg, mem );<br>mov( mem, reg );<br><br>mov( mem16, mem16 );<br>mov( mem32, mem32 );                                                                    | Move. Copies the data from the source (first) operand to the destination (second) operand. The operands must be the same size. Note that the memory to memory moves are an HLA extension. HLA compiles these statements into a push(source)/pop(dest) instruction pair.                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| movsb();<br>rep.movsb();                                                                                                                                                                                                | Move string of bytes. Copies the byte pointed at by ESI to the byte pointed at by EDI and then adjusts ESI and EDI by $\pm 1$ depending on the value of the direction flag. With the REP (repeat) prefix, this instruction moves ECX bytes. See the chapter on the String Instructions for more details.                                                                                                                                                                                                                                                                                                                                                                                                                             |
| movsw();<br>rep.movsw();                                                                                                                                                                                                | Move string of words. Like MOVSB above except it copies words and adjusts ESI/EDI by $\pm 2$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| movsd();<br>rep.movsd();                                                                                                                                                                                                | Move string of double words. Like MOVSB above except it copies double words and adjusts ESI/EDI by $\pm 4$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| movsx( reg, reg );<br>movsx( mem, reg );                                                                                                                                                                                | Move with sign extension. Copies the (smaller) source operand to the (larger) destination operand and sign extends the value to the size of the larger operand. The source operand must be smaller than the destination operand.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| movzx( reg, reg );<br>movzx( mem, reg );                                                                                                                                                                                | Move with zero extension. Copies the (smaller) source operand to the (larger) destination operand and zero extends the value to the size of the larger operand. The source operand must be smaller than the destination operand.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| mul( reg );<br>mul( reg8, al );<br>mul( reg16, ax );<br>mul( reg32, eax );<br>mul( mem );<br>mul( mem8, al );<br>mul( mem16, ax );<br>mul( mem32, eax );<br>mul( imm8, al );<br>mul( imm16, ax );<br>mul( imm32, eax ); | Multiplies the accumulator (AL, AX, or EAX) by the source operand. The source operand will be the same size as the accumulator. The product produces an operand that is twice the size of the two operands with the product winding up in AX, DX:AX, or EDX:EAX. Note that the instructions involving an immediate operand are HLA extensions. HLA creates a memory object holding these constants and then multiplies the accumulator by the contents of this memory location.<br><br>This instruction performs a signed multiplication. Also see INTMUL. The carry and overflow flags are cleared if the H.O. portion of the result is zero, they are set otherwise. The sign and zero flags are undefined after this instruction. |
| neg( reg );<br>neg( mem );                                                                                                                                                                                              | Negate. Computes the two's complement of the operand and leaves the result in the operand. This instruction clears the carry flag if the result is zero, it sets the carry flag otherwise. It sets the overflow flag if the original value was the smallest possible negative value (which has no positive counterpart). It sets the sign and zero flags according to the result obtained.                                                                                                                                                                                                                                                                                                                                           |
| nop();                                                                                                                                                                                                                  | No Operation. Consumes space and time but does nothing else. Same instruction as "xchg( eax, eax );"                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| not( reg );<br>not( mem );                                                                                                                                                                                              | Bitwise NOT. Inverts all the bits in its operand. <b>Note:</b> this instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| or( imm, reg );<br>or( imm, mem );<br>or( reg, reg );<br>or( reg, mem );<br>or( mem, reg );                                                                                                                             | Bitwise OR. Logically ORs the source operand with the destination operand and leaves the result in the destination. The two operands must be the same size. Clears the carry and overflow flags and sets the sign and zero flags according to the result.                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                                   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| out(al, imm8);<br>out(ax, imm8);<br>out(eax, imm8);<br>out(al, dx);<br>out(ax, dx);<br>out(eax, dx); | Outputs the accumulator to the specified port. See the IN instruction for limitations under Win32.                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| pop( reg );<br>pop( mem );                                                                           | Pop a value off the stack. Operands must be 16 or 32 bits.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| popa();                                                                                              | Pops all the 16-bit registers off the stack. The popping order is DI, SI, BP, SP, BX, DX, CX, AX.                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| popad();                                                                                             | Pops all the 32-bit registers off the stack. The popping order is EDI, ESI, EBP, ESP, EBX, EDX, ECX, EAX.                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| popf();                                                                                              | Pops the 16-bit FLAGS register off the stack. Note that in user (application) mode, this instruction ignores the interrupt disable flag value it pops off the stack.                                                                                                                                                                                                                                                                                                                                                                             |
| popfd();                                                                                             | Pops the 32-bit EFLAGS register off the stack. Note that in user (application) mode, this instruction ignores many of the bits it pops off the stack.                                                                                                                                                                                                                                                                                                                                                                                            |
| push( reg );<br>push( mem );                                                                         | Pushes the specified 16-bit or 32-bit register or memory location onto the stack. Note that you cannot push eight-bit objects.                                                                                                                                                                                                                                                                                                                                                                                                                   |
| pusha();                                                                                             | Pushes all the 16-bit general purpose registers onto the stack in the order AX, CX, DX, BX, SP, BP, SI, DI.                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| pushad();                                                                                            | Pushes all the 32-bit general purpose registers onto the stack in the order EAX, ECX, EDX, EBX, ESP, EBP, ESI, EDI.                                                                                                                                                                                                                                                                                                                                                                                                                              |
| pushd( imm );<br>pushd( reg );<br>pushd( mem );                                                      | Pushes the 32-bit operand on to the stack. Generally used to push constants or anonymous variables. Note that this is a synonym for PUSH if you specify a register or typed memory operand.                                                                                                                                                                                                                                                                                                                                                      |
| pushf();                                                                                             | Pushes the value of the 16-bit FLAGS register onto the stack.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| pushfd();                                                                                            | Pushes the value of the 32-bit FLAGS register onto the stack.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| pushw( imm );<br>pushw( reg );<br>pushw( mem );                                                      | Pushes the 16-bit operand on to the stack. Generally used to push constants or anonymous variables. Note that this is a synonym for PUSH if you specify a register or typed memory operand.                                                                                                                                                                                                                                                                                                                                                      |
| rcl( imm, reg );<br>rcl( imm, mem );<br>rcl( cl, reg );<br>rcl( cl, mem );                           | Rotate through carry, left. Rotates the destination (second) operand through the carry the number of bits specified by the first operand, shifting the bits from the L.O. to the H.O. position (i.e., rotate left). The carry flag contains the last bit shifted into it. The overflow flag, which is valid only when the shift count is one, is set if the sign changes as a result of the rotate. This instruction does not affect the other flags. In particular, <b>note that this instruction does not affect the sign or zero flags.</b>   |
| rcr( imm, reg );<br>rcr( imm, mem );<br>rcr( cl, reg );<br>rcr( cl, mem );                           | Rotate through carry, right. Rotates the destination (second) operand through the carry the number of bits specified by the first operand, shifting the bits from the H.O. to the L.O. position (i.e., rotate right). The carry flag contains the last bit shifted into it. The overflow flag, which is valid only when the shift count is one, is set if the sign changes as a result of the rotate. This instruction does not affect the other flags. In particular, <b>note that this instruction does not affect the sign or zero flags.</b> |
| rdtsc();                                                                                             | Read Time Stamp Counter. Returns in EDX:EAX the number of clock cycles that have transpired since the last reset of the processor. You can use this instruction to time events in your code (i.e., to determine whether one instruction sequence takes more time than another).                                                                                                                                                                                                                                                                  |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                               | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|--------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ret();<br>ret( imm16 );                                                                          | Return from subroutine. Pops a return address off the stack and transfers control to that location. The second form of the instruction adds the immediate constant to the ESP register to remove the procedure's parameters from the stack.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| rol( imm, reg );<br>rol( imm, mem );<br>rol( cl, reg );<br>rol( cl, mem );                       | Rotate left. Rotates the destination (second) operand the number of bits specified by the first operand, shifting the bits from the L.O. to the H.O. position (i.e., rotate left). The carry flag contains the last bit shifted into it. The overflow flag, which is valid only when the shift count is one, is set if the sign changes as a result of the rotate. This instruction does not affect the other flags. In particular, <b>note that this instruction does not affect the sign or zero flags.</b>                                                                                                                                                                                                                                   |
| ror( imm, reg );<br>ror( imm, mem );<br>ror( cl, reg );<br>ror( cl, mem );                       | Rotate right. Rotates the destination (second) operand the number of bits specified by the first operand, shifting the bits from the H.O. to the L.O. position (i.e., rotate right). The carry flag contains the last bit shifted into it. The overflow flag, which is valid only when the shift count is one, is set if the sign changes as a result of the rotate. This instruction does not affect the other flags. In particular, <b>note that this instruction does not affect the sign or zero flags.</b>                                                                                                                                                                                                                                 |
| sahf();                                                                                          | Store AH into FLAGS. Copies the value in AH into the L.O. eight bits of the FLAGS register. Note that this instruction will not affect the interrupt disable flag when operating in user (application) mode. Bit #7 of AH goes into the Sign flag, bit #6 goes into the zero flag, bit #4 goes into the auxiliary carry (BCD carry) flag, bit #2 goes into the parity flag, and bit #0 goes into the carry flag. This instruction also clears bits one, three, and five of the FLAGS register. It does not affect any other bits in FLAGS or EFLAGS.                                                                                                                                                                                            |
| sal( imm, reg );<br>sal( imm, mem );<br>sal( cl, reg );<br>sal( cl, mem );                       | Shift Arithmetic Left. Same instruction as SHL. See SHL for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| sar( imm, reg );<br>sar( imm, mem );<br>sar( cl, reg );<br>sar( cl, mem );                       | Shift Arithmetic Right. Shifts the destination (second) operand to the right the specified number of bits using an arithmetic shift right algorithm. The carry flag contains the value of the last bit shifted out of the second operand. The overflow flag is only defined when the bit shift count is one, this instruction always clears the overflow flag. The sign and zero flags are set according to the result.                                                                                                                                                                                                                                                                                                                         |
| sbb( imm, reg );<br>sbb( imm, mem );<br>sbb( reg, reg );<br>sbb( reg, mem );<br>sbb( mem, reg ); | Subtract with borrow. Subtracts the source (first) operand and the carry from the destination (second) operand. Sets the condition code bits according to the result it computes. This instruction sets the flags the same way as the SUB instruction. See SUB for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| scasb();<br>repe.scasb();<br>repne.scasb();                                                      | Scan string byte. Compares the value in AL against the byte that EDI points at and sets the flags accordingly (same as the CMP instruction). Adds $\pm 1$ to EDI after the comparison (based on the setting of the direction flag). With the REPE (repeat while equal) prefix, this instruction will scan through as many as ECX bytes in memory as long as each byte that EDI points at is equal to the value in AL (i.e., it scans for the first value not equal to the value in AL). With the REPNE prefix, this instruction scans through as many as ECX bytes as long as the value that EDI points at is not equal to AL (i.e., it scans for the first byte matching AL's value). See the chapter on string instructions for more details. |
| scasw();<br>repe.scasw();<br>repne.scasw();                                                      | Scan String Word. Compares the value in AX against the word that EDI points at and set the flags. Adds $\pm 2$ to EDI after the operation. Also supports the REPE and REPNE prefixes (see SCASB above).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| scasd();<br>repe.scasd();<br>repne.scasd();                                                      | Scan String Double word. Compares the value in EAX against the double word that EDI points at and set the flags. Adds $\pm 4$ to EDI after the operation. Also supports the REPE and REPNE prefixes (see SCASB above).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax               | Description                                                                                                                                                                                                                                                                          |
|----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| seta( reg );<br>seta( mem );     | Conditional set if (unsigned) above (Carry=0 and Zero=0). Stores a one in the destination operand if the result of the previous comparison found the first operand to be greater than the second using an unsigned comparison. Stores a zero into the destination operand otherwise. |
| setae( reg );<br>setae( mem );   | Conditional set if (unsigned) above or equal (Carry=0). See SETA for details.                                                                                                                                                                                                        |
| setb( reg );<br>setb( mem );     | Conditional set if (unsigned) below (Carry=1). See SETA for details.                                                                                                                                                                                                                 |
| setbe( reg );<br>setbe( mem );   | Conditional set if (unsigned) below or equal (Carry=1 or Zero=1). See SETA for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| sets( reg );<br>sets( mem );                                                                         | Conditional set if sign set(Sign=1). See SETA for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| setz( reg );<br>setz( mem );                                                                         | Conditional set if zero (Zero=1). See SETA for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| shl( imm, reg );<br>shl( imm, mem );<br>shl( cl, reg );<br>shl( cl, mem );                           | Shift left. Shifts the destination (second) operand to the left the number of bit positions specified by the first operand. The carry flag contains the value of the last bit shifted out of the second operand. The overflow flag is only defined when the bit shift count is one, this instruction sets overflow flag if the sign changes as a result of this instruction's execution. The sign and zero flags are set according to the result.                                                                                                                                                                                                                 |
| shld( imm8, reg, reg );<br>shld( imm8, reg, mem );<br>shld( cl, reg, reg );<br>shld( cl, reg, mem ); | Shift Left Double precision. The first operand is a bit count. The second operand is a source and the third operand is a destination. These operands must be the same size and they must be 16- or 32-bit values (no eight bit operands). This instruction treats the second and third operands as a double precision value with the second operand being the L.O. word or double word and the third operand being the H.O. word or double word. The instruction shifts this double precision value the specified number of bits and sets the flags in a manner identical to SHL. Note that this instruction does not affect the source (second) operand's value. |
| shr( imm, reg );<br>shr( imm, mem );<br>shr( cl, reg );<br>shr( cl, mem );                           | Shift right. Shifts the destination (second) operand to the right the number of bit positions specified by the first operand. The last bit shifted out goes into the carry flag. The overflow flag is set if the H.O. bit originally contained one. The sign flag is cleared and the zero flag is set if the result is zero.                                                                                                                                                                                                                                                                                                                                      |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                                    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|-------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| shrd( imm8, reg, reg );<br>shrd( imm8, reg, mem );<br>shrd( cl, reg, reg );<br>shrd( cl, reg, mem );  | Shift Right Double precision. The first operand is a bit count. The second operand is a source and the third operand is a destination. These operands must be the same size and they must be 16- or 32-bit values (no eight bit operands). This instruction treats the second and third operands as a double precision value with the second operand being the H.O. word or double word and the third operand being the L.O. word or double word. The instruction shifts this double precision value the specified number of bits and sets the flags in a manner identical to SHR. Note that this instruction does not affect the source (second) operand's value. |
| stc();                                                                                                | Set Carry. Sets the carry flag to one.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| std();                                                                                                | Set Direction. Sets the direction flag to one. If the direction flag is one, the string instructions decrement ESI and/or EDI after each operation.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| sti();                                                                                                | Set interrupt enable flag. Generally this instruction is not usable in user (application) mode. In kernel mode it allows the CPU to begin processing interrupts.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| stosb();<br>rep.stosb();                                                                              | Store String Byte. Stores the value in AL at the location whose address EDI contains. Then it adds $\pm 1$ to EDI. If the REP prefix is present, this instruction repeats the number of times specified in the ECX register. This instruction is useful for quickly clearing out byte arrays.                                                                                                                                                                                                                                                                                                                                                                      |
| stosw();<br>rep.stosw();                                                                              | Store String Word. Stores the value in AX at location [EDI] and then adds $\pm 2$ to EDI. See STOSB for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| stosd();<br>rep.stosd();                                                                              | Store String Double word. Stores the value in EAX at location [EDI] and then adds $\pm 4$ to EDI. See STOSB for details.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| sub( imm, reg );<br>sub( imm, mem );<br>sub( reg, reg );<br>sub( reg, mem );<br>sub( mem, reg );      | Subtract. Subtracts the first operand from the second operand and leaves the difference in the destination (second) operand. Sets the zero flag if the two values were equal (which produces a zero result), sets the carry flag if there was unsigned overflow or underflow; sets the overflow if there was signed overflow or underflow; sets the sign flag if the result is negative (H.O. bit is one). Note that SUB sets the flags identically to the CMP instruction, so you can use conditional jump or set instructions after SUB the same way you would use them after a CMP instruction.                                                                 |
| test( imm, reg );<br>test( imm, mem );<br>test( reg, reg );<br>test( reg, mem );<br>test( mem, reg ); | Test operands. Logically ANDs the two operands together and sets the flags but does not store the computed result (i.e., it does not disturb the value in either operand). Always clears the carry and overflow flags. Sets the sign flag if the H.O. bit of the computed result is one. Sets the zero flag if the computed result is zero.                                                                                                                                                                                                                                                                                                                        |
| xadd( mem, reg );<br>xadd( reg, reg );                                                                | <p>Adds the first operand to the second operand and then stores the original value of the second operand into the first operand:</p> <pre style="margin-left: 40px;">xadd( source, dest ); temp := dest dest := dest + source source := temp</pre> <p>This instruction sets the flags in a manner identical to the ADD instruction.</p>                                                                                                                                                                                                                                                                                                                            |
| xchg( reg, reg );<br>xchg( reg, mem );<br>xchg( mem, reg );                                           | Swaps the values in the two operands which must be the same size. Does not affect any flags.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| xlat();                                                                                               | Translate. Computes $AL := [EBX + AL]$ ; That is, it uses the value in AL as an index into a lookup table whose base address is in EBX. It copies the specified byte from this table into AL.                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

**Table 1: 80x86 Integer and Control Instruction Set**

| Instruction Syntax                                                                               | Description                                                                                                                                                                                                                                                  |
|--------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| xor( imm, reg );<br>xor( imm, mem );<br>xor( reg, reg );<br>xor( reg, mem );<br>xor( mem, reg ); | Exclusive-OR. Logically XORs the source operand with the destination operand and leaves the result in the destination. The two operands must be the same size. Clears the carry and overflow flags and sets the sign and zero flags according to the result. |

**Table 2: Floating Point Instruction Set**

| Instruction                                            | Description                                                                                                                                                                                                                               |
|--------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| f2xm1();                                               | Compute $2^x-1$ in ST0, leaving the result in ST0.                                                                                                                                                                                        |
| fabs();                                                | Computes the absolute value of ST0.                                                                                                                                                                                                       |
| fadd( mem );<br>fadd( sti, st0 );<br>fadd( st0, sti ); | Add operand to st0 or add st0 to destination register (sti, i=0..7). If the operand is a memory operand, it must be a <i>real32</i> or <i>real64</i> object.                                                                              |
| faddp();<br>faddp( st0, sti );                         | With no operands, this instruction adds st0 to st1 and then pops st0 off the FPU stack.                                                                                                                                                   |
| fblld( mem80 );                                        | This instruction loads a ten-byte (80-bit) packed BCD value from memory and converts it to a real80 object. This instruction does not check for an invalid BCD value. If the BCD number contains illegal digits, the result is undefined. |
| fbstp( mem80 );                                        | This instruction pops the real80 object off the top of the FPU stack, converts it to an 80-bit BCD value, and stores the result in the specified memory location (tbyte).                                                                 |
| fchs();                                                | This instruction negates the floating point value on the top of the stack (st0).                                                                                                                                                          |
| fclex();                                               | This instruction clears the floating point exception flags.                                                                                                                                                                               |
| fcmovea( sti, st0 ); <sup>a</sup>                      | Floating point conditional move if above. Copies sti to st0 if c=0 and z=0 (unsigned greater than after a CMP).                                                                                                                           |
| fcmoveae( sti, st0 );                                  | Floating point conditional move if above or equal. Copies sti to st0 if c=0 (unsigned greater or equal after a CMP).                                                                                                                      |
| fcmoveb( sti, st0 );                                   | Floating point conditional move if below. Copies sti to st0 if c=1 (unsigned less than after a CMP).                                                                                                                                      |
| fcmovebe( sti, st0 );                                  | Floating point conditional move if below or equal. Copies sti to st0 if c=1 or z=1 (unsigned less than or equal after a CMP).                                                                                                             |
| fcmove( sti, st0 );                                    | Floating point conditional move if equal. Copies sti to st0 if z=1 (equal after a CMP).                                                                                                                                                   |
| fcmovea( sti, st0 );                                   | Floating point conditional move if not above. Copies sti to st0 if c=1 or z=1 (unsigned not above after a CMP).                                                                                                                           |
| fcmovea( sti, st0 );                                   | Floating point conditional move if not above or equal. Copies sti to st0 if c=1 (unsigned not above or equal after a CMP).                                                                                                                |
| fcmoveb( sti, st0 );                                   | Floating point conditional move if not below. Copies sti to st0 if c=0 (unsigned not below after a CMP).                                                                                                                                  |

**Table 2: Floating Point Instruction Set**

| Instruction                                                                                    | Description                                                                                                                                                                                                                                                                                                                                                                                     |
|------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| fcmovnbe( <i>sti</i> , <i>st0</i> );                                                           | Floating point conditional move if not below or equal. Copies <i>sti</i> to <i>st0</i> if <i>c</i> =0 and <i>z</i> =0 (unsigned not below or equal after a CMP).                                                                                                                                                                                                                                |
| fcmovne( <i>sti</i> , <i>st0</i> );                                                            | Floating point conditional move if not equal. Copies <i>sti</i> to <i>st0</i> if <i>z</i> =0 (not equal after a CMP).                                                                                                                                                                                                                                                                           |
| fcmovnu( <i>sti</i> , <i>st0</i> );                                                            | Floating point conditional move if not unordered. Copies <i>sti</i> to <i>st0</i> if the last floating point comparison did not produce an unordered result (parity flag = 0).                                                                                                                                                                                                                  |
| fcmovu( <i>sti</i> , <i>st0</i> );                                                             | Floating point conditional move if not unordered. Copies <i>sti</i> to <i>st0</i> if the last floating point comparison produced an unordered result (parity flag = 1).                                                                                                                                                                                                                         |
| fcom();<br>fcom( <i>mem</i> );<br>fcom( <i>st0</i> , <i>sti</i> );                             | Compares the value of <i>ST0</i> with the operand and sets the floating point condition bits based on the comparison. If the operand is a memory operand, it must be a <i>real32</i> or <i>real64</i> value. Note that to test the condition codes you will have to copy the floating point status word to the <i>FLAGS</i> register; see the chapter on floating point arithmetic for details. |
| fcomi( <i>st0</i> , <i>sti</i> ); <sup>b</sup>                                                 | Compares the value of <i>ST0</i> with the second operand and sets the appropriate bits in the <i>FLAGS</i> register.                                                                                                                                                                                                                                                                            |
| fcomip( <i>st0</i> , <i>sti</i> );                                                             | Compares the value of <i>ST0</i> with the second operand, sets the appropriate bits in the <i>FLAGS</i> register, and then pops <i>ST0</i> off the FPU stack.                                                                                                                                                                                                                                   |
| fcomp();<br>fcomp( <i>mem</i> );<br>fcomp( <i>sti</i> );                                       | Compares the value of <i>ST0</i> with the operand, sets the floating point status bits, and then pops <i>ST0</i> off the floating point stack. With no operands, this instruction compares <i>ST0</i> to <i>ST1</i> . Memory operands must be <i>real32</i> or <i>real64</i> objects.                                                                                                           |
| fcompp();                                                                                      | Compares <i>ST0</i> to <i>ST1</i> and then pops both values off the stack. Leaves the result of the comparison in the floating point status register.                                                                                                                                                                                                                                           |
| fcos();                                                                                        | Computes $ST0 = \cos(ST0)$ .                                                                                                                                                                                                                                                                                                                                                                    |
| fdecstp();                                                                                     | Rotates the items on the FPU stack.                                                                                                                                                                                                                                                                                                                                                             |
| fdiv( <i>mem</i> );<br>fdiv( <i>sti</i> , <i>st0</i> );<br>fdiv( <i>st0</i> , <i>sti</i> );    | Floating point division. If a memory operand is present, it must be a <i>real32</i> or <i>real64</i> object; <i>FDIV</i> will divide <i>ST0</i> by the memory operand and leave the quotient in <i>ST0</i> . If the <i>FDIV</i> operands are registers, <i>FDIV</i> divides the destination (second) operand by the source (first) operand and leaves the result in the destination operand.    |
| fdivp();<br>fdivp( <i>sti</i> );                                                               | With no operands, this instruction divides <i>ST1</i> by <i>ST0</i> , pops <i>ST0</i> , and replaces the new top of stack with the quotient (replacing the previous <i>ST1</i> value).                                                                                                                                                                                                          |
| fdivr( <i>mem</i> );<br>fdivr( <i>sti</i> , <i>st0</i> );<br>fdivr( <i>st0</i> , <i>sti</i> ); | Floating point divide with reversed operands. Like <i>FDIV</i> , but computes operand/ <i>ST0</i> rather than <i>ST0</i> /operand.                                                                                                                                                                                                                                                              |
| fdivrp();<br>fdivrp( <i>sti</i> );                                                             | Floating point divide and pop, reversed. Like <i>FDIVP</i> except it computes operand/ <i>ST0</i> rather than <i>ST0</i> /operand.                                                                                                                                                                                                                                                              |
| ffree( <i>sti</i> );                                                                           | Frees the specified floating point register.                                                                                                                                                                                                                                                                                                                                                    |
| fiadd( <i>mem</i> );                                                                           | Memory operand must be a 16-bit or 32-bit signed integer. This instruction converts the integer to a real, pushes the value, and then executes <i>FADDP</i> ();                                                                                                                                                                                                                                 |
| ficom( <i>mem</i> );                                                                           | Floating point compare to integer. Memory operand must be an <i>int16</i> or <i>int32</i> object. This instruction converts the memory operand to a <i>real80</i> value and compares <i>ST0</i> to this value and sets the status bits in the floating point status register.                                                                                                                   |

**Table 2: Floating Point Instruction Set**

| Instruction                | Description                                                                                                                                                                                                                                                                                                                                        |
|----------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ficomp( mem );             | Floating point compare to integer and pop. Memory operand must be an <i>int16</i> or <i>int32</i> object. This instruction converts the memory operand to a <i>real80</i> value and compares ST0 to this value and sets the status bits in the floating point status register. After the comparison, this instructions pop ST0 from the FPU stack. |
| fidiv( mem );              | Floating point divide by integer. Memory operand must be an <i>int16</i> or <i>int32</i> object. These instructions convert their integer operands to a <i>real80</i> value and then divide ST0 by this value, leaving the result in ST0.                                                                                                          |
| fidivr( mem );             | Floating point divide by integer, reversed. Like FIDIV above, except this instruction computes mem/ST0 rather than ST0/mem.                                                                                                                                                                                                                        |
| fld( mem );                | Floating point load integer. Mem operand must be an <i>int16</i> or <i>int32</i> object. This instructions converts the integer to a <i>real80</i> object and pushes it onto the FPU stack.                                                                                                                                                        |
| fimul( mem );              | Floating point multiply by integer. Converts <i>int16</i> or <i>int32</i> operand to a <i>real80</i> value and multiplies ST0 by this result. Leaves product in ST0.                                                                                                                                                                               |
| fincstp();                 | Rotates the registers on the FPU stack.                                                                                                                                                                                                                                                                                                            |
| finit();                   | Initializes the FPU for use.                                                                                                                                                                                                                                                                                                                       |
| fist( mem );               | Converts ST0 to an integer and stores the result in the specified memory operand. Memory operand must be an <i>int16</i> or <i>int32</i> object.                                                                                                                                                                                                   |
| fistp( mem );              | Floating point integer store and pop. Pops ST0 value off the stack, converts it to an integer, and stores the integer in the specified location. Memory operand must be a word, double word, or quad word (64-bit integer) object.                                                                                                                 |
| fisub( mem );              | Floating point subtract integer. Converts <i>int16</i> or <i>int32</i> operand to a <i>real80</i> value and subtracts it from ST0. Leaves the result in ST0.                                                                                                                                                                                       |
| fisubr( mem );             | Floating point subtract integer, reversed. Like FISUB except this instruction compute mem-ST0 rather than ST0-mem. Still leaves the result in ST0.                                                                                                                                                                                                 |
| fld( mem );<br>fld( sti ); | Floating point load. Loads (pushes) the specified operand onto the FPU stack. Memory operands must be <i>real32</i> , <i>real64</i> , or <i>real80</i> objects. Note that FLD(ST0) duplicates the value on the top of the floating point stack.                                                                                                    |
| fld1();                    | Floating point load 1.0. This instruction pushes 1.0 onto the FPU stack.                                                                                                                                                                                                                                                                           |
| fldcw( mem16 );            | Load floating point control word. This instruction copies the word operand into the floating point control register.                                                                                                                                                                                                                               |
| fldenv( mem28 );           | This instruction loads the FPU status from the block of 28 bytes specified by the operand. Generally, only an operating system would use this instruction.                                                                                                                                                                                         |
| fldl2e();                  | Floating point load constant. Loads $\log_2(e)$ onto the stack.                                                                                                                                                                                                                                                                                    |
| fldl2t();                  | Floating point load constant. Loads $\log_2(10)$ onto the stack.                                                                                                                                                                                                                                                                                   |
| fldlg2();                  | Floating point load constant. Loads $\log_{10}(2)$ onto the stack.                                                                                                                                                                                                                                                                                 |
| fldln2();                  | Floating point load constant. Loads $\log_e(2)$ onto the stack.                                                                                                                                                                                                                                                                                    |
| fldpi();                   | Floating point load constant. Loads the value of pi ( $\pi$ ) onto the stack.                                                                                                                                                                                                                                                                      |
| fldz();                    | Floating point load constant. Pushes the value 0.0 onto the stack.                                                                                                                                                                                                                                                                                 |

**Table 2: Floating Point Instruction Set**

| Instruction                                            | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
|--------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| fmul( mem );<br>fmul( sti, st0 );<br>fmul( st0, sti ); | Floating point multiply. If the operand is a memory operand, it must be a <i>real32</i> or <i>real64</i> value; in this case, FMUL multiplies the memory operand and ST0, leaving the product in ST0. For the other two forms, the FMUL instruction multiplies the first operand by the second and leaves the result in the second operand.                                                                                                                   |
| fmlp();<br>fmlp( st0, sti );                           | Floating point multiply and pop. With no operands this instruction computes $ST1:=ST0*ST1$ and then pops ST0. With two register operands, this instruction computes ST0 times the destination register and then pops ST0.                                                                                                                                                                                                                                     |
| fnop();                                                | Floating point no-operation.                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| fpatan();                                              | Floating point partial arctangent. Computes $ATAN( ST1/ST0 )$ , pops ST0, and then stores the result in the new TOS value (previous ST1 value).                                                                                                                                                                                                                                                                                                               |
| fprem();                                               | Floating point remainder. This instruction is retained for compatibility with older programs. Use the FPREM1 instruction instead.                                                                                                                                                                                                                                                                                                                             |
| fprem1();                                              | Floating point partial remainder. This instruction computes the remainder obtained by dividing ST0 by ST1, leaving the result in ST0 (it does not pop either operand). If the C2 flag in the FPU status register is set after this instruction, then the computation is not complete; you must repeatedly execute this instruction until C2 is cleared.                                                                                                       |
| fptan();                                               | Floating point partial tangent. This instruction computes $TAN( ST0 )$ and replaces the value in ST0 with this result. Then it pushes 1.0 onto the stack. This instruction sets the C2 flag if the input value is outside the acceptable range of $\pm 2^{63}$ .                                                                                                                                                                                              |
| frndint();                                             | Floating point round to integer. This instruction rounds the value in ST0 to an integer using the rounding control bits in the floating point control register. Note that the result left on TOS is still a real value. It simply doesn't have a fractional component. You may use this instruction to round or truncate a floating point value by setting the rounding control bits appropriately. See the chapter on floating point arithmetic for details. |
| frstor( mem108);                                       | Restores the FPU status from a 108-byte memory block.                                                                                                                                                                                                                                                                                                                                                                                                         |
| fsave( mem108);                                        | Writes the FPU status to a 108-byte memory block.                                                                                                                                                                                                                                                                                                                                                                                                             |
| fscale();                                              | Floating point scale by power of two. ST1 contains a scaling value. This instruction multiplies ST0 by $2^{ST1}$ .                                                                                                                                                                                                                                                                                                                                            |
| fsin();                                                | Floating point sine. Replaces ST0 with $\sin( ST0 )$ .                                                                                                                                                                                                                                                                                                                                                                                                        |
| fsincos();                                             | Simultaneously computes the sin and cosine values of ST0. Replaces ST0 with the sine of ST0 and then it pushes the cosine of (the original value of) ST0 onto the stack. Original ST0 value must be in the range $\pm 2^{63}$ .                                                                                                                                                                                                                               |
| fsqrt();                                               | Floating point square root. Replaces ST0 with the square root of ST0.                                                                                                                                                                                                                                                                                                                                                                                         |
| fst( mem );<br>fst( sti );                             | Floating point store. Stores a copy of ST0 in the destination operand. Memory operands must be <i>real32</i> or <i>real64</i> objects. When storing the value to memory, FST converts the value to the smaller format using the rounding control bits in the floating point control register to determine how to convert the <i>real80</i> value in ST0 to a <i>real32</i> or <i>real64</i> value.                                                            |
| fstcw( mem16 );                                        | Floating point store control word. Stores a copy of the floating point control word in the specified <i>word</i> memory location.                                                                                                                                                                                                                                                                                                                             |
| fstenv( mem28 );                                       | Floating point store FPU environment. Stores a copy of the 28-byte floating point environment in the specified memory location. Normally, an OS would use this when switch contexts.                                                                                                                                                                                                                                                                          |

**Table 2: Floating Point Instruction Set**

| Instruction                                               | Description                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|-----------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| fstp( mem );<br>fstp( sti );                              | Floating point store and pop. Stores ST0 into the destination operand and then pops ST0 off the stack. If the operand is a memory object, it must be a <i>real32</i> , <i>real64</i> , or <i>real80</i> object.                                                                                                                                                                                                                                         |
| fstsw( ax );<br>fstsw( mem16 );                           | Stores a copy of the 16-bit floating point status register into the specified word operand. Note that this instruction automatically places the C1, C2, C3, and C4 condition bits in appropriate places in AH so that a following SAHF instruction will set the processor flags to allow the use of a conditional jump or conditional set instruction after a floating point comparison. See the chapter on floating point arithmetic for more details. |
| fsub( mem );<br>fsub( st0, sti );<br>fsub( sti, st0 );    | Floating point subtract. With a single memory operand (which must be a <i>real32</i> or <i>real64</i> object), this instruction subtracts the memory operand from ST0. With two register operands, this instruction computes $dest := dest - src$ (where <i>src</i> is the first operand and <i>dest</i> is the second operand).                                                                                                                        |
| fsubp();<br>fsubp( st0, sti );                            | Floating point subtract and pop. With no operands, this instruction computes $ST1 := ST0 - ST1$ and then pops ST0 off the stack. With two operands, this instruction computes $STi := STi - ST0$ and then pops ST0 off the stack.                                                                                                                                                                                                                       |
| fsubr( mem );<br>fsubr( st0, sti );<br>fsubr( sti, st0 ); | Floating point subtract, reversed. With a <i>real32</i> or <i>real64</i> memory operand, this instruction computes $ST0 := mem - ST0$ . For the other two forms, this instruction computes $dest := src - dest$ where <i>src</i> is the first operand and <i>dest</i> is the second operand.                                                                                                                                                            |
| fsubrp();<br>fsubrp( st0, sti );                          | Floating point subtract and pop, reversed. With no operands, this instruction computes $ST1 := ST0 - ST1$ and then pops ST0. With two operands, this instruction computes $STi := ST0 - STi$ and then pops ST0 from the stack.                                                                                                                                                                                                                          |
| ftst();                                                   | Floating point test against zero. Compares ST0 with 0.0 and sets the floating point condition code bits accordingly.                                                                                                                                                                                                                                                                                                                                    |
| fucom( sti );<br>fucom();                                 | Floating point unordered comparison. With no operand, this instruction compares ST0 to ST1. With an operand, this instruction compares ST0 to STi and sets floating point status bits accordingly. Unlike FCOM, this instruction will not generate an exception if either of the operands is an illegal floating point value; instead, this sets a special status value in the FPU status register.                                                     |
| fucomi( sti, st0 );                                       | Floating point unordered comparison.                                                                                                                                                                                                                                                                                                                                                                                                                    |
| fucomp();<br>fucomp( sti );                               | Floating point unorder comparison and pop. With no operands, compares ST0 to ST1 using an unordered comparison (see FUCOM) and then pops ST0 off the stack. With an FPU operand, this instruction compares ST0 to the specified register and then pops ST0 off the stack. See FUCOM for more details.                                                                                                                                                   |
| fucompp();<br>fucompp( sti );                             | Floating point unordered compare and double pop. Compares ST0 to ST1, sets the condition code bits (without raising an exception for illegal values, see FUCOM), and then pops both ST0 and ST1.                                                                                                                                                                                                                                                        |
| fwait();                                                  | Floating point wait. Waits for current FPU operation to complete. Generally an obsolete instruction. Used back in the days when the FPU was on a different chip than the CPU.                                                                                                                                                                                                                                                                           |
| fxam();                                                   | Floating point Examine ST0. Checks the value in ST0 and sets the condition code bits according to the type of the value in ST0. See the chapter on floating point arithmetic for details.                                                                                                                                                                                                                                                               |
| fxch();<br>fxch( sti );                                   | Floating point exchange. With no operands this instruction exchanges ST0 and ST1 on the FPU stack. With a single register operand, this instruction swaps ST0 and STi.                                                                                                                                                                                                                                                                                  |
| fextract();                                               | Floating point exponent/mantissa extraction. This instruction breaks the value in ST0 into two pieces. It replaces ST0 with the real representation of the binary exponent (e.g. $2^5$ becomes 5.0) and then it pushes the mantissa of the value with an exponent of zero.                                                                                                                                                                              |
| fyl2x();                                                  | Floating point partial logarithm computation. Computes $ST1 := ST1 * \log_2(ST0)$ ; and then pops ST0.                                                                                                                                                                                                                                                                                                                                                  |

**Table 2: Floating Point Instruction Set**

| Instruction | Description                                                                                                                                                                                                                                                                                           |
|-------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| fyl2xp1();  | <p>Floating point partial logarithm computation. Computes <math>ST1 := ST1 * \log_2(ST0 + 1.0)</math> and then pops <math>ST0</math> off the stack. Original <math>ST0</math> value must be in the range</p> $\left(-\left(1 - \frac{\sqrt{2}}{2}\right), \left(1 - \frac{\sqrt{2}}{2}\right)\right)$ |

- a. Floating point conditional move instructions are only available on Pentium Pro and later processors.  
b. FCOMIx instructions are only available on Pentium Pro and later processors.

The following table uses these abbreviations:

|        |                                                                                                                             |
|--------|-----------------------------------------------------------------------------------------------------------------------------|
| Reg32- | A 32-bit general purpose (integer) register.                                                                                |
| mmi-   | One of the eight MMX registers, MM0..MM7.                                                                                   |
| imm8-  | An eight-bit constant value; some instructions have smaller ranges that 0..255. See the particular instruction for details. |
| mem64- | A memory location (using an arbitrary addressing mode) that references a <i>qword</i> value.                                |

Note: Most instructions have two operands. Typically the first operand is a source operand and the second operand is a destination operand. For exceptions, see the description of the instruction.

**Table 3: MMX Instruction Set**

| Instruction                                                                              | Description                                                                                                                                                                                                                                                                                                                                                                                                 |
|------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| emms();                                                                                  | Empty MMX State. You must execute this instruction when you are finished using MMX instructions and before any following floating point instructions.                                                                                                                                                                                                                                                       |
| movd( reg32, mmi );<br>movd( mem32, mmi );<br>movd( mmi, reg32 );<br>movd( mmi, mem32 ); | Moves data between a 32-bit integer register or <i>dword</i> memory location and an MMX register (mm0..mm7). If the destination operand is an MMX register, then the source operand is zero-extended to 64 bits during the transfer. If the destination operand is a <i>dword</i> memory location or 32-bit register, this instruction copies only the L.O. 32 bits of the MMX register to the destination. |
| movq( mem64, mmi );<br>movq( mmi, mem64 );<br>movq( mmi, mmi );                          | This instruction moves 64 bits between an MMX register and a <i>qword</i> variable in memory or between two MMX registers.                                                                                                                                                                                                                                                                                  |

**Table 3: MMX Instruction Set**

| Instruction                                      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|--------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| packssdw( mem64, mmi );<br>packssdw( mmi, mmi ); | Pack and saturate two signed double words from source and two signed double words from destination and store result into destination MMX register. This process involves taking these four double words and “saturating” them. This means that if the value is in the range -32768..32768 the value is left unchanged, but if it’s greater than 32767 the value is set to 32767 or if it’s less than -32768 the value is clipped to -32768. The four double words are packed into a single 64-bit MMX register. The source operand supplies the upper two words and the destination operand supplies the lower two words of the packed 64-bit result. See the chapter on the MMX instructions for more details. |
| packsswb( mem64, mmi );<br>packsswb( mmi, mmi ); | Pack and saturate four signed words from source and four signed words from destination and store the result as eight signed bytes into the destination MMX register. See the chapter on the MMX instructions for more details. The bytes obtained from the destination register wind up in the L.O. four bytes of the destination; the bytes computed from the signed saturation of the source register wind up in the H.O. four bytes of the destination register.                                                                                                                                                                                                                                             |
| packusdw( mem64, mmi );<br>packusdw( mmi, mmi ); | Pack and saturate two unsigned double words from source and two unsigned double words from destination and store result into destination MMX register. This process involves taking these four double words and “saturating” them. This means that if the value is in the range 0..65535 the value is left unchanged, but if it’s greater than 65535 the value is clipped to 65535. The four double words are packed into a single 64-bit MMX register. The source operand supplies the upper two words and the destination operand supplies the lower two words of the packed 64-bit result. See the chapter on the MMX instructions for more details.                                                         |
| packuswb( mem64, mmi );<br>packuswb( mmi, mmi ); | Pack and saturate four unsigned words from source and four unsigned words from destination and store the result as eight unsigned bytes into the destination MMX register. Word values greater than 255 are clipped to 255 during the saturation operation. See the chapter on the MMX instructions for more details. The bytes obtained from the destination register wind up in the L.O. four bytes of the destination; the bytes computed from the signed saturation of the source register wind up in the H.O. four bytes of the destination register.                                                                                                                                                      |
| paddb( mem64, mmi );<br>paddb( mmi, mmi );       | Packed Add of Bytes. This instruction adds together the individual bytes of the two operands. The addition of each byte is independent of the other eight bytes; there is no carry from byte to byte. If an overflow occurs in any byte, the value simply wraps around to zero with no indication of the overflow. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                  |
| padd( mem64, mmi );<br>padd( mmi, mmi );         | Packed Add of Double Words. This instruction adds together the individual dwords of the two operands. The addition of each dword is independent of the other two dwords; there is no carry from dword to dword. If an overflow occurs in any dword, the value simply wraps around to zero with no indication of the overflow. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                       |
| paddsb( mem64, mmi );<br>paddsb( mmi, mmi );     | Packed Add of Bytes, signed saturated. This instruction adds together the individual bytes of the two operands. The addition of each byte is independent of the other eight bytes; there is no carry from byte to byte. If an overflow or underflow occurs in any byte, then the value saturates at -128 or +127. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                   |
| paddsw( mem64, mmi );<br>paddsw( mmi, mmi );     | Packed Add of Words, signed saturated. This instruction adds together the individual words of the two operands. The addition of each word is independent of the other four words; there is no carry from word to word. If an overflow or underflow occurs in any word, the value saturates at either -32768 or +32767. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                              |
| paddusb( mem64, mmi );<br>paddusb( mmi, mmi );   | Packed Add of Bytes, unsigned saturated. This instruction adds together the individual bytes of the two operands. The addition of each byte is independent of the other eight bytes; there is no carry from byte to byte. If an overflow or underflow occurs in any byte, then the value saturates at 0 or 255. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                     |

**Table 3: MMX Instruction Set**

| Instruction                                    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

| paddsw( mem64, mmi );<br>paddsw( mmi, mmi );   | Packed Add of Words, unsigned saturated. This instruction adds together the individual words of the two operands. The addition of each word is independent of the other four words; there is no carry from word to word. If an overflow or underflow occurs in any word, the value saturates at either 0 or 65535. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| paddw( mem64, mmi );<br>paddw( mmi, mmi );     | Packed Add of Words. This instruction adds together the individual words of the two operands. The addition of each word is independent of the other four words; there is no carry from word to word. If an overflow occurs in any word, the value simply wraps around to zero with no indication of the overflow. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| pand( mem64, mmi );<br>pand( mmi, mmi );       | Packed AND. This instruction computes the bitwise AND of the source and the destination values, leaving the result in the destination. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| pandn( mem64, mmi );<br>pandn( mmi, mmi );     | Packed AND NOT. This instruction makes a temporary copy of the first operand and inverts all of the bits in this copy; then it ANDs this value with the destination MMX register. This instruction does not affect any flags.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| pavgb( mem64, mmi );<br>pavgb( mmi, mmi );     | Packed Average of Bytes. This instruction computes the average of the eight pairs of bytes in the two operands. It leaves the result in the destination (second) operand.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| pavgw( mem64, mmi );<br>pavgw( mmi, mmi );     | Packed Average of Words. This instruction computes the average of the four pairs of words in the two operands. It leaves the result in the destination (second) operand.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| pcmpeqb( mem64, mmi );<br>pcmpeqb( mmi, mmi ); | Packed Compare for Equal Bytes. This instruction compares the individual bytes in the two operands. If they are equal this instruction sets the corresponding byte in the destination (second) register to \$FF (all ones); if they are not equal, this instruction sets the corresponding byte to zero.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| pcmpeqd( mem64, mmi );<br>pcmpeqd( mmi, mmi ); | Packed Compare for Equal Double Words. This instruction compares the individual double words in the two operands. If they are equal this instruction sets the corresponding double word in the destination (second) register to \$FFFF_FFFF (all ones); if they are not equal, this instruction sets the corresponding dword to zero.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| pcmpeqw( mem64, mmi );<br>pcmpeqw( mmi, mmi ); | Packed Compare for Equal Words. This instruction compares the individual words in the two operands. If they are equal this instruction sets the corresponding word in the destination (second) register to \$FFFF (all ones); if they are not equal, this instruction sets the corresponding word to zero.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| pcmpgtb( mem64, mmi );<br>pcmpgtb( mmi, mmi ); | Packed Compare for Greater Than, Bytes. This instruction compares the individual bytes in the two operands. If the destination (second) operand byte is greater than the source (first) operand byte, then this instruction sets the corresponding byte in the destination (second) register to \$FF (all ones); if they are not equal, this instruction sets the corresponding byte to zero. Note that there is no PCMPLEB instruction. You can simulate this instruction by swapping the operands in the PCMPGTB instruction (i.e., compare in the opposite direction). Also note that these operands are, in a sense, backwards compared with the standard CMP instruction. This instruction compares the second operand to the first rather than the other way around. This was done because the second operand is always the destination operand and, unlike the CMP instruction, this instruction writes data to the destination operand. |

**Table 3: MMX Instruction Set**

| Instruction                                    | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| pcmpgtd( mem64, mmi );<br>pcmpgtd( mmi, mmi ); | Packed Compare for Greater Than, Double Words. This instruction compares the individual dwords in the two operands. If the destination (second) operand dword is greater than the source (first) operand dword, then this instruction sets the corresponding dword in the destination (second) register to \$FFFF_FFFF (all ones); if they are not equal, this instruction sets the corresponding dword to zero. Note that there is no PCMPLED instruction. You can simulate this instruction by swapping the operands in the PCMPGTD instruction (i.e., compare in the opposite direction). Also note that these operands are, in a sense, backwards compared with the standard CMP instruction. This instruction compares the second operand to the first rather than the other way around. This was done because the second operand is always the destination operand and, unlike the CMP instruction, this instruction writes data to the destination operand. |
| pcmpgtw( mem64, mmi );<br>pcmpgtw( mmi, mmi ); | Packed Compare for Greater Than, Words. This instruction compares the individual words in the two operands. If the destination (second) operand word is greater than the source (first) operand word, then this instruction sets the corresponding word in the destination (second) register to \$FFFF (all ones); if they are not equal, this instruction sets the corresponding dword to zero. Note that there is no PCMPLEW instruction. You can simulate this instruction by swapping the operands in the PCMPGTW instruction (i.e., compare in the opposite direction). Also note that these operands are, in a sense, backwards compared with the standard CMP instruction. This instruction compares the second operand to the first rather than the other way around. This was done because the second operand is always the destination operand and, unlike the CMP instruction, this instruction writes data to the destination operand.                 |
| pextrw(imm8, mmi, reg32);                      | Packed Extraction of a word. The imm8 value must be a constant in the range 0..3. This instruction copies the specified word from the MMX register into the L.O. word of the destination 32-bit integer register. This instruction zero extends the 16-bit value to 32 bits in the integer register. Note that there are no extraction instructions for bytes or dwords. However, you can easily extract a byte using PEXTRW and an AND or XCHG instruction (depending on whether the byte number is even or odd). You can use MOVD to extract the L.O. dword. to extract the H.O. dword of an MMX register requires a bit more work; either extract the two words and merge them or move the data to memory and grab the dword you're interested in.                                                                                                                                                                                                              |
| pinsw(imm8, reg32, mmi);                       | Packed Insertion of a word. The imm8 value must be a constant in the range 0..3. This instruction copies the L.O. word from the 32-bit integer register into the specified word of the destination MMX register. This instruction ignores the H.O. word of the integer register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| pmaddwd( mem64, mmi );<br>pmaddwd( mmi, mmi ); | Packed Multiple and Accumulate (Add). This instruction multiplies together the corresponding words in the source and destination operands. Then it adds the two double word products from the multiplication of the two L.O. words and stores this double word sum in the L.O. dword of the destination MMX register. Finally, it adds the two double word products from the multiplication of the H.O. words and stores this double word sum in the H.O. dword of the destination MMX register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| pmaxw( mem64, mmi );<br>pmaxw( mmi, mmi );     | Packed Signed Integer Word Maximum. This instruction compares the four words between the two operands and stores the signed maximum of each corresponding word in the destination MMX register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| pmaxub( mem64, mmi );<br>pmaxub( mmi, mmi );   | Packed Unsigned Byte Maximum. This instruction compares the eight bytes between the two operands and stores the unsigned maximum of each corresponding byte in the destination MMX register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| pminw( mem64, mmi );<br>pminw( mmi, mmi );     | Packed Signed Integer Word Minimum. This instruction compares the four words between the two operands and stores the signed minimum of each corresponding word in the destination MMX register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| pminub( mem64, mmi );<br>pminub( mmi, mmi );   | Packed Unsigned Byte Minimum. This instruction compares the eight bytes between the two operands and stores the unsigned minimum of each corresponding byte in the destination MMX register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

Computes the bitwise OR of the two operands and stores the result in the destination (second) MMX register.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| psadbw( mem64, <i>mmi</i> );<br>psadbw( <i>mmi</i> , <i>mmi</i> );                           | Packed Sum of Absolute Differences. This instruction computes the absolute value of the difference of each of the unsigned bytes between the two operands. Then it adds these eight results together to form a word sum. Finally, the instruction zero extends this word to 64 bits and stores the result in the destination (second) operand.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| pshufw(imm8,mem64, <i>mmi</i> );                                                             | Packed Shuffle Word. This instruction treats the imm8 value as an array of four two-bit values. These bits specify where the destination (third) operand's words obtain their values. Bits zero and one tell this instruction where to obtain the L.O. word, bits two and three specify where word #1 comes from, bits four and five specify the source for word #2, and bits six and seven specify the source of the H.O. word in the destination operand. Each pair of bytes specifies a word number in the source (second) operand. For example, an immediate value of %00011011 tells this instruction to grab word #3 from the source and place it in the L.O. word of the destination; grab word #2 from the source and place it in word #1 of the destination; grab word #1 from the source and place it in word #2 of the destination; and grab the L.O. word of the source and place it in the H.O. word of the destination (i.e., swap all the words in a manner similar to the BSWAP instruction). |
| pslld( mem, <i>mmi</i> );<br>pslld( <i>mmi</i> , <i>mmi</i> );<br>pslld( imm8, <i>mmi</i> ); | Packed Shift Left Logical, Double Words. This instruction shifts the destination (second) operand to the left the number of bits specified by the first operand. Each double word in the destination is treated as an independent entity. Bits are not carried over from the L.O. dword to the H.O. dword. Bits shifted out are lost and this instruction always shifts in zeros.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| psllq( mem, <i>mmi</i> );<br>psllq( <i>mmi</i> , <i>mmi</i> );<br>psllq( imm8, <i>mmi</i> ); | Packed Shift Left Logical, Quad Word. This instruction shifts the destination operand to the left the number of bits specified by the first operand.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| psllw( mem, <i>mmi</i> );<br>psllw( <i>mmi</i> , <i>mmi</i> );<br>psllw( imm8, <i>mmi</i> ); | Packed Shift Left Logical, Words. This instruction shifts the destination (second) operand to the left the number of bits specified by the first operand. Bits shifted out are lost and this instruction always shifts in zeros. Each word in the destination is treated as an independent entity. Bits are not carried over from the L.O. words into the next higher word. Bits shifted out are lost and this instruction always shifts in zeros.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| psard( mem, <i>mmi</i> );<br>psard( <i>mmi</i> , <i>mmi</i> );<br>psard( imm8, <i>mmi</i> ); | Packed Shift Right Arithmetic, Double Word. This instruction treats the two halves of the 64-bit register as two double words and performs separate arithmetic shift rights on them. The bit shifted out of the bottom of the two double words is lost.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

**Table 3: MMX Instruction Set**

| Instruction                                                     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-----------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| psarw( mem, mmi );<br>psarw( mmi, mmi );<br>psarw( imm8, mmi ); | Packed Shift Right Arithmetic, Word. This instruction operates independently on the four words of the 64-bit destination register and performs separate arithmetic shift rights on them. The bit shifted out of the bottom of the four words is lost.                                                                                                                                                                                                        |
| psrld( mem, mmi );<br>psrld( mmi, mmi );<br>psrld( imm8, mmi ); | Packed Shift Right Logical, Double Words. This instruction shifts the destination (second) operand to the right the number of bits specified by the first operand. Each double word in the destination is treated as an independent entity. Bits are not carried over from the H.O. dword to the L.O. dword. Bits shifted out are lost and this instruction always shifts in zeros.                                                                          |
| pslrq( mem, mmi );<br>pslrq( mmi, mmi );<br>pslrq( imm8, mmi ); | Packed Shift Right Logical, Quad Word. This instruction shifts the destination operand to the right the number of bits specified by the first operand.                                                                                                                                                                                                                                                                                                       |
| pslrw( mem, mmi );<br>pslrw( mmi, mmi );<br>pslrw( imm8, mmi ); | Packed Shift Right Logical, Words. This instruction shifts the destination (second) operand to the right the number of bits specified by the first operand. Bits shifted out are lost and this instruction always shifts in zeros. Each word in the destination is treated as an independent entity. Bits are not carried over from the H.O. words into the next lower word. Bits shifted out are lost and this instruction always shifts in zeros.          |
| psubb( mem64, mmi );<br>psubb( mmi, mmi );                      | Packed Subtract of Bytes. This instruction subtracts the individual bytes of the source (first) operand from the corresponding bytes of the destination (second) operand. The subtraction of each byte is independent of the other eight bytes; there is no borrow from byte to byte. If an overflow or underflow occurs in any byte, the value simply wraps around to zero with no indication of the overflow. This instruction does not affect any flags.  |
| psubd( mem64, mmi );<br>psubd( mmi, mmi );                      | Packed Subtract of Double Words. This instruction subtracts the individual dwords of the source (first) operand from the corresponding dwords of the destination (second) operand. The subtraction of each dword is independent of the other; there is no borrow from dword to dword. If an overflow or underflow occurs in any dword, the value simply wraps around to zero with no indication of the overflow. This instruction does not affect any flags. |
| psubsb( mem64, mmi );<br>psubsb( mmi, mmi );                    | Packed Subtract of Bytes, signed saturated. This instruction subtracts the individual bytes of the source operand from the corresponding bytes of the destination operand, saturating to -128 or +127 if overflow or underflow occurs. The subtraction of each byte is independent of the other seven bytes; there is no carry from byte to byte. This instruction does not affect any flags.                                                                |
| psubsw( mem64, mmi );<br>psubsw( mmi, mmi );                    | Packed Subtract of Words, signed saturated. This instruction subtracts the individual words of the source operand from the corresponding words of the destination operand, saturating to -32768 or +32767 if overflow or underflow occurs. The subtraction of each word is independent of the other three words; there is no carry from word to word. This instruction does not affect any flags.                                                            |
| psubusb( mem64, mmi );<br>psubusb( mmi, mmi );                  | Packed Subtract of Bytes, unsigned saturated. This instruction subtracts the individual bytes of the source operand from the corresponding bytes of the destination operand, saturating to 0 if underflow occurs. The subtraction of each byte is independent of the other seven bytes; there is no carry from byte to byte. This instruction does not affect any flags.                                                                                     |
| psubusw( mem64, mmi );<br>psubusw( mmi, mmi );                  | Packed Subtract of Words, unsigned saturated. This instruction subtracts the individual words of the source operand from the corresponding words of the destination operand, saturating to 0 if underflow occurs. The subtraction of each word is independent of the other three words; there is no carry from word to word. This instruction does not affect any flags.                                                                                     |
| psubw( mem64, mmi );<br>psubw( mmi, mmi );                      | Packed Subtract of Words. This instruction subtracts the individual words of the source (first) operand from the corresponding words of the destination (second) operand. The subtraction of each word is independent of the others; there is no borrow from word to word. If an overflow or underflow occurs in any word, the value simply wraps around to zero with no indication of the overflow. This instruction does not affect any flags.             |

**Table 3: MMX Instruction Set**

| Instruction                                        | Description                                                                                                                                                                                                                                                                                                                                                                               |
|----------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| punpckhbw( mem64, mmi );<br>punpckhbw( mmi, mmi ); | Unpack high packed data, bytes to words. This instruction unpacks and interleaves the high-order four bytes of the source (first) and destination (second) operands. It places the H.O. four bytes of the destination operand at the even byte positions in the destination and it places the H.O. four bytes of the source operand in the odd byte positions of the destination operand. |
| punpckhdq( mem64, mmi );<br>punpckhdq( mmi, mmi ); | Unpack high packed data, dwords to qword. This instruction copies the H.O. dword of the source operand to the H.O. dword of the destination operand and it copies the (original) H.O. dword of the destination operand to the L.O. dword of the destination.                                                                                                                              |
| punpckhwd( mem64, mmi );<br>punpckhwd( mmi, mmi ); | Unpack high packed data, words to dwords. This instruction unpacks and interleaves the high-order two words of the source (first) and destination (second) operands. It places the H.O. two words of the destination operand at the even word positions in the destination and it places the H.O. words of the source operand in the odd word positions of the destination operand.       |
| punpcklbw( mem64, mmi );<br>punpcklbw( mmi, mmi ); | Unpack low packed data, bytes to words. This instruction unpacks and interleaves the low-order four bytes of the source (first) and destination (second) operands. It places the L.O. four bytes of the destination operand at the even byte positions in the destination and it places the L.O. four bytes of the source operand in the odd byte positions of the destination operand.   |
| punpckldq( mem64, mmi );<br>punpckldq( mmi, mmi ); | Unpack low packed data, dwords to qword. This instruction copies the L.O. dword of the source operand to the H.O. dword of the destination operand and it copies the (original) L.O. dword of the destination operand to the L.O. dword of the destination (i.e., it doesn't change the L.O. dword of the destination).                                                                   |
| punpcklwd( mem64, mmi );<br>punpcklwd( mmi, mmi ); | Unpack low packed data, words to dwords. This instruction unpacks and interleaves the low-order two words of the source (first) and destination (second) operands. It places the L.O. two words of the destination operand at the even word positions in the destination and it places the L.O. words of the source operand in the odd word positions of the destination operand.         |
| pxor( mem64, mmi );<br>pxor( mmi, mmi );           | Packed Exclusive-OR. This instruction exclusive-ORs the source operand with the destination operand leaving the result in the destination operand.                                                                                                                                                                                                                                        |

# The HLA Standard Library Reference

# Appendix F

To be written when the HLA language settles down a bit. See the HLA Standard Library documentation in the meantime.

# HLA Exceptions

# Appendix G

The HLA Standard Library provides the following exception types<sup>1</sup>:

## ex.StringOverflow

HLA raises this exception if you attempt to store too many characters into preallocated string variable. The following standard library routines can raise this exception:

pat.extract, strealloc, stdin.gets, str.cpy, str.setstr, str.cat, str.substr, str.insert, console.gets, cStrToStr, dToStr, e80ToStr, hToStr, u64ToStr, i64ToStr, qToStr, r80ToStr, tbToStr, wToStr, date.print, date.toString, and date.a\_toString.

## ex.StringIndexError

HLA raises this exception if a routine attempts to use an index that is beyond the last valid character in a string. The following standard library routines can raise this exception:

str.span2, str.rspan2, str.brk2, str.rbrk2, str.substr, str.a\_substr, strToFlt, StrToi8, StrToi16, StrToi32, StrToi64, StrTou8, StrTou16, StrTou32, StrTou64, StrToh, StrTow, StrTod, and StrToq.

## ex.ValueOutOfRange

HLA raises this exception if an arithmetic overflow occurs, if an input parameter is out of range, or if user input is too great for the destination variable. The following standard library routines can raise this exception:

arg.v, arg.delete, rand.urange, rand.range, stdin.geti8, stdin.geti16, stdin.geti32, stdin.geti64, stdin.getu8, stdin.getu16, stdin.getu32, stdin.getu64, stdin.geth, stdin.getw, stdin.getd, stdin.getq, stdin.getf, table.create, console.a\_getRect, console.fillRect, console.fillRectAttr, console.getc, console.getRect, console.gets, console.gotoxy, console.putRect, console.scrollDnRect, console.scrollUpRect, atof, atoh, atoi8, atoi16, atoi32, atoi64, atou8, atou16, atou32, atou64, e80ToStr, r80ToStr, StrToi8, StrToi16, StrToi32, StrToi64, StrTou8, StrTou16, StrTou32, StrTou64, StrToh, StrTow, StrTod, StrToq, fileio.getd, fileio.geth, fileio.getw, fileio.getq, fileio.geti8, fileio.geti16, fileio.geti32, fileio.geti64, fileio.getu8, fileio.getu16, fileio.getu32, fileio.getu64, fileio.pute80pad, fileio.pute64pad, fileio.pute32pad, fileio.putr32Pad, fileio.putr64Pad, and fileio.putr80Pad.

## ex.IllegalChar

Several HLA routines raise this exception if they encounter a non-ASCII character (character code \$80..\$FF) where a delimiter character is expected. Generally, you can treat this error as though it were a conversion error. Routines that raise this exception include:

atoh, atoi8, atoi16, atoi32, atoi64, atou8, atou16, atou32, and atou64.

## ex.ConversionError

Routines in the HLA Standard Library raise this exception if there is an error conversion data from one format to another. Typically this occurs when converting strings to numeric data. Routines that raise this exception include:

---

1. Please note that the HLA Standard Library is under constant revision and the list appearing in this chapter may be slightly out of date. Please consult the HLA Standard Library documentation for an up-to-date listing of exceptions and the routines that raise them.

`stdin.geti8`, `stdin.geti16`, `stdin.geti32`, `stdin.geti64`, `stdin.getu8`, `stdin.getu16`, `stdin.getu32`, `stdin.getu64`, `stdin.geth`, `stdin.getw`, `stdin.getd`, `stdin.getq`, `stdin.getf`, `atof`, `atoh`, `atoi8`, `atoi16`, `atoi32`, `atoi64`, `atou8`, `atou16`, `atou32`, `atou64`, `fgetf`, `fileio.geti8`, `fileio.geti16`, `fileio.geti32`, `fileio.geti64`, `fileio.getu8`, `fileio.getu16`, `fileio.getu32`, `fileio.getu64`, `fileio.geth`, `fileio.getw`, `fileio.getd`, and `fileio.getq`.

#### **ex.BadFileHandle**

The file class method `file.handle` raises this exception if the handle associated with a file class object is illegal (has not been initialized).

#### **ex.FileOpenFailure**

The `fileio.Open`, `fileio.OpenNew`, `file.Open`, and `file.OpenNew` procedures raise this exception if there is an error opening a file.

#### **ex.FileCloseError**

The `fileio.Close` and `file.Close` procedures raise this exception if there is some sort of error when attempting to close a file.

#### **ex.FileWriteError**

Those routines that write data to a file (e.g., `fputi8`) raise this exception if there is an error writing data to the output file.

#### **ex.FileReadError**

Those routines that read data from a file (e.g., `fileio.geti8`) raise this exception if there is a physical error reading the data from the file.

#### **ex.DiskFullError**

Those routines that write data to a file will raise this exception if an attempt is made to write data to a full disk.

#### **ex.EndOfFile**

Those routines that read data from a file will raise this exception if your program attempts to read data beyond the end of the file.

#### **ex.MemoryAllocationFailure**

Routines that allocation storage (e.g., `malloc` and `realloc`) will raise this exception if Windows cannot satisfy the memory allocation request. Several routines in the standard library may raise this exception since they indirectly call the HLA `malloc` routine. Examples include `stdin.a_gets` and almost any other Standard Library routine that has “a\_” as a prefix to the name.

#### **ex.AttemptToDerefNULL**

Several routines in the Standard Library that expect a string pointer will raise this exception if the string pointer (or other pointer) contains NULL (zero). Examples include:

`getf`, `str.cpy`, `str.a_cpy`, `str.setstr`, `str.cat`, `str.a_cat`, `str.index`, `str.rindex`, `str.chpos`, `str.rchpos`, `str.span`, `str.span2`, `str.rspan`, `str.rspan2`, `str.brk`, `str.brk2`, `str.rbrk`, `str.rbrk2`, `str.eq`, `str.ne`, `str.lt`, `str.le`, `str.gt`, `str.ge`, `str.substr`, `str.a_substr`, `str.insert`, `str.a_insert`, `str.delete`, `str.a_delete`, `str.ieq`, `str.ine`, `str.ilt`, `str.ile`, `str.igt`, `str.ige`,

str.upper, str.a\_upper, str.lower, str.a\_lower, str.delspace, str.a\_delspace, str.trim, str.a\_trim, str.tokenize, str.tokenize2, atof, atoi8, atoi16, atoi32, atoi64, atou8, atou16, atou32, atou64, dtostr, htostr, wtostr, qtostr, strToFlt, StrToi8, StrToi16, StrToi32, StrToi64, StrTou8, StrTou16, StrTou64, StrToh, StrTow, StrTod, StrToq, and tbtostr.

#### **ex.WidthTooBig**

HLA routines that print a numeric value within a field width will raise this exception if the specified width exceeds 1,024 characters. Routines that raise this exception include *stdout.put*, *stdout.puti8Size*, *fputu32Size*, and all other *xxxxSize* output routines.

#### **ex.TooManyCmdLnParms**

The *arg.CmdLn* procedure raises this exception if it determines that there are more than 256 command line parameters on the command line (a virtual impossibility since command lines are generally limited to 128 characters). Since all of the other routines in the *args* module can call *arg.CmdLn*, it is possible for any of the routines in this module to raise this exception.

#### **ex.ArrayShapeViolation**

Routines in the arrays module raise this exception if the dimension on some array are inappropriate for the specified operation. For example, the *array.cpy* code will raise this exception if you attempt to copy a source array to a destination whose dimensions don't exactly match the source array.

#### **ex.InvalidDate**

The routines in the datetime module will raise this exception if you pass them an illegal date value as a parameter.

#### **ex.InvalidDateFormat**

The date output routines (*date.print* and *date.toString*) raise this exception if you attempt convert a date to a string but the current (internal) date format variable contains an invalid value. This usually implies that you've passed an incorrect parameter to the *date.SetFormat* procedure.

#### **ex.TimeOverflow**

The *time.secsToHMS* procedure raises this overflow if there is an error converting time in seconds to hours, minutes, and seconds (very rare, only occurs above two billion seconds).

#### **ex.AccessViolation**

This is a hardware exception that Windows raise if your program attempts to access an illegal memory location (generally a NULL reference or an uninitialized pointer).

#### **ex.Breakpoint**

This exception is raised by Windows for debugger programs; you should never see this exception unless you are writing a debugger program.

#### **ex.SingleStep**

This is another exception that is raised by Windows for debugger programs; you should never see this exception unless you are writing a debugger program.

**ex.PrivInstr**

Windows raises this instruction if you attempt to execute a special instruction that is illegal in “user mode” (that is, can only be executed by Windows). Since HLA only compiles a few privileged instructions, and this book doesn’t discuss them at all, the only way you’ll probably see this exception occur is if your program jumps off into (non-code) memory somewhere and begins executing data as instructions.

**ex.IllegalInstr**

Windows raises this exception if the CPU attempts to execute some code that is not a valid instruction. This generally implies that your program has jumped off into data memory and is attempting to execute data as machine instructions.

**ex.BoundInstr**

Windows raises this exception if you execute the BOUND instruction (see “Some Additional Instructions: INTMUL, BOUND, INTO” on page 377) and the register value is outside the specified range.

**ex.IntoInstr**

Windows raises this exception if you execute the INTO instruction and the overflow flag is set (see “Some Additional Instructions: INTMUL, BOUND, INTO” on page 377).

**ex.DivideError**

Windows raises this exception if you attempt an integer division by zero, or if the quotient of a division is too large to fit within the destination operand( AL, AX, or EAX).

**ex.fDenormal****ex.fDivByZero****ex.fInexactResult****ex.fInvalidOperation****ex.fOverflow****ex.fStackCheck****ex.fUnderflow**

Windows raises one of these exceptions if you’ve enabled exceptions on the FPU and one of the specified conditions occurs (e.g., a floating point division by zero will raise the *ex.fDivByZero* exception).

**InvalidHandle**

Windows will raise this exception if you pass an uninitialized or otherwise invalid handle value to a Windows API (application programmer’s interface) routine. Many of the HLA Standard Library routines pass handles to Windows, so this exception could occur as a result of a call to an input/output routine.

**StackOverflow**

Windows raises this exception if the stack exceeds the storage allocated to it (16Mbytes in a typical HLA program).

**ControlC**

HLA raises this exception if the user presses control-C or control-Break during program execution.

# HLA Compile-Time Functions

# Appendix H

## H.1 Conversion Functions

The conversion functions translate data from one format to another. For example, functions in this group can convert integers to strings or strings to integers. These routines provide the compile-time equivalent of the HLA Standard Library CONV module.

The compile-time conversion routines are unusual in the set of compile-time function insofar as they do not require a leading "@" symbol. Instead, the conversion routines use the names of several of the built-in data types. The following table describes each of these functions:

**Table 1: Compile-Time Data Conversion Functions**

| Function | Parameters <sup>a</sup>                                                                                                                                                                                                                | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
|----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| boolean  | boolean( <i>constExpr</i> )<br><br>ConstExpr can be a boolean, integer, character, or string operand.                                                                                                                                  | If <i>constExpr</i> is numeric, this function returns false for zero and true for any other value. For characters, "t" or "f" returns true or false (respectively), anything else is an error. For strings, the operands must be "true" or "false" (else an error occurs). The boolean function returns boolean values unchanged and returns an error for any other type.                                                                                                                                                                                                                                                                                                                                                                                                                         |
| int8     | <i>xxxx</i> ( <i>constExpr</i> )<br><br>Note: <i>xxxx</i> represents one of the function names to the left.<br><br><i>constExpr</i> can be any constant expression that evaluates to a numeric, character, boolean, or string operand. | These functions will convert their operand to the specified data type. These functions generate an error if the resulting value will not fit in the specified data type (e.g., int8(-1000) will generate an error). Note that HLA treats <i>byte</i> , <i>word</i> , and <i>dword</i> functions identically to <i>uns8</i> , <i>uns16</i> , and <i>uns32</i> (respectively).<br><br>For boolean operands, true returns one and false returns zero.<br><br>If the operand is a real value, then these functions truncate the value to obtain the corresponding integer return value.<br><br>For character operands, these function return the corresponding ASCII code of the character.<br><br>For string operands, the string must be a legal sequence of characters that form a decimal number. |
| int16    |                                                                                                                                                                                                                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| int32    |                                                                                                                                                                                                                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

| real32   | <i>xxxxxx</i> ( <i>constExpr</i> )<br><br>Note: <i>xxxxxx</i> represents one of the function names to the left.<br><br><i>constExpr</i> can be any constant expression that evaluates to a numeric or string operand.                  | These functions convert their specified operand to the corresponding real value. These functions convert integer operands to the corresponding real value. If the operand is a string expression, it must be a valid sequence of characters that corresponds to an HLA floating point value. These functions convert that string to the corresponding real value.                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| real64   |                                                                                                                                                                                                                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| real80   |                                                                                                                                                                                                                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

**Table 1: Compile-Time Data Conversion Functions**

| Function | Parameters <sup>a</sup>                                                                                      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|----------|--------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| char     | char( <i>constExpr</i> )<br><br><i>constExpr</i> must be a positive integer value, a character, or a string. | If the parameter is an integer value, this function returns the character with that ASCII code. If the parameter is a string, this function returns the first character of that string. If the operand is a character, this function simply returns that character value.                                                                                                                                                                                                                                                                                                                                                                                          |
| string   | string( <i>constExpr</i> )<br><br><i>constExpr</i> can be any legal constant data type.                      | This function returns the string representation of the specified parameter. For real values, this function returns the scientific notation format for the value. For boolean expressions, this function returns the value "true" or "false". For character operands, this function returns a string containing the single character specified as the operand. For integer parameters, this function returns a string containing the decimal equivalent of that value. For character set operands, this function returns a string listing all the characters in the character set. If the operand is a string expression, this function simply returns that string. |
| cset     | cset( <i>constExpr</i> )<br><br><i>constExpr</i> can be a character, string, or a cset.                      | This function returns a character set containing the characters specified by the operand. If the operand is a character, then this function returns the singleton set containing that single character. If the operand is a string, this function returns the union of all the characters in that string. If the operand is a character set, this function returns that character set.                                                                                                                                                                                                                                                                             |
| text     | text( <i>constExpr</i> )<br><br><i>constExpr</i> : same as for string.                                       | This function takes the same parameters as the string function. Instead of returning a string constant, however, this function expands the text in-line at the point of the function. This function is equivalent to the <code>@text</code> function.                                                                                                                                                                                                                                                                                                                                                                                                              |
| @odd     | @odd( <i>constExpr</i> )<br><br><i>constExpr</i> must be an integer value.                                   | This function returns true if the integer operand is an odd number, it returns false otherwise.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

a. Integer operands can be any of the *intXX*, *unsXX*, *byte*, *word*, or *dword* types.

Internally, HLA generally maintains all numeric constant values as *int32*, *uns32*, *dword*, or *real80*. Therefore, it is unlikely that you would want to use the *int8*, *int16*, *uns8*, *uns16*, *real32*, or *real64* compile-time functions in your program unless you want to force an error if a value is out of range.

Of these conversion functions, the *string* function is, perhaps, the most useful. Many compile-time functions and statements accept only string operands. You can use the *string* function to translate other data types to a string in a situation where you wish to use one of these other data types. For example, the `#ERROR` statement only allows a single string parameter. However, you can construct complex error messages by using the string concatenation operator ("+") with the *string* function, e.g.,

```
#error("Constant value i32=" + string(i32) + " and that is out of range")
```

## H.2 Numeric Functions

These functions provide common mathematical functions. Remember, these functions compute their values at compile-time. Their parameters are constants and they return constant values. These functions are not useable with variables at run-time. See the HLA Standard Library for comparable functions you can call from your assembly language programs while they are running.

**Table 2: Numeric Compile-Time Functions**

| Function | Parameters <sup>a</sup>                                                                                                                                                                                                                        | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|----------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @abs     | @abs( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value.                                                                                                                                                                      | Returns the absolute value of the parameter. The return type is the same as the parameter type.                                                                                                                                                                                                                                                                                                                                                                                                        |
| @byte    | @byte( <i>Expr</i> , <i>select</i> )<br><br><i>Expr</i> must be a 32-bit ordinal expression, a real expression (32, 64, or 80 bits), or a <i>cset</i> expression.<br><br><i>select</i> must be less than the size of <i>Expr</i> 's data type. | This function extracts the specified byte from the value of <i>Expr</i> as selected via the <i>select</i> parameter. If <i>select</i> is zero, this function returns the L.O. byte, higher values for <i>select</i> return the corresponding higher-order bytes of the object.<br><br>Note that HLA usually extends literal constants to the largest representation possible, e.g., HLA treats 1.234 as a real80 value. Use coercion to change this, if necessary (e.g., @byte( real32( 1.234 ), 3 ) ) |
| @ceil    | @ceil( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value.                                                                                                                                                                     | If the parameter is an integer value, this function simply converts it to a real value and returns that value. If the parameter is a real value, then this function returns the smallest integer value larger than or equal to the parameter's value (i.e., this function rounds a real value to the next highest integer if the real value contains a fractional part).                                                                                                                               |
| @cos     | @cos( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value expressing an angle in radians.                                                                                                                                       | This function returns the cosine of the specified parameter value.                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| @exp     | @exp( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value.                                                                                                                                                                      | This function return <i>e</i> raised to the specified power.                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| @floor   | @floor( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value.                                                                                                                                                                    | This function returns the largest integer value that is less than or equal to the numeric value passed as a parameter. For positive real numbers this is equivalent to truncation (for negative numbers, it rounds towards negative infinity).                                                                                                                                                                                                                                                         |
| @log     | @log( <i>constExpr</i> )<br><br><i>constExpr</i> is a non-negative numeric value.                                                                                                                                                              | This function computes the natural (base <i>e</i> ) logarithm of its operand.                                                                                                                                                                                                                                                                                                                                                                                                                          |

**Table 2: Numeric Compile-Time Functions**

| Function   | Parameters <sup>a</sup>                                                                                  | Description                                                                                                                                                                                                                                                                                                                         |
|------------|----------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @log10     | @log10( <i>constExpr</i> )<br><br><i>constExpr</i> is a non-negative numeric value.                      | This function computes the base-10 logarithm of its operand.                                                                                                                                                                                                                                                                        |
| @max       | @max( <i>list</i> )<br><br><i>list</i> is a list of two or more comma separated numeric expressions.     | This function returns the maximum of a set of numeric values. The values in the list must all be the same type.                                                                                                                                                                                                                     |
| @min       | @min( <i>list</i> )<br><br><i>list</i> is a list of two or more comma separated numeric expressions.     | This function returns the minimum of a set of numeric values. The values in the list must all be the same type.                                                                                                                                                                                                                     |
| @random    | @random( <i>intExpr</i> )<br><br><i>intExpr</i> must be a positive integer value.                        | This function returns a pseudo-random number between zero and <i>intExpr-1</i> . Currently HLA uses the random function provided by the C standard library; so don't expect a high quality random number generator here. In particular, if <i>intExpr</i> is a small value, the quality of the random number generator is very low. |
| @randomize | @randomize( <i>intExpr</i> )<br><br><i>intExpr</i> must be a positive integer value.                     | This function attempts to "randomize" the random number generator seed. Then it returns a random number between zero and <i>intExpr-1</i> . You should not call this function multiple times in your source file.                                                                                                                   |
| @sin       | @sin( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value expressing an angle in radians. | This function returns the sine of the specified parameter value.                                                                                                                                                                                                                                                                    |
| @sqrt      | @sqrt( <i>constExpr</i> )<br><br><i>constExpr</i> must be a non-negative numeric value.                  | This function returns the square root of the specified operand value.                                                                                                                                                                                                                                                               |
| @tan       | @tan( <i>constExpr</i> )<br><br><i>constExpr</i> must be a numeric value expressing an angle in radians. | This function returns the tangent of the specified parameter value.                                                                                                                                                                                                                                                                 |

a. Numeric parameters are *intX*, *unsX*, *byte*, *word*, *dword*, or *realX* values.

---

### H.3 Date/Time Functions

The Date/Time compile-time functions return strings holding the current date and time.

**Table 3: HLA Compile-Time Date/Time Functions**

| Function | Parameters | Description                                                                                                                            |
|----------|------------|----------------------------------------------------------------------------------------------------------------------------------------|
| @date    | @date      | This function returns a string specifying the current date. This string typically takes the form "year/month/day", e.g., "2000/12/31". |
| @time    | @time      | This function returns a string specifying the current time. This string typically takes the form "HH:MM:SS xM" (x= A or P).            |

---

## H.4 Classification Functions

These functions test a character or string to see if the characters belong to a certain class (e.g., alphabetic characters). These functions return true or false depending upon the result of the comparison.

If the operand is a character expression, these functions return true if that character belongs to the specified class. If the operand is a string, these functions return true if all characters in the string belong to the specified class.

Also see the HLA Compile-Time Pattern Matching Functions for some different ways to test characters in a string. Remember, these are compile-time functions. The HLA Standard Library contains comparable routines for use at run-time in your programs. See the HLA Standard Library documentation for more details.

**Table 4: HLA Compile-Time Character Classification Functions.**

| Function    | Parameters                                                                                          | Description                                                                                                                                                                                         |
|-------------|-----------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @isalpha    | @isalpha( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression.    | This function returns true if the character operand is an alphabetic character.<br><br>If the parameter is a string, this function returns true if all characters in the string are alphabetic.     |
| @isalphanum | @isalphanum( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression. | This function returns true if the character operand is an alphanumeric character.<br><br>If the parameter is a string, this function returns true if all characters in the string are alphanumeric. |
| @isdigit    | @isdigit( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression.    | This function returns true if the character operand is a decimal digit character.<br><br>If the parameter is a string, this function returns true if all characters in the string are digits.       |

**Table 4: HLA Compile-Time Character Classification Functions.**

| Function  | Parameters                                                                                        | Description                                                                                                                                                                                                                     |
|-----------|---------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @islower  | @islower( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression.  | This function returns true if the character operand is a lower case alphabetic character.<br><br>If the parameter is a string, this function returns true if all characters in the string are lower case alphabetic characters. |
| @isspace  | @isspace( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression.  | This function returns true if the character operand is a space character <sup>a</sup> .<br><br>If the parameter is a string, this function returns true if all characters in the string are spaces.                             |
| @isupper  | @isupper( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression.  | This function returns true if the character operand is an upper case alphabetic character.<br><br>If the parameter is a string, this function returns true if all characters in the string are upper case alphabetic characters |
| @isxdigit | @isxdigit( <i>constExpr</i> )<br><br><i>constExpr</i> must be a character or a string expression. | This function returns true if the character operand is a hexadecimal digit character {0-9, a-f, A-F}.<br><br>If the parameter is a string, this function returns true if all characters in the string are hexadecimal digits.   |

a. "Space" means any white space character. This includes tabs, newlines, etc.

---

## H.5 String and Character Set Functions

The following functions provide a very powerful set of string manipulation functions to the HLA compile-time language. These functions let you easily manipulate data like macro parameters and #text..#end-text blocks.

Remember, these are compile-time functions. The HLA Standard Library contains comparable routines for use at run-time in your programs. See the HLA Standard Library documentation for more details.

The @extract function behaves a little differently than the *cs.extract* function in the HLA Standard Library. @extract does not actually remove the specified character from the character set. Keep this in mind if you use both @extract and *cs.extract* frequently.

**Table 5: HLA Compile-Time String Functions**

| Function   | Parameters                                                                                                                                                                                      | Description                                                                                                                                                                                                                                                                                                                                                                |
|------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @delete    | @delete( <i>strExpr</i> , <i>start</i> , <i>len</i> )<br><br><i>strExpr</i> must be a string expression.<br><br><i>start</i> and <i>len</i> must be positive integer expressions.               | This function returns a string consisting of the <i>strExpr</i> parameter with <i>len</i> characters removed starting at position <i>start</i> in the string. The first character in the string is at position zero. Therefore, @delete( "Hello", 2, 3 ) returns the string "He".                                                                                          |
| @extract   | @extract( <i>csetExpr</i> )<br><br><i>csetExpr</i> must be a character set value.                                                                                                               | This function returns an arbitrary character from the specified character set. Note that this function does not remove that character from the set. You must manually remove the character if you do not want the next call to @extract (with the same parameter) to return the same character, e.g.,<br><br>val<br>c := @extract( someSet );<br>someSet := someSet - {c}; |
| @index     | @index( <i>strExpr</i> , <i>start</i> , <i>findStr</i> )<br><br><i>strExpr</i> and <i>findStr</i> must be string expressions.<br><br><i>start</i> must be a non-negative integer value.         | This function searches for the string specified by <i>findStr</i> within the <i>strExpr</i> string starting at character position <i>start</i> . If this function finds the string, it returns the index into <i>strExpr</i> where it located <i>findStr</i> . If it does not find the string, it returns -1.                                                              |
| @insert    | @insert( <i>destStr</i> , <i>start</i> , <i>strToIns</i> )<br><br><i>destStr</i> and <i>strToIns</i> must be string expressions.<br><br><i>start</i> must be a non-negative integer expression. | This function returns a string consisting of the combination of the <i>destStr</i> and <i>strToIns</i> strings. This function inserts <i>strToIns</i> into <i>destStr</i> at the position specified by <i>start</i> .                                                                                                                                                      |
| @length    | @length( <i>strExpr</i> )<br><br><i>strExpr</i> must be a string expression.                                                                                                                    | This function returns the length of the specified string as an integer result.                                                                                                                                                                                                                                                                                             |
| @lowercase | @lowercase( <i>strExpr</i> , <i>start</i> )<br><br><i>strExpr</i> must be a string expression.<br><br><i>start</i> must be a non-negative integer expression.                                   | This function translates all characters from position <i>start</i> to the end of the string to lower case (if they were previously upper case alphabetic characters).                                                                                                                                                                                                      |

**Table 5: HLA Compile-Time String Functions**

| Function | Parameters                                                                                                                                                                                                                               | Description                                                                                                                                                                                                                                                                                                                                                          |
|----------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @rindex  | @rindex( <i>strExpr</i> , <i>start</i> , <i>findStr</i> )<br><br><i>strExpr</i> and <i>findStr</i> must be string expressions.<br><br><i>start</i> must be a non-negative integer value.                                                 | This function searches backwards to find the last occurrence of the string specified by <i>findStr</i> within the <i>strExpr</i> string. This function will only search back to position <i>start</i> . If this function finds the string, it returns the index into <i>strExpr</i> where it located <i>findStr</i> . If it does not find the string, it returns -1. |
| @strbrk  | @strbrk( <i>strExpr</i> , <i>start</i> , <i>csetExpr</i> )<br><br><i>strExpr</i> must be a string expression.<br><br><i>start</i> must be a non-negative integer expression.<br><br><i>csetExpr</i> must be a character set expression.  | Starting at position <i>start</i> within <i>strExpr</i> , this function searches for the first character of <i>strExpr</i> that is a member of the <i>csetExpr</i> character set. It returns -1 if no such characters exist.                                                                                                                                         |
| @strset  | @strset( <i>charExpr</i> , <i>len</i> )<br><br><i>charExpr</i> must be a character value.<br><br><i>len</i> must be a non-negative integer value.                                                                                        | This function returns the string consisting of <i>len</i> copies of <i>charExpr</i> concatenated together.                                                                                                                                                                                                                                                           |
| @strspan | @strspan( <i>strExpr</i> , <i>start</i> , <i>csetExpr</i> )<br><br><i>strExpr</i> must be a string expression.<br><br><i>start</i> must be a non-negative integer expression.<br><br><i>csetExpr</i> must be a character set expression. | Starting at position <i>start</i> within <i>strExpr</i> , this function searches for the first character of <i>strExpr</i> that is not a member of the <i>csetExpr</i> character set. It returns the length of the string if all remaining characters are in the specified character set.                                                                            |
| @substr  | @substr( <i>strExpr</i> , <i>start</i> , <i>len</i> )<br><br><i>strExpr</i> must be a string expression.<br><br><i>start</i> and <i>len</i> must be non-negative integer values.                                                         | This function returns the sequence of <i>len</i> characters (the "substring") starting at position <i>start</i> in the <i>strExpr</i> string.                                                                                                                                                                                                                        |

**Table 5: HLA Compile-Time String Functions**

| Function   | Parameters                                                                                                                                                                                                                                                            | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @tokenize  | <p>@tokenize( <i>strExpr</i>, <i>start</i>, <i>Delims</i>, <i>Quotes</i> )</p> <p><i>strExpr</i> must be a string expression.</p> <p><i>start</i> must be a non-negative integer value.</p> <p><i>Delims</i> and <i>Quotes</i> must be character set expressions.</p> | <p>This function returns an array of strings consisting of the various substrings in <i>strExpr</i> obtained by separating the substrings using the <i>Delims</i> character set.</p> <p>This "lexical scan" operation begins at position <i>start</i> in <i>strExpr</i>. The function first skips over all characters in <i>Delims</i> and the collects all characters until it finds another delimiter character from the <i>Delims</i> set. It repeats this process, adding each scanned string to the array it returns, until it reaches the end of the string.</p> <p>The fourth parameter, <i>Quotes</i>, specifies special quoting characters. Typically, this character set is the empty set. However, if it contains a character, then that character is a quote character and all characters between two occurrences of the quote symbol constitute a single string, even if delimiters appear within that string. Typical characters in the <i>Quotes</i> character set would be apostrophes or quotation marks. If "(", "[", or "{" appears in the <i>Quotes</i> set, then the corresponding closing symbol must also appear and tokenize uses the pair of quote objects to surround a quoted item.</p> <p>This function is unusual insofar as it returns an array constant as its result. Typically you would assign this to a VAL or CONST object so you can gain access to the individual items in the array. To determine the number of elements in this array, use the @elements function.</p> |
| @trim      | <p>@trim( <i>strExpr</i> )</p> <p><i>strExpr</i> must be a string expression.</p>                                                                                                                                                                                     | <p>This function returns the specified string operand with leading and trailing spaces removed.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

## H.6 Pattern Matching Functions

The HLA compile-time language provides a large set of pattern matching functions similar to the run-time functions available in the PATTERNS.HHF module of the HLA Standard Library. These pattern matching functions, combined with the string processing functions of the previous section, provide you with

the ability to write your own scanners and parsers (i.e., compilers) within the HLA compile-time language. Indeed, one of the primary purposes of the HLA compile-time language is to let you expand the HLA language to suit your needs. The pattern matching functions, along with macros, provide the backbone for this capability in HLA.

Note that there are some pretty serious differences between the HLA compile-time pattern matching functions and the routines in the PATTERNS.HHF module. Perhaps the biggest difference is the fact that the compile-time functions do not support backtracking while the run-time routines do. Fortunately, it is not that difficult to simulate backtracking on your own within the compile-time language.

Another difference between the compile-time functions and their run-time counterparts is the parameter list. The compile-time functions typically have a couple of optional parameters that let you extract information about the pattern match if it was successful. Consider, for a moment, the @matchStr function:

```
@matchStr(Str, tstStr)
```

When you call this function using the syntax above, this function will return true if the string expression *Str* begins with the sequence of characters found in *tstStr*. It returns false otherwise. Now consider the following invocation:

```
@matchStr(Str, tstStr, remainder)
```

This call to the function also returns true if *Str* begins with the characters found in the *tstStr* string. If this function returns true, then this function also copies the remaining characters (i.e., those characters in *Str* that following the *tstStr* characters at the beginning of *Str*) to the *remainder* VAL object. If @matchStr returns false, the value of *remainder* is undefined (with the single exception noted below).

It is perfectly legal to specify the same string as the *Str* and *remainder* parameters. For example, consider the following invocation:

```
@matchStr(str, "Hello ", str)
```

If *str* begins with the string "Hello " then this function will return true and replace *str*'s value with the string containing all characters beyond the sixth character of the string. If *str* does not begin with "Hello " then this function does not modify *str*'s value.

Most of the HLA compile-time pattern matching functions also allow a second optional parameter. Consider the following invocation of the @oneOrMoreCset function:

```
@oneOrMoreCset(str, {'0'..'9'}, remainder, matched)
```

If this function returns true it will copied the sequence of characters at the beginning of *str* that are members of the specified character set (i.e., digits) to the *matched* VAL object. This function returns all characters beyond the digits in the *remainder* VAL object. If this function returns false, then *remainder* and *matched* will contain undefined values and this function will not affect *str*.

## H.6.1 String/Cset Pattern Matching Functions

Among the most useful of the pattern matching functions are those that checking the leading characters of a string to see if they are members of a particular character set. The following rich set of functions provides this capability in the compile-time language.

**Table 6: HLA Compile-time Cset Pattern Matching Functions**

| Function  | Parameters                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |

## H.6.2 String/Character Pattern Matching Functions

Though not always as useful as the character set pattern matching functions, the HLA compile-time character matching functions are more efficient than the character set routines when matching single characters.

**Table 7: HLA Compile-time Character Matching Functions**

| Function       | Parameters                                                                                                                                                                                                                                                                                                                                                                                                                                                                        | Description                                                                                                                                                                                                                                                                                                                                                                                           |
|----------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

### H.6.3 String/Case Inensitive Character Pattern Matching Functions

HLA provides two sets of character matching routines: the previous section described the standard character matching routines, this section presents the case insensitive versions of those same routines.

**Table 8: HLA Compile-time Case Inensitive Character Matching Functions**

| Function         | Parameters                                                                                                             | Description                                                                   |
|------------------|------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------|
| @peekiChar       | <p>@peekiChar( <i>str</i>, <i>char</i>, <i>rem</i>, <i>matched</i> )</p> <p>See @peekChar for details.</p>             | Case insensitive version of @peekChar. See @peekChar for details.             |

| @exactlyNToMiChar | @exactlyNToMiChar( <i>str, char, n, m, rem, matched</i> )<br>See @exactlyNToMChar for details. | Case insensitive version of @exactlyNToMChar. See @exactlyNToMChar for details. |

## H.6.4 String/String Pattern Matching Functions

Another set of popular pattern matching routines in the compile-time function set are the string matching routines. These routines check to see if a string begins with some specified sequence of characters. Next to the character set matching functions, these are probably the most commonly used pattern matching functions.

**Table 9: Compile-Time String Matching Functions**

| Function  | Parameters                                                                                                                                                                                                                                                                                                                                                                                                                                      | Description                                                                                                                                                                                                                                                                |
|-----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @matchStr | @matchStr( <i>str, tstStr, rem, matched</i> )<br><br><i>str</i> must be a string expression.<br><i>tstStr</i> must be a string expression.<br><br><i>rem</i> and <i>matched</i> are optional arguments (both are optional, but if <i>matched</i> is present, <i>rem</i> must also be present).<br>The types of <i>rem</i> and <i>matched</i> are irrelevant but they must be VAL objects. This function stores a result into these two objects. | This function returns true if <i>str</i> begins with the characters found in <i>tstStr</i> .<br><br>If this function returns true, it also returns <i>tstStr</i> in <i>matched</i> and all characters in <i>str</i> following the <i>tstStr</i> characters in <i>rem</i> . |

**Table 9: Compile-Time String Matching Functions**

| Function     | Parameters                                                                                                                                         | Description                                                                                                                                                                                                                                                                                                                                                    |

## H.6.5 String/Misc Pattern Matching Functions

This last group of compile-time pattern matching functions check for certain special types of strings, such as HLA identifiers, numeric constants, whitespace, and the end of the string.

**Table 10: Miscellaneous Compile-time Pattern Matching Functions**

| Function        | Parameters                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|-----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @matchID        | <p>@matchID( <i>str</i>, <i>rem</i>, <i>matched</i> )</p> <p><i>str</i> must be a string expression.</p> <p><i>rem</i> and <i>matched</i> are optional arguments (both are optional, but if <i>matched</i> is present, <i>rem</i> must also be present).</p> <p>The types of <i>rem</i> and <i>matched</i> are irrelevant but they must be VAL objects. This function stores a result into these two objects.</p>                                                                                                               | <p>This function returns true if the first sequence of characters in <i>str</i> match the definition of an HLA identifier.</p> <p>An HLA identifier is any sequence of characters that begins with an underscore or an alphabetic character that is followed by zero or more underscore or alphanumeric characters.</p> <p>If this function returns true, it copies the identifier to <i>matched</i> and all following characters to <i>rem</i>.</p> |
| @matchIntConst  | <p>@matchIntConst( <i>str</i>, <i>rem</i>, <i>matched</i> )</p> <p><i>str</i> must be a string expression.</p> <p><i>rem</i> and <i>matched</i> are optional arguments (both are optional, but if <i>matched</i> is present, <i>rem</i> must also be present).</p> <p>The type of <i>rem</i> is irrelevant but it must be a VAL object. If <i>matched</i> is present, it must be an <i>int32</i> or <i>uns32</i> object.</p> <p><b>Note: unlike most pattern matching functions, <i>matched</i> is not a string object.</b></p> | <p>This function returns true if the leading characters of <i>str</i> are decimal digits (as per HLA, underscores are legal in the interior of the integer string).</p> <p>If this function returns true, it converts the matched integer string to integer form and stores this value in <i>matched</i>. This function returns the remaining characters after the numeric digits in <i>rem</i>.</p>                                                 |
| @matchRealConst | <p>@matchRealConst( <i>str</i>, <i>rem</i>, <i>matched</i> )</p> <p><i>str</i> must be a string expression.</p> <p><i>rem</i> and <i>matched</i> are optional arguments (both are optional, but if <i>matched</i> is present, <i>rem</i> must also be present).</p> <p>The type of <i>rem</i> is irrelevant but it must be a VAL object. If <i>matched</i> is present, it must be an <i>real80</i> object.</p> <p><b>Note: unlike most pattern matching functions, <i>matched</i> is not a string object.</b></p>               | <p>This function returns true if the leading characters of <i>str</i> correspond to the HLA definition of a real literal constant.</p> <p>If this function returns true, it also returns the remaining characters in <i>rem</i> and it converts the real string to <i>real80</i> format and stores this value in <i>matched</i>.</p>                                                                                                                 |

**Table 10: Miscellaneous Compile-time Pattern Matching Functions**

| Function           | Parameters                                                                                                                                                                                                                              | Description                                                                                                                                                                                                                                                                                                                                           |
|--------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @matchNumericConst | @matchNumericConst( str, rem, matched)<br><br>Same parameters as @matchIntConst or @matchRealConst; see those functions for details.                                                                                                    | This is a combination of @matchIntConst and @matchRealConst. If this function matches a string at the beginning of <i>str</i> that is a legal numeric constant, it will convert that value to numeric form ( <i>int32</i> or <i>real80</i> ) and store the value into <i>matched</i> . This function returns any following characters in <i>rem</i> . |
| @matchStrConst     | @matchStrConst( str, rem, matched)<br><br>Same parameters as @matchID; see @matchID for details.                                                                                                                                        | This function returns true if <i>str</i> begins with an HLA compatible literal string constant. If this function matches such a constant, it will store the matched string, minus the delimiting quotes, into the <i>matched</i> variable. It will also store any following characters into <i>rem</i> .                                              |
| @zeroOrMoreWS      | @zeroOrMoreWS( str, rem )<br><br><i>str</i> must be a string expression.<br><br><i>rem</i> is an optional argument.<br>The type of <i>rem</i> is irrelevant but it must be a VAL object.                                                | This function always returns true. It matches zero or more "whitespace" characters at the beginning of <i>str</i> .<br><br>Whitespace includes spaces, newlines, tabs, and certain other special characters.<br><br>Note that this function does not return the matched string. To return matched whitespace characters, use @zeroOrMoreCset.         |
| @oneOrMoreWS       | @oneOrMoreWS( str, rem )<br><br><i>str</i> must be a string expression.<br><br><i>rem</i> is an optional argument.<br>The type of <i>rem</i> is irrelevant but it must be a VAL object. This function stores a result into this object. | This function returns true if it matches at least one whitespace character. If it returns true, it also returns any characters following the leading whitespace characters in the <i>rem</i> variable.                                                                                                                                                |

**Table 10: Miscellaneous Compile-time Pattern Matching Functions**

| Function   | Parameters                                                                                                                                                                                                                                         | Description                                                                                                                                                                                                                                                                                                                                                                                                                               |
|------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @wsOrEOS   | @wsOrEOS( <i>str</i> , <i>rem</i> )<br><br><i>str</i> must be a string expression.<br><br><i>rem</i> is an optional argument.<br>The type of <i>rem</i> is irrelevant but it must be a VAL object. This function stores a result into this object. | This function succeeds if there is whitespace at the beginning of <i>str</i> or if <i>str</i> is the empty string. If it succeeds and there is leading whitespace, this function returns the remaining characters in <i>rem</i> . If this function succeeds and the string was empty, this function returns the empty string in <i>rem</i> . This function fails if the string is not empty and it begins with non-whitespace characters. |
| @wsThenEOS | @wsThenEOS( <i>str</i> )<br><br><i>str</i> must be a string expression.                                                                                                                                                                            | This function returns true if <i>str</i> contains zero or more whitespace characters followed by the end of the string. It fails if there are any other characters in the string.                                                                                                                                                                                                                                                         |
| @peekWS    | @peekWS( <i>str</i> , <i>rem</i> )<br><br><i>str</i> must be a string expression.<br><br><i>rem</i> is an optional argument.<br>The type of <i>rem</i> is irrelevant but it must be a VAL object. This function stores a result into this object.  | This function returns true if the next character in <i>str</i> is a whitespace character. This function returns a copy of <i>str</i> in <i>rem</i> if it is successful.                                                                                                                                                                                                                                                                   |
| @eos       | @eos( <i>str</i> )<br><br><i>str</i> must be a string expression.                                                                                                                                                                                  | This function returns true if and only if <i>str</i> is the empty string.                                                                                                                                                                                                                                                                                                                                                                 |

## H.7 HLA Information and Symbol Table Functions

The symbol table functions provide access to information in HLA's internal symbol table database. These functions are particularly useful within macros to determine how to generate code for a particular macro parameter.

**Table 11: HLA Information and Compile-time Symbol Table Information Functions**

| Function    | Parameters                                                                                                                                       | Description                                                                                                                                                                                                                                                                       |
|-------------|--------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @name       | @name( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                                                        | This function returns a string specifying the name of the specified identifier. The name this function returns is computed after macro and text constant expansion. This function is useful mainly in macros to determine the name of a macro parameter.                          |
| @type       | @type( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                                                        | This function returns a <i>dword</i> constant that should be unique for any given type in the program. You can use this to compare the types of two different objects. For guaranteed uniqueness, see @typeName.                                                                  |
| @typeName   | @typeName( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                                                    | This function returns a string that specifies the type of of the parameter.                                                                                                                                                                                                       |
| @pType      | @pType( identifierOrExpression )<br><br><i>identifierOrExpression</i> may be a defined symbol in the HLA program or a constant expression.       | This function returns a small numeric constant that specifies the primitive type of the object. See the ptXXXXX constants in the HLA.HHF header file for the actual values this function returns.                                                                                 |
| @class      | @class( identifierOrExpression )<br><br><i>identifierOrExpression</i> may be a defined symbol in the HLA program or a constant expression.       | This function returns a small numeric constant that classifies the identifier or expression as to whether it is a constant, VAL, variable, parameter, static object, procedure, etc. See the cXXXX constants in the HLA.HHF header file for a list of the possible return values. |
| @size       | @size( identifierOrExpression )<br><br><i>identifierOrExpression</i> may be a defined symbol in the HLA program or a constant expression.        | This function returns the size, in bytes of the specified object.                                                                                                                                                                                                                 |
| @offset     | @offset( identifier )<br><br><i>identifier</i> must be a defined VAR or parameter symbol in the HLA program.                                     | This function returns a numeric constant providing the offset into a procedure's activation record for a VAR or parameter object.                                                                                                                                                 |
| @staticName | @staticName( identifier )<br><br><i>identifier</i> must be a defined static, procedure, method, iterator, or external symbol in the HLA program. | This function returns a string that specifies the internal name that HLA uses for the object.                                                                                                                                                                                     |

**Table 11: HLA Information and Compile-time Symbol Table Information Functions**

| Function     | Parameters                                                                                                     | Description                                                                                                                                                                                                                                                                                                                                                                           |
|--------------|----------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @lex         | @lex( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                       | This function returns a small integer constant the specifies the static nesting level for the specified symbol. All symbols appearing in the main program have a lex level of zero. Symbols you define in procedures within the main program have a lex level of one. Higher lex level values are possible if you define procedures inside procedures.                                |
| @isExternal  | @isExternal( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                | This function returns true if the specified identifier is an external symbol. Note that this function will return true if the symbol is defined external and a declaration for the symbol appears later in the code.                                                                                                                                                                  |
| @arity       | @arity( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                     | This function returns zero if the specified symbol is not an array. It returns a small integer constant denoting the number of dimensions if the identifier is an array object.                                                                                                                                                                                                       |
| @dim         | @dim( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                       | If the specified identifier is an array object, this function returns an array constant with one element for each dimension in the array. Each element of this array constant specifies the number of elements for each dimension of the array. If the identifier is not an array object, this function returns an array with a single element and that element's value will be zero. |
| @elements    | @elements( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                  | This function returns the number of elements in an array object. If the specified identifier is not an array object, this function returns zero. For multi-dimensional arrays, this function returns the product of each of the dimensions.                                                                                                                                           |
| @elementSize | @elementSize( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.               | This function returns the size, in bytes, of an element of the specified array.                                                                                                                                                                                                                                                                                                       |
| @defined     | @defined( identifier )<br><br><i>identifier</i> must be a defined symbol in the HLA program.                   | This function returns true if the specified symbol is defined prior to that point in the program.                                                                                                                                                                                                                                                                                     |
| @pClass      | @pClass( identifier )<br><br><i>identifier</i> must be a parameter in the current procedure of an HLA program. | This function returns a small integer constant specifying the parameter passing mechanism for the specified parameter. The HLA.HHF header file defines the return values for this function (see the XXXX_pc constant declarations).                                                                                                                                                   |

**Table 11: HLA Information and Compile-time Symbol Table Information Functions**

| Function | Parameters                                                                                                                                    | Description                                                                                                               |
|----------|-----------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------|
| @isConst | @isConst( identifierOrExpression )<br><br><i>identifierOrExpression</i> may be a defined symbol in the HLA program or a constant expression.  | This function returns true if the expression is a constant expression that HLA can evaluate at that point in the program. |
| @isReg   | @isReg(Expression )<br><br><i>Expression</i> may be arbitrary text, but it is typically a register object.                                    | This function returns true if the operand corresponds to an 80x86 general purpose register.                               |
| @isReg8  | @isReg8(Expression )<br><br><i>Expression</i> may be arbitrary text, but it is typically a register object.                                   | This function returns true if the operand corresponds to an eight-bit 80x86 general purpose register.                     |
| @isReg16 | @isReg16(Expression )<br><br><i>Expression</i> may be arbitrary text, but it is typically a register object.                                  | This function returns true if the operand corresponds to a 16-bit 80x86 general purpose register.                         |
| @isReg32 | @isReg32(Expression )<br><br><i>Expression</i> may be arbitrary text, but it is typically a register object.                                  | This function returns true if the operand corresponds to a 32-bit 80x86 general purpose register.                         |
| @isFReg  | @isFReg(Expression )<br><br><i>Expression</i> may be arbitrary text, but it is typically a register object.                                   | This function returns true if the operand corresponds to an FPU register.                                                 |
| @isMem   | @isMem(Expression )<br><br><i>Expression</i> may be arbitrary text, but it is typically a memory object (including various addressing modes). | This function returns true if the specified parameter corresponds to a legal 80x86 memory address.                        |
| @isClass | @isClass( Text )<br><br><i>Text</i> may be arbitrary text, but it is typically a class object.                                                | This function returns true if the text parameter is a class name or a class object.                                       |
| @isType  | @isClass( Text )<br><br><i>Text</i> may be arbitrary text, but it is typically a type name.                                                   | This function returns true if the specified text is a type identifier.                                                    |

**Table 11: HLA Information and Compile-time Symbol Table Information Functions**

| Function   | Parameters | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

| @section   | @section   | <p>This function returns a 32-bit value that specifies which portion of the program HLA is currently processing. This information is mainly useful in macros to determine where a macro expansion is taking place. This function returns the following bit values:</p> <p>Bit 0: Currently in the CONST section.<br/>           Bit 1: Currently in the VAL section.<br/>           Bit 2: Currently in the TYPE section.<br/>           bit 3: Currently in the VAR section.<br/>           bit 4: Currently in the STATIC section.<br/>           bit 5: In the READONLY section.<br/>           Bit 6: In the STORAGE section.<br/>           Bit 7: Currently in the DATA section.</p> <p>Bits 8-11: reserved.</p> <p>Bit 12: Processing statements in main.<br/>           Bit 13: Statements in a procedure.<br/>           Bit 14: Statements in a method.<br/>           Bit 15: Statements in an iterator.<br/>           Bit 16: Statements in a macro.<br/>           Bit 17: Statements in a keyword macro.<br/>           Bit 18: In a Terminator macro.<br/>           Bit 19: Statements in a Thunk.</p> <p>Bits 20-22: reserved.</p> <p>Bit 23: Processing statements in a Unit.<br/>           Bit 24: Statements in a Program.</p> <p>Bit 25: Processing a Record declaration.<br/>           Bit 26: Processing a Union declaration.<br/>           Bit 27: Processing a Class declaration.<br/>           Bit 28: Processing a Namespace declaration.</p> <p>Bits 29-31: reserved.</p> |
| @curLex    | @curLex    | Returns the current lex level of this statement within the program.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| @curOffset | @curOffset | Returns the current offset into the activation record. This is the offset of the last VAR object declared in the current program/procedure.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

**Table 11: HLA Information and Compile-time Symbol Table Information Functions**

| Function    | Parameters  | Description                                                                                                                                                                                                                                                                                   |
|-------------|-------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @curDir     | @curDir     | Returns +1 if processing parameters, -1 otherwise. This corresponds to whether offsets are increasing or decreasing in an activation record during compilation. This function also returns +1 when processing fields in a record or class; it returns zero when processing fields of a union. |
| @addofs1st  | @addofs1st  | This function returns true when processing local variables, it returns false when processing parameters and record/class/union declarations.                                                                                                                                                  |
| @lastObject | @lastObject | This function returns a string containing the name of the last macro object processed.                                                                                                                                                                                                        |
| @lineNumber | @lineNumber | This function returns an <i>uns32</i> value specifying the current line number in the file.                                                                                                                                                                                                   |

---

## H.8 Compile-Time Variables

The HLA compile-time variables are special symbols that not only return values, but allow you to modify their internal values as well. You may use these symbols exactly like any VAL object in your program with the exception that you cannot change the type (generally *int32* or *boolean*) of these objects. By changing the values of these *pseudo-variables*, you can affect the way HLA generates code in your programs.

**Table 12: HLA Compile-time Variables**

| Pseudo-Variable | Description                                                                                                                                                                                                                                                                                                                     |
|-----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @parmOffset     | This variable specifies the starting offset for parameters in a function. This should be eight for most procedures. If you change this value, HLA's automatic code generation for procedure calls may fail.                                                                                                                     |
| @localOffset    | This variable specifies the starting offset for local variables in a procedure. This is typically zero. If you change this value, it will affect the offsets of all local symbols in the activation record, hence you should modify this value only if you really know what you're doing (and have a good reason for doing it). |
| @enumSize       | This variable specifies the size (in bytes) of enum objects in your program. By default, this value is one. If you want word or dword sized enum objects you can change this variable to two or four. Other values may create problems for the compiler.                                                                        |
| @minParmSize    | This variable specifies the minimum number of bytes for each parameter. Under Windows, this should always be four.                                                                                                                                                                                                              |

**Table 12: HLA Compile-time Variables**

| Pseudo-Variable | Description                                                                                                                                                                                                                                                                                     |
|-----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @bound          | This boolean variable, whose default value is true, controls the compilation of the BOUND instruction. If this variable contains false, HLA does not compile BOUND instructions. You can set this value to true or false throughout your program to control the emission of bound instructions. |
| @into           | This boolean variable, whose default value is false, controls the compilation of the INTO instruction. If this variable contains false, HLA does not compile INTO instructions. You can set this value to true or false throughout your program to control the emission of INTO instructions.   |
| @trace          | Enables HLA's statement tracing facilities. See the separate appendix for details.                                                                                                                                                                                                              |
| @exceptions     | If true (the default) then HLA uses the full exception handling package in the HLA Standard Library. If false, HLA uses a truncated version. This allows programmers to write their own exception handling code.                                                                                |

---

## H.9 Miscellaneous Compile-Time Functions

This last category contains various functions and objects that are quite useful in compile-time programs.

**Table 13: Miscellaneous HLA Compile-time Functions and Objects**

| Function                     | Parameters                                                                                                        | Description                                                                                                                                                                                                                                    |
|------------------------------|-------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| @text                        | @text( <i>str</i> )<br><i>str</i> must be a string constant expression.                                           | This function expands the string constant in-line as text, replacing this function invocation with the specified text.                                                                                                                         |
| @eval                        | @eval( <i>text</i> )<br><i>text</i> is an arbitrary sequence of textual characters.                               | This function is useable only within macro invocation parameter lists. It immediately evaluates the text object and passes the resulting text as the parameter to the macro. This provides eager evaluation capabilities for macro parameters. |
| @string: <i>identifier</i>   | @string: <i>identifier</i><br><i>identifier</i> must be a <i>text</i> constant.                                   | This function returns a string constant corresponding to the string data in the specified identifier. It does not otherwise affect the value or type of <i>identifier</i> .                                                                    |
| @toString: <i>identifier</i> | @string: <i>identifier</i><br><i>identifier</i> must be a <i>text</i> constant.                                   | This function converts the type of <i>identifier</i> from <i>text</i> to <i>string</i> and then returns the value of that string object.                                                                                                       |
| @global: <i>identifier</i>   | @string: <i>identifier</i><br><i>identifier</i> must be an HLA identifier declared outside the current namespace. | @global is legal only within a namespace declaration. It provides access to identifiers outside the namespace.                                                                                                                                 |

# Installing HLA on Your System

# Appendix I

The latest version of HLA is available from the Webster web server at

<http://webster.cs.ucr.edu>

Go to this web site and following the HLA links to the “HLA Download” page. From here you should select the latest version of HLA for download to your computer. The HLA distribution is provided in a “Zip File” compressed format. You will need a decompressor program like PKUNZIP or WinZip in order to extract the HLA files from this zipped archive file. The use of these decompression products is beyond the scope of this appendix, please consult the software vendor’s documentation or their web page for information concerning the use of these products. There are several files you can download associated with HLA. For this text, you’ll need at least the executables and the examples downloads. You may download other files at your own discretion.

This text assumes that you have unzipped the HLA distribution into the root directory of your C: drive. You can certainly install HLA anywhere you want, but you will have to adjust the following descriptions if you install HLA somewhere else. Note: if you are using computers in a school laboratory, your system administrator or instructor may have already installed HLA on the system; please consult the administrator or instructor for details.

HLA is a command window/console application. In order to run the HLA compiler you must run the command window program (this is “command.com” on Windows 95 and 98, “cmd.exe” on Windows NT and Windows 2000). Most Windows distributions let you run the command prompt windows from the Start menu or from a submenu hanging off the start menu. Otherwise, you can find the executable in the “C:\Windows” directory or in the “C:\WinNT\System32” directory<sup>1</sup>. This text assumes that you are familiar with the Windows command window and you know how to use some basic command window commands (e.g., dir, del, rename, etc.). If you have never before used the Windows command line interpreter, you should consult an appropriate text to learn a few basic commands.

Before you can actually run the HLA compiler, you must set the system execution path and set up various environment variables. Some versions of Windows (e.g., NT) let you permanently set up these values. However, an easy and universal way to set up the path and environment variables is to use a *batch file*. A batch file is a sequence of command window commands that you store into a file (with a “.BAT” extension) to quickly execute by typing the filename (sans extension). This is the method we will use to initialize the system.

The following text provides a suitable “ihla.bat” (initialize HLA) file that sets up the important variables, assuming you’ve installed HLA on your “C:” drive in the “C:\HLA” subdirectory:

```
path=c:\hla;%path%
set lib=c:\hla\hlalib;%lib%
set include=c:\hla\include;%include%
set hlainc=c:\hla\include
set hlalib=c:\hla\hlalib\hlalib.lib
```

Enter these lines of text into a suitable text editor (not a word processor) and save them as “ihla.bat” in the “c:\hla” subdirectory. For your convenience, this batch file also appears in the “AoA\_Software” directory of the HLA distribution.

The first line in this batch file tells the system to execute the HLA.EXE and HLPARSE.EXE files directly from the HLA subdirectory without your having to specify the full pathname. That is, you can type “hla” rather than “c:\hla\hla” in order to run the HLA compiler. Obviously, this saves a lot of typing and is quite worthwhile<sup>2</sup>. The second and third lines of this batch file insert the HLA include directory and HLA Standard Library directory into the search list used by compilers on the system. HLA doesn’t actually use these variables, but other tools might, hence their inclusion in the batch file. The last two entries in the batch

1. Assuming you’ve installed Windows on your “C:” drive. Adjust the drive letter appropriately if you’ve installed Windows on a different drive.

2. Alternately, you can move the HLA.EXE and HLPARSE.EXE files to a subdirectory already in the execution path.

file set up the HLA-specific environment variables that provide the paths to the HLA include file directory and the HLA standard library file (hlalib.lib). The HLA compiler expects to find these variables in the system environment. **Compilation will probably fail if you haven't set up these environment variables.**

In addition to the HLA distribution files, you will also need some additional Microsoft tools in order to use the HLA system. Specifically, you will need a copy of Microsoft's Macro Assembler (MASM) and a copy of the Microsoft Linker in order to use HLA. Fortunately, you may download these programs for free from the internet. Instructions on how to do so are available on the net. The Webster web site (see the "Randall Hyde's Assembly Page" link) maintains a link to a site that explains how to download MASM and LINK from Microsoft's web page. You will need to obtain the ml.exe, ml.err, link.exe, and the MspdbX0.dll (x=5, 6, or some other integer) files. Place these files in the HLA directory along with the HLA.EXE and HLA-PARSE.EXE files<sup>3</sup>. In addition to these files, you will need a copy of Microsoft's "kernel32.lib" library package. This comes with Visual C++ and other Microsoft tools and compilers. If this file is not in the current path specified by the "lib" environment variable, put a copy in the "c:\hla\hlalib" subdirectory.

Getting HLA up and running is a complex process because there are so many different files that have to all be located in the right spot. If you are having trouble getting HLA running on your system, be sure that:

- HLA.EXE and HLPARSE.EXE are in the "c:\hla" subdirectory.
- ml.exe, ml.err, and link.exe are in the "c:\hla" subdirectory.
- mspdbX0.dll (x=5, 6, or greater) is in the "c:\hla" subdirectory (win95 and win98 users).
- msvcr.dll is in the c:\hla" subdirectory (Win NT and Win 2000 users).
- kernel32.lib is in the path specified by the "set lib=..." statement (e.g., the "c:\hla\hlalib" subdirectory).

To verify the proper operation of HLA, open up a command window (i.e., from the START button in Windows), type "c:\hla\ihla" to run the "ihla.bat" file to initialize the path and important environment variables. Then type "hla -?" at the command line. HLA should display the current version number along with a list of legal command line parameters. If you get this display, the system can find the HLA compiler, so go on to the next step. If you do not get this message, then type "SET" at the command line prompt and verify that the path is correct and that the lib, include, hlalib, and hlainc environment variables are set correctly. If not, rerun the ihla.bat file and try again<sup>4</sup>.

Once you've verified the proper operation of the HLA compiler, the next step is to verify the proper operation of the MASM assembler. You can do this by typing "ML -?" at the Windows command line prompt. MASM should display its current version number and all the command line parameters it supports. You will not directly run MASM, so you can ignore all this information. The important issue is whether the information appears. If it does not, an HLA compile will fail. If the ML command does not bring up this information, verify that ml.exe and ml.err are in an execution path (e.g., in the "c:\hla" subdirectory).

The next step is to verify that the Microsoft linker is operational. You can do this by typing "link -?" at the Windows command line prompt. The program should display a message like "Microsoft (R) Incremental Linker Version 6.00.xxxx". If you do not get a linker message at all, verify that the link.exe program is installed in a subdirectory in the execution path (e.g., "c:\hla"). Also make sure that the mspdbX0.dll (X=5 or greater, this should match the version of the linker) and msvcr.dll files appear in this same directory. Warning: depending on where you got your copy of MASM, it may have come with a 16-bit linker. 16-bit linkers are not compatible with HLA. You must use the newer 32-bit linkers that come with Visual C++ and other Microsoft languages.

Note: most of the Microsoft tools and libraries you will need can be found at the following WEB address:

<http://www.pbq.com.au/home/hutch/masm.htm>

There is also a link on Webster (<http://webster.cs.ucr.edu>) to a page that explains how to extract MASM and other tools from the Microsoft site.

---

3. Actually, you may install these files in any directory that is in the execution path. So if you've purchased a commercial version of MASM, or have installed the linker via Visual C++, there is no need to move or copy these files to the HLA directory.

4. Be sure the ihla.bat file contains appropriate drive letters in front of the pathnames if you are having problems.

At this point, you should have successfully installed the HLA system and it should be ready to use. After a description of the HLA distribution in the next section, you'll get an opportunity to test out your installation.

---

## I.1 What's Included in the HLA Distribution Package

Although HLA is relatively flexible about where you put it on your system, this text assumes you've installed HLA on your C: drive under a Win32 operating system (e.g., Windows 95, 98, NT, 2000, and later versions that are 32-bit compatible). This text also assumes the standard directory placement for the HLA files, which has the following layout

- HLA directory
  - Doc directory
  - Examples directory
  - AoA\_Software directory
    - Volume1
      - Ch01 directory
      - Ch02 directory
      - etc.
    - Volume2
      - Ch01 directory
      - Ch02 directory
      - etc.
    - etc.
  - hlalib directory
  - include directory
  - Tests directory

The main *HLA* directory contains the executable code for the compiler. This consists of two files, HLA.EXE and HLPARSE.EXE. These two programs must be in the current execution path in order to run the compiler (the "path" command in the ihla.bat file sets the execution path). It wouldn't hurt to put the ml.exe, ml.err, link.exe, mspdbX0.dll (x=5, 6, or greater), and msvcrt.dll files in this directory as well.

The *Doc* directory contains reference material for HLA in PDF and HTML formats. If you have a copy of Adobe Acrobat Reader, you will probably want to read the PDF versions since they are much nicer than the HTML versions. These documents contain the most up-to-date information about the HLA language; you should consult them if you have a question about the HLA language or the HLA Standard Library. Generally, material in this documentation supersedes information appearing in this text since the HLA document is electronic and is probably more up to date.

The *Examples* directory contains a large set of HLA programs that demonstrate various features in the HLA language. If you have a question about an HLA feature, you can probably find an example program that demonstrates that feature in the *Examples* directory. Such examples provide invaluable insight that is often superior to a written description of the feature.

The *AoA\_Software* directory contains the code specific to this textbook. This directory contains all the source code to (complete) programs appearing in this text. It also contains the programs appearing in the Laboratory Exercises section of each chapter. Therefore, this directory is very important to you. Within this subdirectory, the information is further divided up by chapter. The material for Chapter One appears in the AoA\_Software\Volume1\Ch01 subdirectory, the material for Chapter Two appears in the AoA\_Software\Volume1\Ch02 subdirectory, etc..

The *hlalib* directory contains the source and object code for the HLA Standard Library. As you become more competent with HLA, you may want to take a look at how HLA implements various library functions. In the meantime, this directory contains the hlalib.lib file which you must link with your own programs that make calls to the standard library. Linking instructions appear a little later in this chapter.

The *include* directory contains the HLA Standard Library include files. These special files (that end with a “.hhf” suffix, for HLA Header File) are needed during assembly to provide prototype and other information to your program. The example programs in this chapter all include the HLA header file “stdlib.hhf” that, in turn, includes all the other HLA header files in the standard library.

The *Tests* directory contains various test files that test the correct operation of the HLA system. HLA includes these files as part of the distribution package because they provide additional examples of HLA coding.

## I.2 Using the HLA Compiler

If you’ve made it through the previous two sections, it’s now time to test out your installation and verify that it is correct. In this section you’ll also learn how to run the compiler and the executables it produces.

To begin with, open a command prompt window. This is usually accomplished by selecting the “command prompt” program from the Windows Start menu (or one of its submenus). You can also use the “run” command (from the Start button) and type “command” for Windows 95 & 98 or “cmd” for Windows NT & 2000. Once you are faced with the command prompt window, type the following (boldfaced) commands to initialize the HLA system:<sup>5</sup>

```
c:> cd c:\hla
c:> ihla
```

If your command prompt opens up a drive other than C:, you may need to switch to the “C:” drive (or whatever drive contains the HLA subdirectory) before issuing these commands. You can switch the default drive by simply typing the drive letter followed by a colon. For example, to switch to the C: drive, you would use the following command:

```
x:> c:
```

After running the “ihla” batch file to initialize the system, you can test for the presence of the HLA compiler by entering the following command:

```
c:\hla> hla -?
```

This should display some internal information about HLA along with a description of the syntax for the HLA command. If you get an error message complaining about a missing command, you’ve probably not installed HLA properly or the path hasn’t been properly set. If you believe you’ve installed HLA properly, try running the *ihla.bat* file again, and check to be sure that the batch file contains the correct data.

Warning: every time you start a new command prompt window, you will need to re-run the *ihla.bat* file. Generally, you should only have to open a command prompt window once per programming session. However, if you close the window for some reason, keep in mind that you must rerun *ihla.bat* before you can run HLA.

## I.3 Compiling Your First Program

Once HLA is operational, the next step is to compile an actual working program. The HLA distribution contains lots of example HLA programs, including the HLA programs appearing in this text. Since these examples are already written, tested, and ready to compile and run, it makes sense to work with one of these example files when compiling your first program.

5. This text typically displays the entire command line text when showing the execution of a command window command. The non-boldfaced text is printed by the command line processor, the boldfaced text is user input. Note that this text assumes that you are working on the “C:” disk drive. If you’re working on a different drive (e.g., a network drive containing your personal account), you will see a slightly different prompt and you will need to adjust the drive letters in the commands presented in this text.

A good first program is the “Hello World” program appearing in program Volume One (repeated below):

```
program helloWorld;
#include("stdlib.hhf");

begin helloWorld;

 stdout.put("Hello, World of Assembly Language", nl);

end helloWorld;
```

The source code for this program appears in the “C:\hla\AoA\_Software\Volume1\Ch02\HelloWorld.hla” file. To compile this program, type the following at the command prompt:

```
c:\lab1> hla HelloWorld
```

After a few moments, the Windows command prompt (“C:>”) should reappear. At this point, your program has been successfully compiled. To run the executable (HelloWorld.exe) that HLA has produced, you would use the following command:

```
C:\hla\AoA_Software\Volume1\Ch02> HelloWorld
```

The program should run, display “Hello World”, and then terminate. At that time the command window should be waiting for another command.

If you have not successfully completed the previous steps, return to the previous section and repeat the steps to verify that HLA is operational on your system. Remember, each time you start a new command window, you must execute the “ihla.bat” file (or otherwise set up the environment) in order to make HLA accessible in that command window.

## I.4 Win 2000 Installation Notes Taken from comp.lang.asm.x86

Here’s some installation information I’ve received from “Sam” on the internet. You can obtain more information from his web site at <http://www.idmcomp.com/discus/messages/11/327.html>.

### I.4.1 To Install HLA

How to get HLA running conveniently in Win2000; and also how to configure Ultraedit32 to save file, pass to HLA compiler, and run program, all with a UE keyboard shortcut. Reply here in group if any problems.

This is the way \*I\* have set things up in Win2k Pro, and so I can only say that if you set up exactly like I did, it may have a good chance of working. WARNING: Have your Win2k CD on hand to repair damaged installation if anything goes wrong....

1.-- Go to [http://webster.cs.ucr.edu/Page\\_hla/hla.html](http://webster.cs.ucr.edu/Page_hla/hla.html) and read the first few paragraphs, down to "Once that above is achieved, you can run the HLA compiler..." This will tell you what we're trying to do, and what you need to run HLA, but is necessarily vague (for legal reasons I presume) on WHERE to get some of these files...you can get MASM 615 by following instructions at

<http://www.easystreet.com/~jkirwan/pctools.html>

2.-- The only way I have found to get sufficiently recent versions of link.exe, kernel32.lib, user32.lib and gdi32.lib (plus all needed DLLs) is to have a friend with VC++ 6.0. (RLH note: version 5 of the 32-bit linker is okay. You can get the files from the MASM32 home page on the Internet; just search for MASM32 in Altavista or some other search engine [this is still vague for legal reasons]).

3.-- Once you have all needed files, create c:\hla and make sure it includes the subdirectories and files in the list at the end of this text.

4.-- Open System Properties (Winkey-Break is a convenient shortcut) and go to Advanced tab, then Environment Variables. Add "c:\hla" to the Path in SYSTEM VARIABLES, not in "User variables for <your win2k login name>". Click OK, but keep the Environment Variables window open, we're not done.

5.-- Look at the contents of ihla.bat, reproduced here for your convenience:

```
path=c:\hla;%path%
set lib=c:\hla\hlalib;%lib%
set include=c:\hla\include;%include%
set hlainc=c:\hla\include
set hlalib=c:\hla\hlalib\hlalib.lib
```

In "User Variables for <your login name>", you must end up with each of these settings. For example, to create hlainc, you click the "New..." button, type "hlainc" as the name of the variable, and type "c:\hla\include" as the Variable value (all without quotes of course). If there is already a path set, and it already has some value, add this immediately to the end: ";c:\hla;%path%" and that will preserve your existing User and System paths as well as adding c:\hla.

For example, suppose you opened up your User Variables for <login name> and it already said "C:\Private

Files\PantiePix;c:\winnt\system32;c:\winnt;c:\winnt\System32\Wbem;d:\lcc\bin;D:\PROGRA~1\ULTRAE~1;D:\4NT300;C:\msoffice\Office;c:\hla",

you would click on Edit and type "C:\Private Files\PantiePix;c:\hla;%path%"

(Same advice for preserving existing lib and include settings)

6.-- Once you reboot the computer, you should be all set for "Hello world of assembly language"!

## I.4.2 SETTING UP UEDIT32

In Uedit32's Advanced/Tool Configuration, create a new item called HLA.

Command line:

```
c:\HLA\hla.exe "%f" & "%n" & echo. & echo. & echo. & echo. & pause
```

-- You can read all about these switches in the Help, but basically what this command does is start hla.exe, pass it the current UE file (the .hla program you're building), run it once HLA has finished with it, and pause at the end, so you can examine the output before you press the "any" key which will close the console. (I haven't figured out a way to keep one console constantly open and simply run every new build of the program in it, as of yet....)

Working directory:

c:\hla

Menu Item Name:

HLA

Check "Save All Files First" if you like. Close and restart UEDIT32.

To run this baby, edit your .hla file as usual, then when you wish to \make it go, press the appropriate key combination for "HLA" (It's in the Advanced menu in case you forget; it will default to Ctrl-Shift-<0 or 1 or whatever>.

The program will echo compiler/linker messages to a console which will pop up (hit Alt-spacebar, then Properties, to set up that console window the way you like it)....

**SYNTAX HIGHLIGHTING:** Study ultraedit/wordfile.txt to see how Syntax Highlighting is handled, then create a new language, HLA. I simply copied and edited the Assembly x86 syntax highlighting (you may have to download this file from [www.ultraedit.com](http://www.ultraedit.com), I forget) but I'm a beginning programmer and not sure of the different categories of HLA tokens to be highlighted, so I will spare you my clumsy efforts. It works fine though.

# Debugging HLA Programs

# Appendix J

## 1.1 The @TRACE Pseudo-Variable

HLA v1.x has a few serious defects in its design. One major issue is debugging support. HLA v1.x emits MASM code that it runs through MASM in order to produce executable object files. Unfortunately, while this scheme makes the development, testing, and debugging of HLA easier, it effectively eliminates the possibility of using existing source level debugging tools to locate defects in an HLA program<sup>1</sup>. Starting with v1.24, HLA began supporting a new feature to help you debug your programs: the “@trace” pseudo-variable. This appendix will explain the purpose of this compile-time variable and how you can use it to locate defects in your programs.

By default, the compile-time variable `@trace` contains false. You can change its value with any variation of the following statement:

```
?@trace := <<boolean constant expression>>;
```

Generally, “<<boolean constant expression>>” is either *true* or *false*, but you could use any compile-time constant expression to set `@trace`'s value.

Once you set `@trace` to true, HLA begins generating extra code in your program. In fact, before almost every executable statement HLA injects the following code:

```
traceLine(filename, lineNumber);
```

The *filename* parameter is a string specifying the name of the current source file, the *linenumber* parameter is an uns32 value that is the current line number of the file. The `_traceLine_` procedure uses this information to display an appropriate trace value while the program is running.

HLA will automatically emit the above procedure call in between almost all instructions appearing in your program<sup>2</sup>. Assuming that the `_traceLine_` procedure simply prints the filename and line number, when you run your application it will create a log of each statement it executes.

You can control the emission of the `_traceLine_` procedure calls in your program by alternately setting `@trace` to *true* or *false* throughout your code. This lets you selectively choose which portions of your code will provide trace information during program execution. This feature is very important because if you're displaying the trace information to the console, your program runs thousands, if not millions, of times slower during the trace operation. It wouldn't do to have to trace through a really long loop in order to trace through following code that you're concerned about. By setting `@trace` to *false* prior to the long loop and setting it to true immediately after the loop, you can execute the loop at full speed and then begin tracing the code you want to check once the loop completes execution.

HLA does not supply the `_traceLine_` procedure; it is your responsibility to write the code for this procedure. The following is a typical implementation:

```
procedure trace(filename:string; linenum:uns32); external("_traceLine_");
procedure trace(filename:string; linenum:uns32); nodisplay;
begin trace;

 pushfd();
 stdout.put(filename, ": #", linenum, nl);
 popfd();

end trace;
```

---

1. Of course, you can also debug the MASM output using a source level debugger, but this is not a very pleasant experience.  
 2. HLA does not emit this procedure call between statements that are composed and a few other miscellaneous statements. However, your programs probably get better than 95% coverage so this will be sufficient for most purposes.

This particular procedure simply prints the filename and line number each time HLA calls it. Therefore, you'll get a trace sent to the standard output device that looks something like the following:

```
t.hla: #19
t.hla: #20
t.hla: #21
t.hla: #22
etc.
```

A very important thing to note about this sample implementation of `_traceLine_` is that it preserves the FLAGS register. The `_traceLine_` procedure must preserve all registers including the flags. The example code above only preserves the FLAGS because the `stdout.put` macro always preserves all the registers. However, were this code to modify other registers or call some procedure that modifies some registers, you would want to preserve those register values as well. Remember, HLA calls this procedure between most instructions, if you do not preserve the registers and flags within this procedure, it will adversely affect the running of your program.

**This is very important:** the `@trace` variable must contain false while HLA is compiling your `_traceLine_` procedure. If HLA emits trace code inside the trace procedure, this will create an infinite loop via infinite recursion which will crash your program. Always make sure `@trace` is false across the compilation of your `_traceLine_` procedure.

Here's a sample program using the `@trace` variable and sample output for the program:

```
program t;
#includeOnce("stdlib.hhf")

procedure trace(filename:string; linenum:uns32); external("_traceLine_");

?@trace := false; // Must be false for TRACE routine.

procedure trace(filename:string; linenum:uns32); nodisplay;
begin trace;

 stdout.put(filename, ": #", linenum, nl);

end trace;

?@trace := true;

begin t;

 mov(0, ecx); // Line 22
 if(ecx == 0) then // Line 23

 mov(10, ecx); // Line 25

 else

 mov(5, ecx);

 endif;
 while(ecx > 0) do // Line 32

 dec(ecx); // Line 34

 endwhile;
 for(mov(0, ecx); ecx < 5; inc(ecx)) do // Line 37
```

```

#if(@defined(DEBUG)) // If DEBUG is not defined, then don't emit code.

 #if(DEBUG) // DEBUG has to be a boolean const equal to true.

 #if(@isConst(runTimeFlag))

 #if(runTimeFlag)

 stdout.put(msg, nl);

 #endif

 #else // runTimeFlag is a run-time variable

 if(runTimeFlag) then

 stdout.put(msg, nl);

 endif;

 #endif // runTimeFlag is/is not Constant

 #endif // DEBUG

#endif // DEBUG is defined

endmacro;

```

With this macro defined, you can write a statement like the following to print/not print a message at run-time:

```
myDebugMsg(BooleanValue, "This is a debug message");
```

The *BooleanValue* expression is either a boolean constant expression, a boolean variable, or a register. If this value is true, then the program will print the message; if this value is false, the program does not print the message. Since this is a variable, you can control debugging output at run-time by changing the value of the *BooleanValue* parameter.

As *myDebugMsg* is written, you must define the boolean constant *DEBUG* and set it to true or the program will not compile the debugging statements. If *DEBUG* is a VAL object, you can actually

You can certainly expand upon this macro by providing support for a variable number of parameters. This would allow you to specify an list of values to display in the *stdout.put* macro invocation. See the chapter on Macros for more information about variable parameter lists in macros if you want to do this.

# HLA Code Generation for HLL Statements Appendix L

One of the principal advantages of using assembly language over high level languages is the control that assembly provides. High level languages (HLLs) represent an abstraction of the underlying hardware. Those who write HLL code give up this control in exchange for the engineering efficiencies enjoyed by HLL programmers. Some advanced HLL programmers (who have a good mastery of the underlying machine architecture) are capable of writing fairly efficient programs by recognizing what the compiler does with various high level control constructs and choosing the appropriate construct to emit the machine code they want. While this “low-level programming in a high level language” does leave the programmer at the mercy of the compiler-writer, it does provide a mechanism whereby HLL programmers can write more efficient code by choosing those HLL constructs that compile into efficient machine code.

Although the High Level Assembler (HLA) allows a programmer to work at a very low level, HLA also provides structured high-level control constructs that let assembly programmers use higher-level code to help make their assembly code more readable. Those assembly language programmers who need (or want) to exercise maximum control over their programs will probably want to avoid using these statements since they tend to obscure what is happening at a really low level. At the other extreme, those who would always use these high-level control structures might question if they really want to use assembly language in their applications; after all, if they’re writing high level code, perhaps they should use a high level language and take advantage of optimizing technology and other fancy features found in modern compilers. Between these two extremes lies the typical assembly language programmer. The one who realizes that most code doesn’t need to be super-efficient and is more interested in productively producing lots of software rather than worrying about how many CPU cycles the one-time initialization code is going to consume. HLA is perfect for this type of programmer because it lets you work at a high level of abstraction when writing code whose performance isn’t an issue and it lets you work at a low level of abstraction when working on code that requires special attention.

Between code whose performance doesn’t matter and code whose performance is critical lies a big gray region: code that should be reasonably fast but speed isn’t the number one priority. Such code needs to be reasonably readable, maintainable, and as free of defects as possible. In other words, code that is a good candidate for using high level control and data structures if their use is reasonably efficient.

Unlike various HLL compilers, HLA does not (yet!) attempt to optimize the code that you write. This puts HLA at a disadvantage: it relies on the optimizer between your ears rather than the one supplied with the compiler. If you write sloppy high level code in HLA then a HLL version of the same program will probably be more efficient if it is compiled with a decent HLL compiler. For code where performance matters, this can be a disturbing revelation (you took the time and bother to write the code in assembly but an equivalent C/C++ program is faster). The purpose of this appendix is to describe HLA’s code generation in detail so you can intelligently choose when to use HLA’s high level features and when you should stick with low-level assembly language.

---

## L.1 The HLA Standard Library

The HLA Standard Library was designed to make learning assembly language programming easy for beginning programmers. Although the code in the library isn’t terrible, very little effort was made to write top-performing code in the library. At some point in the future this may change as work on the library progresses, but if you’re looking to write very high-performance code you should probably avoid calling routines in the HLA Standard Library from (speed) critical sections of your program.

Don’t get the impression from the previous paragraph that HLA’s Standard Library contains a bunch of slow-poke routines, however. Many of the HLA Standard Library routines use decent algorithms and data structures so they perform quite well in typical situations. For example, the HLA string format is far more efficient than strings in C/C++. The world’s best C/C++ *strlen* routine is almost always going to be slower than HLA *strlen* function. This is because HLA uses a better definition for string data than C/C++, it has little to do with the actual implementation of the *strlen* code. This is not to say that HLA’s *strlen* routine cannot be improved; but the routine is very fast already.

One problem with using the HLA Standard Library is the frame of mind it fosters during the development of a program. The HLA Standard Library is strongly influenced by the C/C++ Standard Library and libraries common in other high level languages. While the HLA Standard Library is a wonderful tool that can help you write assembly code faster than ever before, it also encourages you to think at a higher level. As any expert assembly language programmer can tell you, the real benefits of using assembly language occur only when you “think in assembly” rather than in a high level language. No matter how efficient the routines in the Standard Library happen to be, if you’re “writing C++ programs with MOV instructions” the result is going to be little better than writing the code in C++ to begin with.

One unfortunate aspect of the HLA Standard Library is that it encourages you to think at a higher level and you’ll often miss a far more efficient low-level solution as a result. A good example is the set of string routines in the HLA Standard Library. If you use those routines, even if they were written as efficiently as possible, you may not be writing the fastest possible program you can because you’ve limited your thinking to string objects which are a higher level abstraction. If you did not have the HLA Standard Library laying around and you had to do all the character string manipulation yourself, you might choose to treat the objects as character arrays in memory. This change of perspective can produce dramatic performance improvement under certain circumstances.

The bottom line is this: the HLA Standard Library is a wonderful collection of routines and they’re not particularly inefficient. They’re very easy and convenient to use. However, don’t let the HLA Standard Library lull you into choosing data structures or algorithms that are not the most appropriate for a given section of your program.

## L.2 Compiling to MASM Code -- The Final Word

The remainder of this document will discuss, in general, how HLA translates various HLL-style statements into assembly code. Sometimes a general discussion may not provide specific answers you need about HLA’s code generation capabilities. Should you have a specific question about how HLA generates code with respect to a given code sequence, you can always run the compiler and observe the output it produces. To do this, it is best to create a simple program that contains only the construct you wish to study and compile that program to assembly code. For example, consider the following very simple HLA program:

```
program t;
begin t;
 if(eax = 0) then
 mov(1, eax);
 endif;
end t;
```

If you compile this program using the command window prompt “hla -s t.hla” then HLA produces a (MASM) file similar to the following<sup>1</sup>:

```
if @Version lt 612
.586
else
.686
.mmx
.xmm
```

1. Because the code generator in HLA is changing all the time, this file may not reflect an accurate compilation of the above HLA code. However, the concepts will be the same.

?HLAMain proc near32

; Set up the Structured Exception Handler record
; for this program.

 push offset32 ??DfltExHndlr
 push ebp

```

```

 push offset32 ?MainPgmCoroutine
 push offset32 ??HWexcept
 push ?ExceptionPtr
 mov ?ExceptionPtr, esp
 mov dword ptr ?MainPgmCoroutine+12, esp

 pushd 0 ;No Dynamic Link.
 mov ebp, esp ;Pointer to Main's locals
 push ebp ;Main's display.
 mov [ebp+16], esp
 cmp eax, 0
 jne ?1_false
 mov eax, 1
?1_false:
 push 0
 call dword ptr __imp__ExitProcess@4
?HLAMain
cseg endp
 ends
 end

```

The code of interest in this example is at the very end, after the comment “;Main’s display” appears in the text. The actual code sequence that corresponds to the IF statement in the main program is the following:

```

 cmp eax, 0
 jne ?1_false
 mov eax, 1
?1_false:

```

Note: you can verify that this is the code emitted by the IF statement by simply removing the IF, recompiling, and comparing the two assembly outputs. You’ll find that the only difference between the two assembly output files is the four lines above. Another way to “prove” that this is the code sequence emitted by the HLA IF statement is to insert some comments into the assembly output file using HLA’s #ASM..#ENDASM directives. Consider the following modification to the “t.hla” source file:

```

program t;

begin t;

 #asm
 ; Start of IF statement:
 #endasm

 if(eax = 0) then

 mov(1, eax);

 endif;

 #asm
 ; End if IF statement.
 #endasm

```

```
end t;
```

HLA's #asm directive tells the compiler to simply emit everything between the #asm and #endasm keywords directly to the assembly output file. In this example the HLA program uses these directives to emit a pair of comments that will bracket the code of interest in the output file. Compiling this to assembly code (and stripping out the irrelevant stuff before the HLA main program) yields the following:

```

 public ?HLAMain
?HLAMain proc near32

; Set up the Structured Exception Handler record
; for this program.

 push offset32 ??DfltExHndlr
 push ebp
 push offset32 ?MainPgmCoroutine
 push offset32 ??HWexcept
 push ?ExceptionPtr
 mov ?ExceptionPtr, esp
 mov dword ptr ?MainPgmCoroutine+12, esp

 pushd 0 ;No Dynamic Link.
 mov ebp, esp ;Pointer to Main's locals
 push ebp ;Main's display.
 mov [ebp+16], esp

;#asm

 ; Start of IF statement:
 ;#endasm

 cmp eax, 0
 jne ?1_false
 mov eax, 1

?1_false:

;#asm

 ; End if IF statement.
 ;#endasm

 push 0
 call dword ptr __imp__ExitProcess@4
?HLAMain endp
cseg ends
 end
```

This technique (embedding bracketing comments into the assembly output file) is very useful if it is not possible to isolate a specific statement in its own source file when you want to see what HLA does during compilation.

### L.3 The HLA if..then..endif Statement, Part I

Although the HLA IF statement is actually one of the more complex statements the compiler has to deal with (in terms of how it generates code), the IF statement is probably the first statement that comes to mind when something thinks about high level control structures. Furthermore, you can implement most of the other control structures if you have an IF and a GOTO (JMP) statement, so it makes sense to discuss the IF statement first. Nevertheless, there is a bit of complexity that is unnecessary at this point, so we'll begin our discussion with a simplified version of the IF statement; for this simplified version we'll not consider the ELSEIF and ELSE clauses of the IF statement.

The basic HLA IF statement uses the following syntax:

```
if(simple_boolean_expression) then
 << statements to execute if the expression evaluates true >>
endif;
```

At the machine language level, what the compiler needs to generate is code that does the following:

```
<< Evaluate the boolean expression >>
<< Jump around the following statements if the expression was false >>
<< statements to execute if the expression evaluates true >>
<< Jump to this point if the expression was false >>
```

The example in the previous section is a good demonstration of what HLA does with a simple IF statement. As a reminder, the HLA program contained

```
if(eax = 0) then
 mov(1, eax);
endif;
```

and the HLA compiler generated the following assembly language code:

```
 cmp eax, 0
 jne ?1_false
?1_false:
 mov eax, 1
```

Evaluation of the boolean expression was accomplished with the single “cmp eax, 0” instruction. The “jne ?1\_false” instruction jumps around the “mov eax, 1” instruction (which is the statement to execute if the expression evaluates true) if the expression evaluates false. Conversely, if EAX is equal to zero, then the code falls through to the MOV instruction. Hence the semantics are exactly what we want for this high level control structure.

HLA automatically generates a unique label to branch to for each IF statement. It does this properly even if you nest IF statements. Consider the following code:

```

program t;
begin t;
 if(eax > 0) then
 if(eax < 10) then
 inc(eax);
 endif;
 endif;
end t;

```

The code above generates the following assembly output:

```

 cmp eax, 0
 jna ?1_false
 cmp eax, 10
 jnb ?2_false
 inc eax
?2_false:
?1_false:

```

As you can tell by studying this code, the INC instruction only executes if the value in EAX is greater than zero and less than ten.

Thus far, you can see that HLA's code generation isn't too bad. The code it generates for the two examples above is roughly what a good assembly language programmer would write for approximately the same semantics.

## L.4 Boolean Expressions in HLA Control Structures

The HLA IF statement and, indeed, most of the HLA control structures rely upon the evaluation of a boolean expression in order to direct the flow of the program. Unlike high level languages, HLA restricts boolean expressions in control structures to some very simple forms. This was done for two reasons: (1) HLA's design frowns upon side effects like register modification in the compiled code, and (2) HLA is intended for use by beginning assembly language students; the restricted boolean expression model is closer to the low level machine architecture and it forces them to start thinking in these terms right away.

With just a few exceptions, HLA's boolean expressions are limited to what HLA can easily compile to a CMP and a condition jump instruction pair or some other simple instruction sequence. Specifically, HLA allows the following boolean expressions:

*operand1 relop operand2*

*relop* is one of:

```
= or == (either one, both are equivalent)
<> or != (either one, both are equivalent)
<
<=
>
>=
```

In the expressions above *operand<sub>1</sub>* and *operand<sub>2</sub>* are restricted to those operands that are legal in a `CMP` instruction. This is because HLA translates expressions of this form to the two instruction sequence:

```
cmp(operand1, operand2);
jXX someLabel;
```

where “jXX” represents some condition jump whose sense is the opposite of that of the expression (e.g., “`eax > ebx`” generates a “JNA” instruction since “NA” is the opposite of “>”).

Assuming you want to compare the two operands and jump around some sequence of instructions if the relationship does not hold, HLA will generate fairly efficient code for this type of expression. One thing you should watch out for, though, is that HLA’s high level statements (e.g., `IF`) make it very easy to write code like the following:

```
if(i = 0) then
 ...
elseif(i = 1) then
 ...
elseif(i = 2) then
 ...
.
.
.
endif;
```

This code looks fairly innocuous, but the programmer who is aware of the fact that HLA emits the following would probably not use the code above:

```
 cmp(i, 0);
 jne lbl;
 .
 .
 .
lbl: cmp(i, 1);
 jne lbl2;
 .
 .
 .
lbl2: cmp(i, 2);
```

·  
·  
·

A good assembly language programmer would realize that it's much better to load the variable "i" into a register and compare the register in the chain of CMP instructions rather than compare the variable each time. The high level syntax slightly obscures this problem; just one thing to be aware of.

HLA's boolean expressions do not support conjunction (logical AND) and disjunction (logical OR). The HLA programmer must manually synthesize expressions involving these operators. Doing so forces the programmer to link in lower level terms, which is usually more efficient. However, there are many common expressions involving conjunction that HLA could efficiently compile into assembly language. Perhaps the most common example is a test to see if an operand is within (or outside) a range specified by two constants. In a HLL like C/C++ you would typically use an expression like "(value >= low\_constant && value <= high\_constant)" to test this condition. HLA allows four special boolean expressions that check to see if a register or a memory location is within a specified range. The allowable expressions take the following forms:

```
register in constant .. constant
register not in constant .. constant
```

```
memory in constant .. constant
memory not in constant .. constant
```

Here is a simple example of the first form with the code that HLA generates for the expression:

```
if(eax in 1..10) then
 mov(1, ebx);
endif;
```

Resulting (MASM) assembly code:

```
 cmp eax, 1
 jnb ?1_false
 cmp eax, 10
 jnb ?1_false
 mov ebx, 1
?1_false:
```

Once again, you can see that HLA generates reasonable assembly code without modifying any register values. Note that if modifying the EAX register is okay, you can write slightly better code by using the following sequence:

```
 dec eax
 cmp eax, 9
 jnb ?1_false
 mov ebx, 1
?1_false:
```

While, in general, a simplification like this is not possible you should always remember how HLA generates code for the range comparisons and decide if it is appropriate for the situation.

By the way, the "not in" form of the range comparison does generate slightly different code than the form above. Consider the following:

```

if(eax not in 1..10) then

 mov(1, eax);

endif;

```

HLA generates the following (MASM) assembly language code for the sequence above:

```

 cmp eax, 1
 jnb ?2_true
 cmp eax, 10
 jna ?1_false
?2_true:
 mov eax, 1
?1_false:

```

As you can see, though the code is slightly different it is still exactly what you would probably write if you were writing the low level code yourself.

HLA also allows a limited form of the boolean expression that checks to see if a character value in an eight-bit register is a member of a character set constant or variable. These expressions use the following general syntax:

```

reg8 in CSet_Constant
reg8 in CSet_Variable

reg8 not in CSet_Constant
reg8 not in CSet_Variable

```

These forms were included in HLA because they are so similar to the range comparison syntax. However, the code they generate may not be particularly efficient so you should avoid using these expression forms if code speed and size need to be optimal. Consider the following:

```

if(al in { 'A'..'Z', 'a'..'z', '0'..'9' }) then

 mov(1, eax);

endif;

```

This generates the following (MASM) assembly code:

```

strings segment page public 'data'
?1_cset byte 00h,00h,00h,00h,00h,00h,0ffh,03h
 byte 0feh,0ffh,0ffh,07h,0feh,0ffh,0ffh,07h
strings ends

 push eax
 movzx eax, al
 bt dword ptr ?1_cset, eax
 pop eax
 jnc ?1_false
 mov eax, 1
?1_false:

```

This code is rather lengthy because HLA never assumes that it can disturb the values in the CPU registers. So right off the bat this code has to push and pop EAX since it disturbs the value in EAX. Next, HLA doesn't assume that the upper three bytes of EAX already contain zero, so it zero fills them. Finally, as you can see above, HLA has to create a 16-byte character set in memory in order to test the value in the AL register. While this is convenient, HLA does generate a lot of code and data for such a simple looking expression. Hence, you should be careful about using boolean expressions involving character sets if speed and space is important. At the very least, you could probably reduce the code above to something like:

```

movzx(charToTest, eax);
bt(eax, { 'A'..'Z', 'a'..'z', '0'..'9' });
jnc SkipMov;
mov(1, eax);
SkipMov:

```

This generates code like the following:

```

strings segment page public 'data'
?cset_3 byte 00h,00h,00h,00h,00h,00h,0ffh,03h
 byte 0feh,0ffh,0ffh,07h,0feh,0ffh,0ffh,07h
strings ends

 movzx eax, byte ptr ?1_charToTest[0] ;charToTest
 bt dword ptr ?cset_3, eax
 jnc ?4_SkipMov
 mov eax, 1

?4_SkipMov:

```

As you can see, this is slightly more efficient. Fortunately, testing an eight-bit register to see if it is within some character set (other than a simple range, which the previous syntax handles quite well) is a fairly rare operation, so you generally don't have to worry about the code HLA generates for this type of boolean expression.

HLA lets you specify a register name or a memory location as the only operand of a boolean expression. For registers, HLA will use the TEST instruction to see if the register is zero or non-zero. For memory locations, HLA will use the CMP instruction to compare the memory location's value against zero. In either case, HLA will emit a JNE or JE instruction to branch around the code to skip (e.g., in an IF statement) if the result is zero or non-zero (depending on the form of the expression).

```

register
!register

memory
!memory

```

You should not use this trick as an efficient way to test for zero or not zero in your code. The resulting code is very confusing and difficult to follow. If a register or memory location appears as the sole operand of a boolean expression, that register or memory location should hold a boolean value (true or false). Do not think that "if( eax ) then..." is any more efficient than "if(eax<>0) then..." because HLA will actually emit the same exact code for both statements (i.e., a TEST instruction). The second is a lot easier to understand if you're really checking to see if EAX is not zero (rather than it contains the boolean value true), hence it is always preferable even if it involves a little extra typing.

Example:

```

if(eax != 0) then
 mov(1, ebx);
endif;

if(eax) then
 mov(2, ebx);
endif;

```

The code above generates the following assembly instruction sequence:

```

 test eax, eax ;Test for zero/false.
 je ?2_false
 mov ebx, 1
?2_false:
 test eax, eax ;Test for zero/false.
 je ?3_false
 mov ebx, 2
?3_false:

```

Note that the pertinent code for both sequences is identical. Hence there is never a reason to sacrifice readability for efficiency in this particular case.

The last form of boolean expression that HLA allows is a flag designation. HLA uses symbols like @c, @nc, @z, and @nz to denote the use of one of the flag settings in the CPU FLAGS register. HLA supports the use of the following flag names in a boolean expression:

```

@c, @nc, @o, @no, @z, @nz, @s, @ns,
@a, @na, @ae, @nae, @b, @nb, @be, @nbe,
@l, @nl, @g, @ne, @le, @nle, @ge, @nge,
@e, @ne

```

Whenever HLA encounters a flag name in a boolean expression, it efficiently compiles the expression into a single conditional jump instruction. So the following IF statement's expression compiles to a single instruction:

```

if(@c) then
 << do this if the carry flag is set >>
endif;

```

The above code is completely equivalent to the sequence:

```

jnc SkipStmts;

<< do this if the carry flag is set >>

SkipStmts:

```

The former version, however, is more readable so you should use the IF form wherever practical.

---

## L.5 The JT/JF Pseudo-Instructions

The JT (jump if true) and JF (jump if false) pseudo-instructions take a boolean expression and a label. These instructions compile into a conditional jump instruction (or sequence of instructions) that jump to the target label if the specified boolean expression evaluates false. The compilation of these two statements is almost exactly as described for boolean expressions in the previous section.

The following are a couple of examples that show the usage and code generation for these two statements.

```
lbl2:
 jt(eax > 10) label;
label:
 jf(ebx = 10) lbl2;
```

; Translated Code:

```
?2_lbl2:
 cmp eax, 10
 ja ?4_label

?4_label:
 cmp ebx, 10
 jne ?2_lbl2
```

---

## L.6 The HLA if..then..elseif..else..endif Statement, Part II

With the discussion of boolean expressions out of the way, we can return to the discussion of the HLA IF statement and expand on the material presented earlier. There are two main topics to consider: the inclusion of the ELSEIF and ELSE clauses and the HLA hybrid IF statement. This section will discuss these additions.

The ELSE clause is the easiest option to describe, so we'll start there. Consider the following short HLA code fragment:

```
if(eax < 10) then
 mov(1, ebx);
else
 mov(0, ebx);
endif;
```

HLA's code generation algorithm emits a JMP instruction upon encountering the ELSE clause; this JMP transfers control to the first statement following the ENDIF clause. The other difference between the IF/ELSE/ENDIF and the IF/ENDIF statement is the fact that a false expression evaluation transfers control to the ELSE clause rather than to the first statement following the ENDIF. When HLA compiles the code above, it generates machine code like the following:

```

 cmp eax, 10
 jnb ?2_false ;Branch to ELSE section if false

 mov ebx, 1
 jmp ?2_endif ;Skip over ELSE section

; This is the else section:

?2_false:
 mov ebx, 0
?2_endif:

```

About the only way you can improve upon HLA's code generation sequence for an IF/ELSE statement is with knowledge of how the program will operate. In some rare cases you can generate slightly better performing code by moving the ELSE section somewhere else in the program and letting the THEN section fall straight through to the statement following the ENDIF (of course, the ELSE section must jump back to the first statement after the ENDIF if you do this). This scheme will be slightly faster if the boolean expression evaluates true most of the time. Generally, though, this technique is a bit extreme.

The ELSEIF clause, just as its name suggests, has many of the attributes of an ELSE and an IF clause in the IF statement. Like the ELSE clause, the IF statement will jump to an ELSEIF clause (or the previous ELSEIF clause will jump to the current ELSEIF clause) if the previous boolean expression evaluates false. Like the IF clause, the ELSEIF clause will evaluate a boolean expression and transfer control to the following ELSEIF, ELSE, or ENDIF clause if the expression evaluates false; the code falls through to the THEN section of the ELSEIF clause if the expression evaluates true. The following examples demonstrate how HLA generates code for various forms of the IF..ELSEIF.. statement:

Single ELSEIF clause:

```

if(eax < 10) then

 mov(1, ebx);

elseif(eax > 10) then

 mov(0, ebx);

endif;

```

; Translated code:

```

 cmp eax, 10
 jnb ?2_false
 mov ebx, 1
 jmp ?2_endif
?2_false:
 cmp eax, 10
 jna ?3_false
 mov ebx, 0
?3_false:
?2_endif:

```

Single ELSEIF clause with an ELSE clause:

## Appendix L

```
if(eax < 10) then
 mov(1, ebx);
elseif(eax > 10) then
 mov(0, ebx);
else
 mov(2, ebx);
endif;
```

; Converted code:

```
 cmp eax, 10
 jnb ?2_false
 mov ebx, 1
 jmp ?2_endif
?2_false:
 cmp eax, 10
 jna ?3_false
 mov ebx, 0
 jmp ?2_endif
?3_false:
 mov ebx, 2
?2_endif:
```

**IF statement with two ELSEIF clauses:**

```
if(eax < 10) then
 mov(1, ebx);
elseif(eax > 10) then
 mov(0, ebx);
elseif(eax = 5) then
 mov(2, ebx);
endif;
```

; Translated code:

```
 cmp eax, 10
 jnb ?2_false
 mov ebx, 1
 jmp ?2_endif
?2_false:
 cmp eax, 10
 jna ?3_false
 mov ebx, 0
 jmp ?2_endif
```

```
?3_false:
 mov ebx, 2
?2_endif:
```

IF statement with two ELSEIF clauses and an ELSE clause:

```
if(eax < 10) then
 mov(1, ebx);
elseif(eax > 10) then
 mov(0, ebx);
elseif(eax = 5) then
 mov(2, ebx);
else
 mov(3, ebx);
endif;
```

; Translated code:

```
 cmp eax, 10
 jnb ?2_false
 mov ebx, 1
 jmp ?2_endif
?2_false:
 cmp eax, 10
 jna ?3_false
 mov ebx, 0
 jmp ?2_endif
?3_false:
 cmp eax, 5
 jne ?4_false
 mov ebx, 2
 jmp ?2_endif
?4_false:
 mov ebx, 3
?2_endif:
```

This code generation algorithm generalizes to any number of ELSEIF clauses. If you need to see an example of an IF statement with more than two ELSEIF clauses, feel free to run a short example through the HLA compiler to see the result.

In addition to processing boolean expressions, the HLA IF statement supports a hybrid syntax that lets you combine the structured nature of the IF statement with the unstructured nature of typical assembly language control flow. The hybrid form gives you almost complete control over the code generation process without completely sacrificing the readability of an IF statement. The following is a typical example of this form of the IF statement:

```

if
{
 cmp(eax, 10);
 jna false;
}

 mov(0, eax);

endif;

```

; The above generates the following assembly code:

```

 cmp eax, 10
 jna ?2_false
?2_true:
 mov eax, 0
?2_false:

```

Of course, the hybrid IF statement fully supports ELSE and ELSEIF clauses (in fact, the IF and ELSEIF clauses can have a potpourri of hybrid or traditional boolean expression forms). The hybrid forms, since they let you specify the sequence of instructions to compile, put the issue of efficiency squarely in your lap. About the only contribution that HLA makes to the inefficiency of the program is the insertion of a JMP instruction to skip over ELSEIF and ELSE clauses.

Although the hybrid form of the IF statement lets you write very efficient code that is more readable than the traditional “compare and jump” sequence, you should keep in mind that the hybrid form is definitely more difficult to read and comprehend than the IF statement with boolean expressions. Therefore, if the HLA compiler generates reasonable code with a boolean expression then by all means use the boolean expression form; it will probably be easier to read.

## L.7 The While Statement

The only difference between an IF statement and a WHILE loop is a single JMP instruction. Of course, with an IF and a JMP you can simulate most control structures, the WHILE loop is probably the most typical example of this. The typical translation from WHILE to IF/JMP takes the following form:

```

while(expr) do

 << statements >>

endwhile;

// The above translates to:

label:
 if(expr) then

 << statements >>
 jmp label;

 endif;

```

Experienced assembly language programmers know that there is a slightly more efficient implementation if it is likely that the boolean expression is true the first time the program encounters the loop. That translation takes the following form:

```

 jmp testlabel;
label:

 << statements >>

testlabel:
 JT(expr) label; // Note: JT means jump if expression is true.

```

This form contains exactly the same number of instructions as the previous translation. The difference is that a JMP instruction was moved out of the loop so that it executes only once (rather than on each iteration of the loop). So this is slightly more efficient than the previous translation. HLA uses this conversion algorithm for WHILE loops with standard boolean expressions.

If you look at HLA's output code, you'll discover that it is really complex and messy. The reason has to do with HLA's code generation algorithm. In order to move code around in the program (required in order to move the test of the boolean expression below the statements that comprise the body of the loop) HLA writes a MASM macro at the top of the loop and then expands that macro at the bottom of the loop. The following short example demonstrates how HLA transforms WHILE statements:

```

while(eax > 0) do

 mov(0, eax);

endwhile;

; Translated code:

 jmp ?2_continue

?2_true:
?2_while:

?2_macro macro
?2_continue:

 cmp eax, 0
 ja ?2_while
 endm

 mov eax, 0
 ?2_macro

?2_exitloop:

```

As you'll find by carefully studying this code, HLA emits a macro definition at the point it encounters the WHILE statement. Then it emits an expansion of that macro at the bottom of the loop. This effectively moves the code associated with the computation of the boolean expression to the bottom of the loop.

Because of this code motion, there is very little overhead associated with a WHILE loop that you haven't already seen (i.e., the IF statement). Therefore, with one exception, the WHILE and IF statements share the same efficiency concerns. The single exception is the hybrid WHILE statement. For technical reasons, HLA cannot move the code associated with the termination check of a hybrid WHILE loop to the bottom of the loop. Therefore, whenever you use the hybrid form of the WHILE statement HLA compiles the code you supply at the top of the loop, it adds a JMP instruction to the bottom of the loop, and that JMP instruction executes on each iteration. If this is a problem for your code, you should probably consider a different implementation of the loop.

Example of the compilation of a hybrid WHILE loop:

```

while
{
 cmp(eax, 0);
 jne false;

}

 mov(0, eax);

endwhile;

; Translated code:

?2_while:
?2_continue:
 cmp eax, 0
 jne ?2_false
?2_true:
 mov eax, 0
 jmp ?2_while
?2_exitloop:
?2_false:

```

## Q

Quicksort 544  
Quicktime 105  
QWORD data type 381  
qwords 46

## R

radix 51  
RAISE statement 409, 713  
Range of a function 627  
RCL instruction 70  
RCR instruction 70  
Read control line 134  
Read/write input/output ports 315  
Read/write ports 317  
Reading from memory 136  
Reading integer values 35  
Read-only (input) ports 315  
READONLY declaration section 160  
Read-only ports 316  
READONLY variables as constants 382  
Realloc function 396  
Rearranging expressions to make them more efficient 750  
Record constants 467  
Record field alignment 472  
Record offsets 471  
Records 465  
Records as record fields 468  
Recursion 543  
Reference parameters 806, 808  
Register addressing modes 151  
Register indirect addressing mode 153  
Register indirect jump instruction 731  
Register preservation 523  
Register preservation in a TRY..ENDTRY statement 717  
Register Renaming 257  
Register type coercion 168  
Register usage in loops 771  
Registers 16  
Registers (electronic implementation) 221  
Registers (in the memory hierarchy) 293  
Registers as procedure parameters 794, 1305, 1306  
Registers as signed integer values 168  
Relational operators 22

Remainder (floating point) 606  
Removing unwanted data from the stack 176  
REPEAT 21  
Repeat Until loop 765  
REPEAT..UNTIL loops 764  
REPEAT..UNTIL statement 26  
Replacement policy (for caches) 300  
Representing audio information 100  
Required macro parameters 947  
Resume frame (for iterators) 1274  
RET instruction 521, 781  
RETURNS Option 540  
Reverse polish notation 612  
Reversing a bit string 899  
RGB color space 98  
Right associative operators 196, 580  
Right shift operation 67  
Rising edge of a clock 145  
ROL instruction 69  
ROR instruction 69  
Rotate left 68  
Rotate right 68  
Rounding a floating point value to an integer 606  
Rounding control 593  
Rounding control (FPU) 593  
Row major ordering 450, 451  
RPN 612  
Run of ones 881  
Run of zeros 881  
Run-time language 921  
Run-time Type Information 1062

## S

SAHF instruction 74, 607  
sahf instruction 74  
SAR instruction 68  
Saturation 63  
Saturation arithmetic 1087  
Saving the machine state 523  
SBB instruction 830  
Scanning for bits 895  
SCAS 907, 918  
Schematic Symbols 213  
Scope 1337  
Scope (of a name) 527  
Searching for a bit 895  
Searching for a bit pattern 903  
Searching for data within a string 907  
secant 617  
Self-modifying code 371  
Separate compilation 549  
Sequential logic 220  
Set/reset flip-flop (SR flip-flop) 220  
SETcc Instructions 573  
setOutputAttr routine (standard library) 188  
Setting selected bits 883
