Volume One: Data Representation

- Chapter One: Foreword
An introduction to this text and the purpose behind this text.
- Chapter Two: Hello, World of Assembly Language
A brief introduction to assembly language programming using the HLA language.
- Chapter Three: Data Representation
A discussion of numeric representation on the computer.
- Chapter Four: More Data Representation
Advanced numeric and non-numeric computer data representation.
- Chapter Five: Questions, Projects, and Laboratory Exercises
Test what you've learned in the previous chapters!

These five chapters are appropriate for all courses teaching machine organization and assembly language programming.

Volume One:

Data Representation

Nearly every text has a throw-away chapter as Chapter One. Here's my version. Seriously, though, some important copyright, instructional, and support information appears in this chapter. So you'll probably want to read this stuff. Instructors will definitely want to review this material.

- **Foreward to the HLA Version of "The Art of Assembly..."**

In 1987 I began work on a text I entitled "How to Program the IBM PC, Using 8088 Assembly Language." First, the 8088 faded into history, shortly thereafter the phrase "IBM PC" and even "IBM PC Compatible" became far less dominate in the industry, so I retitled the text "The Art of Assembly Language Programming." I used this text in my courses at Cal Poly Pomona and UC Riverside for many years, getting good reviews on the text (not to mention lots of suggestions and corrections). Sometime around 1994-1995, I converted the text to HTML and posted an electronic version on the Internet. The rest, as they say is history. A week doesn't go by that I don't get several emails praising me for releasing such a fine text on the Internet. Indeed, I only hear three really big complaints about the text: (1) It's a University textbook and some people don't like to read textbooks, (2) It's 16-bit DOS-based, and (3) there isn't a print version of the text. Well, I make no apologies for complaint #1. The whole reason I wrote the text was to support my courses at Cal Poly and UC Riverside. Complaint #2 is quite valid, that's why I wrote this version of the text. As for complaint #3, it was really never cost effective to create a print version; publishers simply cannot justify printing a text 1,500 pages long with a limited market. Furthermore, having a print version would prevent me from updating the text at will for my courses.

The astute reader will note that I haven't updated the electronic version of "The Art of Assembly Language Programming" (or "AoA") since about 1996. If the whole reason for keeping the book in electronic form has been to make updating the text easy, why haven't there been any updates? Well, the story is very similar to Knuth's "The Art of Computer Programming" series: I was sidetracked by other projects¹.

The static nature of AoA over the past several years was never really intended. During the 1995-1996 time frame, I decided it was time to make a major revision to AoA. The first version of AoA was MS-DOS based and by 1995 it was clear that MS-DOS was finally becoming obsolete; almost everyone except a few die-hards had switched over to Windows. So I knew that AoA needed an update for Windows, if nothing else.

I also took some time to evaluate my curriculum to see if I couldn't improve the pedagogical (teaching) material to make it possible for my students to learn even more about 80x86 assembly language in a relatively short 10-week quarter.

One thing I've learned after teaching an assembly language course for over a decade is that support software makes all the difference in the world to students writing their first assembly language programs. When I first began teaching assembly language, my students had to write all their own I/O routines (including numeric to string conversions for numeric I/O). While one could argue that there is some value to having students write this code for themselves, I quickly discovered that they spent a large percentage of their project time over the quarter writing I/O routines. Each moment they spent writing these relatively low-level routines was one less moment available to them for learning more advanced assembly language programming techniques. While, I repeat, there is some value to learning how to write this type of code, it's not all that related to assembly language programming (after all, the same type of problem has to be solved for *any* language that allows numeric I/O). I wanted to free the students from this drudgery so they could learn more about assembly language programming. The result of this observation was "The UCR Standard Library for 80x86 Assembly Language Programmers." This is a library containing several hundred I/O and utility functions that students could use in their assembly language programs. More than

1. Actually, another problem is the effort needed to maintain the HTML version since it was a manual conversion from Adobe Framemaker. But that's another story...

nearly anything else, the UCR Standard Library improved the progress students made in my courses.

It should come as no surprise, then, that one of my first projects when rewriting AoA was to create a new, more powerful, version of the UCR Standard Library. This effort (the UCR Stdlib v2.0) ultimately failed (although you can still download the code written for v2.0 from <http://webster.cs.ucr.edu>). The problem was that I was trying to get MASM to do a little bit more than it was capable of and so the project was ultimately doomed.

To condense a really long story, I decided that I needed a new assembler. One that was powerful enough to let me write the new Standard Library the way I felt it should be written. However, this new assembler should also make it much easier to learn assembly language; that is, it should relieve the students of some of the drudgery of assembly language programming just as the UCR Standard Library had. After three years of part-time effort, the end result was the “High Level Assembler,” or HLA.

HLA is a radical step forward in teaching assembly language. It combines the syntax of a high level language with the low-level programming capabilities of assembly language. Together with the HLA Standard Library, it makes learning and programming assembly language almost as easy as learning and programming a High Level Language like Pascal or C++. Although HLA isn’t the first attempt to create a hybrid high level/low level language, nor is it even the first attempt to create an assembly language with high level language syntax, it’s certainly the first complete system (with library and operating system support) that is suitable for teaching assembly language programming. Recent experiences in my own assembly language courses show that HLA is a major improvement over MASM and other traditional assemblers when teaching machine organization and assembly language programming.

The introduction of HLA is bound to raise lots of questions about its suitability to the task of teaching assembly language programming (as well it should). Today, the primary purpose of teaching assembly language programming at the University level isn’t to produce a legion of assembly language programmers; it’s to teach machine organization and introduce students to machine architecture. Few instructors realistically expect more than about 5% of their students to wind up working in assembly language as their primary programming language². Doesn’t turning assembly language into a high level language defeat the whole purpose of the course? Well, if HLA let you write C/C++ or Pascal programs and attempted to call these programs “assembly language” then the answer would be “Yes, this defeats the purpose of the course.” However, despite the name and the high level (and very high level) features present in HLA, HLA is still assembly language. An HLA programmer still uses 80x86 machine instructions to accomplish most of the work. And those high level language statements that HLA provides are purely optional; the “purist” can use nothing but 80x86 assembly language, ignoring the high level statements that HLA provides. Those who argue that HLA is not *true* assembly language should note that Microsoft’s MASM and Inprise’s TASM both provide many of the high level control structures found in HLA³.

Perhaps the largest deviation from traditional assemblers that HLA makes is in the declaration of variables and data in a program. HLA uses a very Pascal-like syntax for variable, constant, type, and procedure declarations. However, this does not diminish the fact that HLA is an assembly language. After all, at the machine language (vs. assembly language) level, there is no such thing as a data declaration. Therefore, any syntax for data declaration is an abstraction of data representation in memory. I personally chose to use a syntax that would prove more familiar to my students than the traditional data declarations used by assemblers.

Indeed, perhaps the principle driving force in HLA’s design has been to leverage the student’s existing knowledge when teaching them assembly language. Keep in mind, when a student first learns assembly language programming, there is so much more for them to learn than a handful of 80x86 machine instructions and the machine language programming paradigm. They’ve got to learn assembler directives, how to declare variables, how to write and call procedures, how to comment their code, what constitutes good programming style in an assembly language program, etc.

2. My experience suggests that only about 10-20% of my students will ever write *any* assembly language again once they graduate; less than 5% ever become regular assembly language users.

3. Indeed, in some respects the MASM and TASM HLL control structures are actually *higher* level than HLA’s. I *specifically* restricted the statements in HLA because I did not want students writing “C/C++ programs with MOV instructions.”

Unfortunately, with most assemblers, these concepts are completely different in assembly language than they are in a language like Pascal or C/C++. For example, the indentation techniques students master in order to write readable code in Pascal just don't apply to (traditional) assembly language programs. That's where HLA deviates from traditional assemblers. By using a high level syntax, HLA lets students leverage their high level language knowledge to write good readable programs. HLA will not let them avoid learning machine instructions, but it doesn't force them to learn a whole new set of programming style guidelines, new ways to comment your code, new ways to create identifiers, etc. HLA lets them use the knowledge they already possess in those areas that really have little to do with assembly language programming so they can concentrate on learning the important issues in assembly language.

So let there be no question about it: HLA is an assembly language. It is not a high level language masquerading as an assembler⁴. However, it is a system that makes learning and using assembly language easier than ever before possible.

Some long-time assembly language programmers, and even many instructors, would argue that making a subject easier to learn diminishes the educational content. Students don't get as much out of a course if they don't have to work very hard at it. Certainly, students who don't apply themselves as well aren't going to learn as much from a course. I would certainly agree that if HLA's only purpose was to make it easier to learn a fixed amount of material in a course, then HLA would have the negative side-effect of reducing what the students learn in their course. However, the real purpose of HLA is to make the educational process more efficient; not so the students spend less time learning a fixed amount of material (although HLA could certainly achieve this), but to allow the students to learn the same amount of material in less time *so they can use the additional time available to them to advance their study of assembly language*. Remember what I said earlier about the UCR Standard Library- its introduction into my course allowed me to teach even more advanced topics in my course. The same is true, even more so, for HLA. Keep in mind, I've got ten weeks in a quarter. If using HLA lets me teach the same material in seven weeks that took ten weeks with MASM, I'm not going to dismiss the course after seven weeks. Instead, I'll use this additional time to cover more advanced topics in assembly language programming. That's the real benefit to using pedagogical tools like HLA.

Of course, once I've addressed the concerns of assembly language instructors and long-time assembly language programmers, the need arises to address questions a student might have about HLA. Without question, the number one concern my students have had is "If I spend all this time learning HLA, will I be able to use this knowledge once I get out of school?" A more blunt way of putting this is "Am I wasting my time learning HLA?" Let me address these questions three ways.

First, as pointed out above, most people (instructors and experienced programmers) view learning assembly language as an educational process. Most students will probably never program full-time in assembly language, indeed, few programmers write more than a tiny fraction (less than 1%) of their code in assembly language. One of the main reasons most Universities require their students to take an assembly language course is so they will be familiar with the low-level operation of their machine and so they can appreciate what the compiler is doing for them (and help them to write better HLL code once they realize how the compiler processes HLL statements). HLA is an assembly language and learning HLA will certainly teach you the concepts of machine organization, the real purpose behind most assembly language courses.

The second point to ponder is that learning assembly language consists of two main activities; learning the assembler's syntax and learning the assembly language programming paradigm (that is, learning to *think* in assembly language). Of these two, the second activity is, by far, the more difficult. HLA, since it uses a high level language-like syntax, simplifies learning the assembly language syntax. HLA also simplifies the initial process of learning to program in assembly language by providing a crutch, the HLA high level statements, that allows students to use high level language semantics when writing their first programs. However, HLA does allow students to write "pure" assembly language programs, so a good instructor will ensure that they master the full assembly language programming paradigm before they complete the course. Once a student masters the semantics (i.e., the programming paradigm) of assembly language, learning a new syntax is

4. The C-- language is a good example of a low-level non-assembly language, if you need a comparison.

relatively easy. Therefore, a typical student should be able to pick up MASM in about a week after mastering HLA⁵.

As for the third and final point: to those that would argue that this is still extra effort that isn't worthwhile, I would simply point out that none of the existing assemblers have more than a cursory level of compatibility. Yes, TASM can assemble most MASM programs, but the reverse is not true. And it's certainly not the case that NASM, A86, GAS, MASM, and TASM let you write interchangeable code. If you master the syntax of one of these assemblers and someone expects you to write code in a different assembler, you're still faced with the prospect of having to learn the syntax of the new assembler. And that's going to take you about a week (assuming the presence of well-written documentation). In this respect, HLA is no different than any of the other assemblers.

Having addressed these concerns you might have, it's now time to move on and start teaching assembly language programming using HLA.

• Intended Audience

No single textbook can be all things to all people. This text is no exception. I've geared this text and the accompanying software to University level students who've never previously learned assembly language programming. This is not to say that others cannot benefit from this work; it simply means that as I've had to make choices about the presentation, I've made choices that should prove most comfortable for this audience I've chosen.

A secondary audience who could benefit from this presentation is any motivated person that really wants to learn assembly language. Although I assume a certain level of mathematical maturity from the reader (i.e., high school algebra), most of the "tough math" in this textbook is incidental to learning assembly language programming and you can easily skip over it without fear that you'll miss too much. High school students and those who haven't seen a school in 40 years have effectively used this text (and its DOS counterpart) to learn assembly language programming.

The organization of this text reflects the diverse audience for which it is intended. For example, in a standard textbook each chapter typically has its own set of questions, programming exercises, and laboratory exercises. Since the primary audience for this text is University students, such pedagogical material does appear within this text. However, recognizing that not everyone who reads this text wants to bother with this material (e.g., downloading it), this text moves such pedagogical material to the end of each volume in the text and places this material in a separate chapter. This is somewhat of an unusual organization, but I feel that University instructors can easily adapt to this organization and it saves burdening those who aren't interested in this material.

One audience to whom this book is specifically not directed are those persons who are already comfortable programming in 80x86 assembly language. Undoubtedly, there is a lot of material such programmers will find of use in this textbook. However, my experience suggests that those who've already learned x86 assembly language with an assembler like MASM, TASM, or NASM rebel at the thought of having to relearn basic assembly language syntax (as they would to have to learn HLA). If you fall into this category, I humbly apologize for not writing a text more to your liking. However, my goal has always been to teach those who don't already know assembly language, not extend the education of those who do. If you happen to fall into this category and you don't particularly like this text's presentation, there is some good news: there are dozens of texts on assembly language programming that use MASM and TASM out there. So you don't really need this one.

• Teaching From This Text

The first thing any instructor will notice when reviewing this text is that it's far too large for any reasonable course. That's because assembly language courses generally come in two flavors: a machine organization course (more hardware oriented) and an assembly language programming course (more software oriented). No text that is "just the right size" is suitable for both types of

5. This is very similar to mastering C after learning C++.

classes. Combining the information for both courses, plus advanced information students may need after they finish the course, produces a large text, like this one.

If you're an instructor with a limited schedule for teaching this subject, you'll have to carefully select the material you choose to present over the time span of your course. To help, I've included some brief notes at the beginning of each Volume in this text that suggests whether a chapter in that Volume is appropriate for a machine organization course, an assembly language programming course, or an advanced assembly programming course. These brief course notes can help you choose which chapters you want to cover in your course.

If you would like to offer hard copies of this text in the bookstore for your students, I will attempt to arrange with some "Custom Textbook Publishing" houses to make this material available on an "as-requested" basis. As I work out arrangements with such outfits, I'll post ordering information on Webster (<http://webster.cs.ucr.edu>). If your school has a printing and reprographics department, or you have a local business that handles custom publishing, you can certainly request copyright clearance to print the text locally.

If you're not taking a formal course, just keep in mind that you don't have to read this text straight through, chapter by chapter. If you want to learn assembly language programming and some of the machine organization chapters seem a little too hardware oriented for your tastes, feel free to skip those chapters and come back to them later on, when you understand the need to learn this information.

• Copyright Notice

The full contents of this text is copyrighted material. Here are the rights I hereby grant concerning this material. You have the right to

- Read this text on-line from the <http://webster.cs.ucr.edu> web site or any other approved web site.
- Download an electronic version of this text for your own personal use and view this text on your own personal computer.
- Make a single printed copy for your own personal use.

I usually grant instructors permission to use this text in conjunction with their courses at recognized academic institutions. There are two types of reproduction I allow in this instance: electronic and printed. I grant electronic reproduction rights for one school term; after which the institution must remove the electronic copy of the text and obtain new permission to repost the electronic form (I require a new copy for each term so that corrections, changes, and additions propagate across the net). If your institution has reproduction facilities, I will grant hard copy reproduction rights for one academic year (for the same reasons as above). You may obtain copyright clearance by emailing me at

rhyde@cs.ucr.edu

I will respond with clearance via email. My returned email plus this page should provide sufficient acknowledgement of copyright clearance. If, for some reason, your reproduction department needs to have me physically sign a copyright clearance, I will have to charge \$75.00 U.S. to cover my time and effort needed to deal with this. To obtain such clearance, please email me at the address above. Presumably, your printing and reproduction department can handle producing a master copy from PDF files. If not, I can print a master copy on a laser printer (800x400dpi), please email me for the current cost of this service.

All other rights to this text are expressly reserved by the author. In particular, it is a copyright violation to

- Post this text (or some portion thereof) on some web site without prior approval.
- Reproduce this text in printed or electronic form for non-personal (e.g., commercial) use.

The software accompanying this text is all public domain material unless an explicit copyright notice appears in the software. Feel free to use the accompanying software in any way you feel fit.

- **How to Get a Hard Copy of This Text**

This text is distributed in electronic form only. It is not available in hard copy form nor do I personally intend to have it published. If you want a hard copy of this text, the copyright allows you to print one for yourself. The PDF distribution format makes this possible (though the length of the text will make it somewhat expensive).

If you're wondering why I don't get this text published, there's a very simple reason: it's too long. Publishing houses generally don't want to get involved with texts for specialized subjects as it is; the cost of producing this text is prohibitive given its limited market. Rather than cut it down to the 500 or so 6" x 9" pages that most publishers would accept, my decision was to stick with the full text and release the text in electronic form on the Internet. The upside is that you can get a free copy of this text; the downside is that you can't readily get a hard copy.

Note that the copyright notice forbids you from copying this text for anything other than personal use (without permission, of course). If you run a "Print to Order/Custom Textbook" publishing house and would like to make copies for people, feel free to contact me and maybe we can work out a deal for those who just have to have a hard copy of this text.

The data might also be available via ftp from the following Internet address:

<ftp.cs.ucr.edu>

Log onto <ftp.cs.ucr.edu> using the anonymous account name and any password. Switch to the "/pub/pc/ibmpcdir" subdirectory (this is UNIX so make sure you use lowercase letters). You will find the appropriate files by searching through this directory.

The exact filename(s) of this material may change with time, and different services use different names for these files. Check on Webster for any important changes in addresses. If for some reason, Webster disappears in the future, you should use a web-based search engine like "AltaVista" and search for "Art of Assembly" to locate the current home site of this material.

- **Where to Get Help**

If you're reading this text and you've got questions about how to do something, please post a message to one of the following Internet newsgroups:

`comp.lang.asm.x86`
`alt.lang.asm`

Hundreds of knowledgeable individuals frequent these newsgroups and as long as you're not simply asking them to do your homework assignment for you, they'll probably be more than happy to help you with any problems that you have with assembly language programming.

I certainly welcome corrections and bug reports concerning this text at my email address. However, I regret that I do not have the time to answer general assembly language programming questions via email. I do provide support in public forums (e.g., the newsgroups above and on Webster at <http://webster.cs.ucr.edu>) so please use those avenues rather than emailing questions directly

to me. Due to the volume of email I receive daily, I regret that I cannot reply to all emails that I receive; so if you're looking for a response to a question, the newsgroup is your best bet (not to mention, others might benefit from the answer as well).

- **Other Materials You Will Need**

In addition to this text and the software I provide, you will need a machine running a 32-bit version of Windows (Windows 9x, NT, 2000, ME, etc.), a copy of Microsoft's MASM and a 32-bit linker, some sort of text editor, and other rudimentary general-purpose software tools you normally use. MASM and MS-Link are freely available on the internet. Alas, the procedure you must follow to download these files from Microsoft seems to change on a monthly basis. However, a quick post to comp.lang.asm.x86 should turn up the current site from which you may obtain this software. Almost all the software you need to use this text is part of Windows (e.g., a simple text editor like Notepad.exe) or is freely available on the net (MASM, LINK, and HLA). You shouldn't have to purchase anything.

Hello, World of Assembly Language

Chapter Two

2.0 Chapter Overview

This chapter is a “quick-start” chapter that lets you start writing basic assembly language programs right away. This chapter presents the basic syntax of an HLA (High Level Assembly) program, introduces you to the Intel CPU architecture, provides a handful of data declarations and machine instructions, describes some utility routines you can call in the HLA Standard Library, and then shows you how to write some simple assembly language programs. By the conclusion of this chapter, you should understand the basic syntax of an HLA program and be prepared to start learning new language features in subsequent chapters.

Note: this chapter assumes that you have successfully installed HLA on your system. Please see Appendix I for details concerning the installation of HLA (alternately, you can read the HLA documentation or check out the laboratory exercises associated with this volume).

2.1 The Anatomy of an HLA Program

An HLA program typically takes the following form:

PROGRAM, BEGIN, and END are HLA reserved words that delineate the program. Note the placement of the semicolons in this program.

Figure 2.1 Basic HLA Program Layout

The *pgmID* in the template above is a user-defined program identifier. You must pick an appropriate, descriptive, name for your program. In particular, *pgmID* would be a horrible choice for any real program. If you are writing programs as part of a course assignment, your instructor will probably give you the name to use for your main program. If you are writing your own HLA program, you will have to choose this name.

Identifiers in HLA are very similar to identifiers in most high level languages. HLA identifiers may begin with an underscore or an alphabetic character, and may be followed by zero or more alphanumeric or underscore characters. HLA’s identifiers are *case neutral*. This means that the identifiers are case sensitive insofar as you must always spell an identifier exactly the same way (even with respect to upper and lower case) in your program. However, unlike other case sensitive languages, like C/C++, you may not declare two identifiers in the program whose name differs only by the case of alphabetic characters appearing in an identifier. Case neutrality enforces the good programming style of always spelling your names exactly the same way (with respect to case) and never declaring two identifiers whose only difference is the case of certain alphabetic characters.

A traditional first program people write, popularized by K&R's "The C Programming Language" is the "Hello World" program. This program makes an excellent concrete example for someone who is learning a new language. Here's what the "Hello World" program looks like in HLA:

```
program helloWorld;
#include( "stdlib.hhf" );

begin helloWorld;

    stdout.put( "Hello, World of Assembly Language", nl );

end helloWorld;
```

Program 2.1 The Hello World Program

The `#include` statement in this program tells the HLA compiler to include a set of declarations from the `stdlib.hhf` (standard library, HLA Header File). Among other things, this file contains the declaration of the `stdout.put` code that this program uses.

The `stdout.put` statement is the typical "print" statement for the HLA language. You use it to write data to the standard output device (generally the console). To anyone familiar with I/O statements in a high level language, it should be obvious that this statement prints the phrase "Hello, World of Assembly Language". The `nl` appearing at the end of this statement is a constant, also defined in "stdlib.hhf", that corresponds to the newline sequence.

Note that semicolons follow the program, `BEGIN`, `stdout.put`, and `END` statements¹. Technically speaking, a semicolon is generally allowable after the `#INCLUDE` statement. It is possible to create include files that generate an error if a semicolon follows the `#INCLUDE` statement, so you may want to get in the habit of not putting a semicolon here (note, however, that the HLA standard library include files always allow a semicolon after the corresponding `#INCLUDE` statement).

The `#INCLUDE` is your first introduction to HLA declarations. The `#INCLUDE` itself isn't actually a declaration, but it does tell the HLA compiler to substitute the file "stdlib.hhf" in place of the `#INCLUDE` directive, thus inserting several declarations at this point in your program. Most HLA programs you will write will need to include at least some of the HLA Standard Library header files ("stdlib.hhf" actually includes all the standard library definitions into your program; for more efficient compiles, you might want to be more selective about which files you include. You will see how to do this in a later chapter).

Compiling this program produces a *console* application. Under Win32², running this program in a command window prints the specified string and then control returns back to the Windows command line interpreter.

2.2 Some Basic HLA Data Declarations

HLA provides a wide variety of constant, type, and data declaration statements. Later chapters will cover the declaration section in more detail but it's important to know how to declare a few simple variables in an HLA program.

1. Technically, from a language design point of view, these are not all statements. However, this chapter will not make that distinction.

2. This text will use the phrase Win32 to denote any version of 32-bit version of Windows including Windows NT, Windows 95, Windows 98, Windows 2000, and later versions of Windows that run on processors supporting the Intel 32-bit 80x86 instruction set.

HLA predefines three different signed integer types: *int8*, *int16*, and *int32*, corresponding to eight-bit (one byte) signed integers, 16-bit (two byte) signed integers, and 32-bit (four byte) signed integers respectively³. Typical variable declarations occur in the HLA *static variable section*. A typical set of variable declarations takes the following form

```
static
i8: int8;
i16: int16;
i32: int32;
```

"static" is the keyword that begins the variable declaration section.

i8, i16, and i32 are the names of the variables to declare here.

int8, int16, and int32 are the names of the data types for each declaration

Figure 2.2 Static Variable Declarations

Those who are familiar with the Pascal language should be comfortable with this declaration syntax. This example demonstrates how to declare three separate integers, *i8*, *i16*, and *i32*. Of course, in a real program you should use variable names that are a little more description. While names like "i8" and "i32" describe the type of the object, they do not describe its purpose. Variable names should describe the purpose of the object.

In the STATIC declaration section, you can also give a variable an initial value that the operating system will assign to the variable when it loads the program into memory. The following figure demonstrates the syntax for this:

```
static
i8: int8 := 8;
i16: int16 := 1600;
i32: int32 := -320000;
```

The operand after the constant assignment operator must be a constant whose type is compatible with the variable you are initializing

The constant assignment operator, ":= " tells HLA that you wish to initialize the specified variable with an initial value.

Figure 2.3 Static Variable Initialization

It is important to realize that the expression following the assignment operator (":=") must be a constant expression. You cannot assign the values of other variables within a STATIC variable declaration.

Those familiar with other high level languages (especially Pascal) should note that you may only declare one variable per statement. That is, HLA does not allow a comma delimited list of variable names followed by a colon and a type identifier. Each variable declaration consists of a single identifier, a colon, a type ID, and a semicolon.

Here is a simple HLA program that demonstrates the use of variables within an HLA program:

```
Program DemoVars;
#include( "stdlib.hhf" );

static
  InitDemo:      int32 := 5;
```

3. A discussion of bits and bytes will appear in the next chapter if you are unfamiliar with these terms.

```

    NotInitialized: int32;

begin DemoVars;

    // Display the value of the pre-initialized variable:

    stdout.put( "InitDemo's value is ", InitDemo, nl );

    // Input an integer value from the user and display that value:

    stdout.put( "Enter an integer value: " );
    stdin.get( NotInitialized );
    stdout.put( "You entered: ", NotInitialized, nl );

end DemoVars;

```

Program 2.2 Variable Declaration and Use

In addition to `STATIC` variable declarations, this example introduces three new concepts. First, the `stdout.put` statement allows multiple parameters. If you specify an integer value, `stdout.put` will convert that value to the string representation of that integer's value on output. The second new feature this sample program introduces is the `stdin.get` statement. This statement reads a value from the standard input device (usually the keyboard), converts the value to an integer, and stores the integer value into the `NotInitialized` variable. Finally, this program also introduces the syntax for (one form of) HLA comments. The HLA compiler ignores all text from the `/*` sequence to the end of the current line. Those familiar with C++ and Delphi should recognize these comments.

2.3 Boolean Values

HLA and the HLA Standard Library provides limited support for boolean objects. You can declare boolean variables, use boolean literal constants, use boolean variables in boolean expressions (e.g., in an `IF` statement), and you can print the values of boolean variables.

Boolean literal constants consist of the two predefined identifiers `true` and `false`. Internally, HLA represents the value `true` using the numeric value one; HLA represents `false` using the value zero. Most programs treat zero as `false` and anything else as `true`, so HLA's representations for `true` and `false` should prove sufficient.

To declare a boolean variable, you use the `boolean` data type. HLA uses a single byte (the least amount of memory it can allocate) to represent boolean values. The following example demonstrates some typical declarations:

```

static
    BoolVar:   boolean;
    HasClass: boolean := false;
    IsClear:  boolean := true;

```

As you can see in this example, you may declare initialized as well as uninitialized variables.

Since boolean variables are byte objects, you can manipulate them using eight-bit registers and any instructions that operate directly on eight-bit values. Furthermore, as long as you ensure that your boolean variables only contain zero and one (for `false` and `true`, respectively), you can use the 80x86 `AND`, `OR`, `XOR`, and `NOT` instructions to manipulate these boolean values (we'll describe these instructions a little later).

You can print boolean values by making a call to the `stdout.put` routine, e.g.,

```

    stdout.put( BoolVar )

```

This routine prints the text “true” or “false” depending upon the value of the boolean parameter (zero is false, anything else is true). Note that the HLA Standard Library does not allow you to read boolean values via *stdin.get*.

2.4 Character Values

HLA lets you declare one-byte ASCII character objects using the *char* data type. You may initialize character variables with a literal character value by surrounding the character with a pair of apostrophes. The following example demonstrates how to declare and initialize character variables in HLA:

```
static
  c: char;
  LetterA: char := 'A';
```

You can print character variables use the *stdout.put* routine.

2.5 An Introduction to the Intel 80x86 CPU Family

Thus far, you’ve seen a couple of HLA programs that will actually compile and run. However, all the statements utilized to this point have been either data declarations or calls to HLA Standard Library routines. There hasn’t been any *real* assembly language up to this point. Before we can progress any farther and learn some real assembly language, a detour is necessary. For unless you understand the basic structure of the Intel 80x86 CPU family, the machine instructions will seem mysterious indeed.

The Intel CPU family is generally classified as a *Von Neumann Architecture Machine*. Von Neumann computer systems contain three main building blocks: the *central processing unit* (CPU), *memory*, and *input/output devices* (I/O). These three components are connected together using the *system bus*. The following block diagram shows this relationship:

Figure 2.4 Von Neumann Computer System Block Diagram

Memory and I/O devices will be the subjects of later chapters; for now, let’s take a look inside the CPU portion of the computer system, at least at the components that are visible to the assembly language programmer.

The most prominent items within the CPU are the registers. The Intel CPU registers can be broken down into four categories: general purpose registers, special purpose application accessible registers, segment registers, and special purpose kernel mode registers. This text will not consider the last two sets of registers. The segment registers are not used much in modern 32-bit operating systems (e.g., Windows, BeOS, and Linux); since this text is geared around programs written for Windows, there is little need to discuss the segment registers. The special purpose kernel mode registers are intended for use by people who write operating systems, debuggers, and other system level tools. Such software construction is well beyond the scope of this text, so once again there is little need to discuss the special purpose kernel mode registers.

The 80x86 (Intel family) CPUs provide several general purpose registers for application use. These include eight 32-bit registers that have the following names:

EAX, EBX, ECX, EDX, ESI, EDI, EBP, and ESP

The “E” prefix on each name stands for *extended*. This prefix differentiates the 32-bit registers from the eight 16-bit registers that have the following names:

AX, BX, CX, DX, SI, DI, BP, and SP

Finally, the 80x86 CPUs provide eight 8-bit registers that have the following names:

AL, AH, BL, BH, CL, CH, DL, and DH

Unfortunately, these are not all separate registers. That is, the 80x86 does not provide 24 independent registers. Instead, the 80x86 overlays the 32-bit registers with the 16-bit registers and it overlays the 16-bit registers with the 8-bit registers. The following diagram shows this relationship:

Figure 2.5 80x86 (Intel CPU) General Purpose Registers

The most important thing to note about the general purpose registers is that they are not independent. Modifying one register will modify at least one other register and may modify as many as three other registers. For example, modification of the EAX register may very well modify the AL, AH, and AX registers as well. This fact cannot be overemphasized here. A very common mistake in programs written by beginning

assembly language programmers is register value corruption because the programmer did not fully understand the ramifications of the above diagram.

The EFLAGS register is a 32-bit register that encapsulates several single-bit boolean (true/false) values. Most of the bits in the EFLAGS register are either reserved for kernel mode (operating system) functions, or are of little interest to the application programmer. Eight of these bits (or *flags*) are of interest to application programmers writing assembly language programs. These are the overflow, direction, interrupt disable⁴, sign, zero, auxiliary carry, parity, and carry flags. The following diagram shows their layout within the lower 16-bits of the EFLAGS register.

Figure 2.6 Layout of the FLAGS Register (Lower 16 bits of EFLAGS)

Of the eight flags that are usable by application programmers, four flags in particular are extremely valuable: the overflow, carry, sign, and zero flags. Collectively, we will call these four flags the *condition codes*⁵. The state of these flags (boolean variables) will let you test the results of previous computations and allow you to make decisions in your programs. For example, after comparing two values, the state of the condition code flags will tell you if one value is less than, equal to, or greater than a second value. The 80x86 CPUs provide special machine instructions that let you test the flags, alone or in various combinations.

The last register of interest is the EIP (instruction pointer) register. This 32-bit register contains the *memory address* of the next machine instruction to execute. Although you will manipulate this register directly in your programs, the instructions that modify its value treat this register as an implicit operand. Therefore, you will not need to remember much about this register since the 80x86 instruction set effectively hides it from you.

One important fact that comes as a surprise to those just learning assembly language is that almost all calculations on the 80x86 CPU must involve a register. For example, to add two (memory) variables together, storing the sum into a third location, you must load one of the memory operands into a register, add the second operand to the value in the register, and then store the register away in the destination memory location. Registers are a *middleman* in nearly every calculation. Therefore, registers are very important in 80x86 assembly language programs.

Another thing you should be aware of is that although the general purpose registers have the name “general purpose” you should not infer that you can use any register for any purpose. The SP/ESP register for example, has a very special purpose (it’s the *stack pointer*) that effectively prevents you from using it for any other purpose. Likewise, the BP/EBP register has a special purpose that limits its usefulness as a general

4. Applications programs cannot modify the interrupt flag, but we’ll look at this flag in the next volume of this series, hence the discussion of this flag here.

5. Technically the parity flag is also a condition code, but we will not use that flag in this text.

purpose register. All the 80x86 registers have their own special purposes that limit their use in certain contexts. For the time being, you should simply avoid the use of the ESP and EBP registers for generic calculations and keep in mind that the remaining registers are not completely interchangeable in your programs.

2.6 Some Basic Machine Instructions

The 80x86 CPUs provide just over a hundred to many thousands of different machine instructions, depending on how you define a machine instruction. Even at the low end of the count (greater than 100), it appears as though there are far too many machine instructions to learn in a short period of time. Fortunately, you don't need to know all the machine instructions. In fact, most assembly language programs probably use around 30 different machine instructions⁶. Indeed, you can certainly write several meaningful programs with only a small handful of machine instructions. The purpose of this section is to provide a small handful of machine instructions so you can start writing simple HLA assembly language programs right away.

Without question, the MOV instruction is the most often-used assembly language statement. In a typical program, anywhere from 25-40% of the instructions are typically MOV instructions. As its name suggests, this instruction moves data from one location to another⁷. The HLA syntax for this instruction is

```
mov( source_operand, destination_operand );
```

The *source_operand* can be a register, a memory variable, or a constant. The *destination_operand* may be a register or a memory variable. Technically the 80x86 instruction set does not allow both operands to be memory variables; HLA, however, will automatically translate a MOV instruction with two 16- or 32-bit memory operands into a pair of instructions that will copy the data from one location to another. In a high level language like Pascal or C/C++, the MOV instruction is roughly equivalent to the following assignment statement:

```
destination_operand = source_operand ;
```

Perhaps the major restriction on the MOV instruction's operands is that they must both be the same size. That is, you can move data between two eight-bit objects, between two 16-bit objects, or between two 32-bit objects; you may not, however, mix the sizes of the operands. The following table lists all the legal combinations:

Table 1: Legal 80x86 MOV Instruction Operands

| Source | Destination |
|-------------------------------|-------------------|
| Reg ₈ ^a | Reg ₈ |
| Reg ₈ | Mem ₈ |
| Mem ₈ | Reg ₈ |
| constant ^b | Reg ₈ |
| constant | Mem ₈ |
| | |
| Reg ₁₆ | Reg ₁₆ |
| Reg ₁₆ | Mem ₁₆ |

6. Different programs may use a different set of 30 instructions, but few programs use more than 30 distinct instructions.

7. Technically, MOV actually copies data from one location to another. It does not destroy the original data in the source operand. Perhaps a better name for this instruction should have been COPY. Alas, it's too late to change it now.

Table 1: Legal 80x86 MOV Instruction Operands

| | |
|-------------------|-------------------|
| Mem ₁₆ | Reg ₁₆ |
| constant | Reg ₁₆ |
| constant | Mem ₁₆ |
| | |
| Reg ₃₂ | Reg ₃₂ |
| Reg ₃₂ | Mem ₃₂ |
| Mem ₃₂ | Reg ₃₂ |
| constant | Reg ₃₂ |
| constant | Mem ₃₂ |

- a. The suffix denotes the size of the register or memory location.
- b. The constant must be small enough to fit in the specified destination operand

You should study this table carefully. Most of the general purpose 80x86 instructions use this same syntax. Note that in addition to the forms above, the HLA MOV instruction lets you specify two memory operands as the source and destination. However, this special translation that HLA provides only applies to the MOV instruction; it does not generalize to the other instructions.

The 80x86 ADD and SUB instructions let you add and subtract two operands. Their syntax is nearly identical to the MOV instruction:

```
add( source_operand, destination_operand );
sub( source_operand, destination_operand );
```

The ADD and SUB operands must take the same form as the MOV instruction, listed in the table above⁸. The ADD instruction does the following:

```
destination_operand = destination_operand + source_operand ;
destination_operand += source_operand; // For those who prefer C syntax
```

Similarly, the SUB instruction does the calculation:

```
destination_operand = destination_operand - source_operand ;
destination_operand -= source_operand ; // For C fans.
```

With nothing more than these three instructions, plus the HLA control structures that the next section discusses, you can actually write some sophisticated programs. Here's a sample HLA program that demonstrates these three instructions:

```
program DemoMOVaddSUB;

#include( "stdlib.hhf" );

static
    i8:    int8:= -8;
    i16:int16:= -16;
```

8. Remember, though, that ADD and SUB do not support memory-to-memory operations.

```

i32:int32:= -32;

begin DemoMOVaddSUB;

    // First, print the initial values
    // of our variables.

    stdout.put
    (
        nl,
        "Initialized values: i8=", i8,
        ", i16=", i16,
        ", i32=", i32,
        nl
    );

    // Compute the absolute value of the
    // three different variables and
    // print the result.
    // Note, since all the numbers are
    // negative, we have to negate them.
    // Using only the MOV, ADD, and SUB
    // instruction, we can negate a value
    // by subtracting it from zero.

    mov( 0, al );// Compute i8 := -i8;
    sub( i8, al );
    mov( al, i8 );

    mov( 0, ax );// Compute i16 := -i16;
    sub( i16, ax );
    mov( ax, i16 );

    mov( 0, eax );// Compute i32 := -i32;
    sub( i32, eax );
    mov( eax, i32 );

    // Display the absolute values:

        ", i16=", i16,
        ", i32=", i32,
        nl
    );

    // Demonstrate ADD and constant-to-memory

Program 2.3 Demonstration of MOV, ADD, and SUB Instructions

2.7 Some Basic HLA Control Structures

The MOV, ADD, and SUB instructions, while valuable, aren't sufficient to let you write meaningful programs. You will need to complement these instructions with the ability to make decisions and create loops in your HLA programs before you can write anything other than a trivial program. HLA provides several high level control structures that are very similar to control structures found in high level languages. These include IF..THEN..ELSEIF..ELSE..ENDIF, WHILE..ENDWHILE, REPEAT..UNTIL, and so on. By learning these statements you will be armed and ready to write some real programs.

Before discussing these high level control structures, it's important to point out that these are not real 80x86 assembly language statements. HLA compiles these statements into a sequence of one or more real assembly language statements for you. Later in this text, you'll learn how HLA compiles the statements and you'll learn how to write pure assembly language code that doesn't use them. However, you'll need to learn many new concepts before you get to that point, so we'll stick with these high level language statements for now since you're probably already familiar with statements like these from your exposure to high level languages.

Another important fact to mention is that HLA's high level control structures are *not* as high level as they first appear. The purpose behind HLA's high level control structures is to let you start writing assembly language programs as quickly as possible, not to let you avoid the use of real assembly language altogether. You will soon discover that these statements have some severe restrictions associated with them and you will quickly outgrow their capabilities (at least the restricted forms appearing in this section). This is intentional. Once you reach a certain level of comfort with HLA's high level control structures and decide you need more power than they have to offer, it's time to move on and learn the real 80x86 instructions behind these statements.

2.7.1 Boolean Expressions in HLA Statements

Several HLA statements require a boolean (true or false) expression to control their execution. Examples include the IF, WHILE, and REPEAT..UNTIL statements. The syntax for these boolean expressions represents the greatest limitation to the HLA high level control structures. This is one area where your familiarity with a high level language will work against you – you'll want to use the same boolean expressions you use in a high level language and HLA only supports some basic forms.

HLA boolean expressions always take the following forms⁹:

```

flag_specification
!flag_specification
register
!register
Boolean_variable
!Boolean_variable
mem_reg relop mem_reg_const
register in LowConst..HiConst
register not in LowConst..HiConst

```

A flag specification is one of the following symbols:

- @c carry: True if the carry is set (1), false if the carry is clear (0).
- @nc no carry: True if the carry is clear (0), false if the carry is set (1).
- @z zero: True if the zero flag is set, false if it is clear.

9. Technically, there are a few more, advanced, forms, but you'll have to wait a few chapters before seeing these additional formats.

- @nz not zero: True if the zero flag is clear, false if it is set.
- @o overflow: True if the overflow flag is set, false if it is clear.
- @no no overflow: True if the overflow flag is clear, false if it is set.
- @s sign: True if the sign flag is set, false if it is clear.
- @ns no sign: True if the sign flag is clear, false if it is set.

The use of the flag values in a boolean expression is somewhat advanced. You will begin to see how to use these boolean expression operands in the next chapter.

A register operand can be any of the 8-bit, 16-bit, or 32-bit general purpose registers. The expression evaluates false if the register contains a zero; it evaluates true if the register contains a non-zero value.

If you specify a boolean variable as the expression, the program tests it for zero (false) or non-zero (true). Since HLA uses the values zero and one to represent false and true, respectively, the test works in an intuitive fashion. Note that HLA requires that stand-alone variables be of type *boolean*. HLA rejects other data types. If you want to test some other type against zero/not zero, then use the general boolean expression discussed next.

The most general form of an HLA boolean expression has two operands and a relational operator. The following table lists the legal combinations:

Table 2: Legal Boolean Expressions

| Left Operand | Relational Operator | Right Operand |
|---|---------------------|---|
| Memory Variable or Register | = or == | Memory Variable, Register, or Constant |
| | <> or != | |
| | < | |
| | <= | |
| | > | |
| | >= | |

Note that both operands cannot be memory operands. In fact, if you think of the Right Operand as the source operand and the Left Operand as the destination operand, then the two operands must be the same as those allowed for the ADD and SUB instructions.

Also like the ADD and SUB instructions, the two operands must be the same size. That is, they must both be eight-bit operands, they must both be 16-bit operands, or they must both be 32-bit operands. If the Right Operand is a constant, its value must be in the range that is compatible with the Left Operand.

There is one other issue of which you need to be aware. If the Left Operand is a register and the Right Operand is a positive constant or another register, HLA uses an *unsigned* comparison. The next chapter will discuss the ramifications of this; for the time being, do not compare negative values in a register against a constant or another register. You may not get an intuitive result.

The IN and NOT IN operators let you test a register to see if it is within a specified range. For example, the expression “EAX in 2000..2099” evaluates true if the value in the EAX register is between 2000 and 2099 (inclusive). The NOT IN (two words) operator lets you check to see if the value in a register is outside the specified range. For example, “AL not in ‘a’..‘z’” evaluates true if the character in the AL register is not a lower case alphabetic character.

Here are some examples of legal boolean expressions in HLA:

```

@c
Bool_var
al
ESI
EAX < EBX
EBX > 5
i32 < -2
i8 > 128
al < i8
eax in 1..100
ch not in 'a'..'z'

```

2.7.2 The HLA IF..THEN..ELSEIF..ELSE..ENDIF Statement

The HLA IF statement uses the following syntax:

Figure 2.7 HLA IF Statement Syntax

The expressions appearing in this statement must take one of the forms from the previous section. If the associated expression is true, the code after the THEN executes, otherwise control transfers to the next ELSEIF or ELSE clause in the statement.

Since the ELSEIF and ELSE clauses are optional, an IF statement could take the form of a single IF..THEN clause, followed by a sequence of statements, and a closing ENDIF clause. The following is an example of just such a statement:

```
if( eax = 0 ) then

    stdout.put( "error: NULL value", nl );

endif;
```

If, during program execution, the expression evaluates true, then the code between the THEN and the ENDIF executes. If the expression evaluates false, then the program skips over the code between the THEN and the ENDIF.

Another common form of the IF statement has a single ELSE clause. The following is an example of an IF statement with an optional ELSE:

```
if( eax = 0 ) then

    stdout.put( "error: NULL pointer encountered", nl );

else

    stdout.put( "Pointer is valid", nl );

endif;
```

If the expression evaluates true, the code between the THEN and the ELSE executes; otherwise the code between the ELSE and the ENDIF clauses executes.

You can create sophisticated decision-making logic by incorporating the ELSEIF clause into an IF statement. For example, if the CH register contains a character value, you can select from a menu of items using code like the following:

```
if( ch = 'a' ) then

    stdout.put( "You selected the 'a' menu item", nl );

elseif( ch = 'b' ) then

    stdout.put( "You selected the 'b' menu item", nl );

elseif( ch = 'c' ) then

    stdout.put( "You selected the 'c' menu item", nl );

else

    stdout.put( "Error: illegal menu item selection", nl );

endif;
```

Although this simple example doesn't demonstrate it, HLA does not require an ELSE clause at the end of a sequence of ELSEIF clauses. However, when making multi-way decisions, it's always a good idea to provide an ELSE clause just in case an error arises. Even if you think it's impossible for the ELSE clause to execute, just keep in mind that future modifications to the code could possibly void this assertion, so it's a good idea to have error reporting statements built into your code.

2.7.3 The WHILE..ENDWHILE Statement

The WHILE statement uses the following basic syntax:

Figure 2.8 HLA While Statement Syntax

This statement evaluates the boolean expression. If it is false, control immediately transfers to the first statement following the ENDWHILE clause. If the value of the expression is true, then control falls through to the body of the loop. After the loop body executes, control transfers back to the top of the loop where the WHILE statement retests the loop control expression. This process repeats until the expression evaluates false.

Note that the WHILE loop, like its high level language siblings, tests for loop termination at the top of the loop. Therefore, it is quite possible that the statements in the body of the loop will not execute (if the expression is false when the code first executes the WHILE statement). Also note that the body of the WHILE loop must, at some point, modify the value of the boolean expression or an infinite loop will result.

```
mov( 0, i );
while( i < 10 ) do

    stdout.put( "i=", i, nl );
    add( 1, i );

endwhile;
```

2.7.4 The FOR..ENDFOR Statement

The HLA FOR loop takes the following general form:

```
for( Initial_Stmt; Termination_Expression; Post_Body_Statement ) do

    << Loop Body >>

endfor;
```

This is equivalent to the following WHILE statement:

```
Initial_Stmt;
while( Termination_expression ) do

    << loop_body >>

    Post_Body_Statement;

endwhile;
```

Initial_Stmt can be any single HLA/80x86 instruction. Generally this statement initializes a register or memory location (the loop counter) with zero or some other initial value. *Termination_expression* is an

HLA boolean expression (same format that WHILE allows). This expression determines whether the loop body will execute. The *Post_Body_Statement* executes at the bottom of the loop (as shown in the WHILE example above). This is a single HLA statement. Usually it is an instruction like ADD that modifies the value of the loop control variable.

The following gives a complete example:

```
for( mov( 0, i ); i < 10; add(1, i ) ) do

    stdout.put( "i=", i, nl );

endfor;

// The above, rewritten as a while loop, becomes:

mov( 0, i );
while( i < 10 ) do

    stdout.put( "i=", i, nl );

    add( 1, i );

endwhile;
```

2.7.5 The REPEAT..UNTIL Statement

The HLA repeat..until statement uses the following syntax:

Figure 2.9 HLA Repeat..Until Statement Syntax

The HLA REPEAT..UNTIL statement tests for loop termination at the bottom of the loop. Therefore, the statements in the loop body always execute at least once. Upon encountering the UNTIL clause, the program will evaluate the expression and repeat the loop if the expression is false (that is, it repeats while false). If the expression evaluates true, the control transfers to the first statement following the UNTIL clause.

The following simple example demonstrates one use for the REPEAT..UNTIL statement:

```
mov( 10, ecx );
repeat

    stdout.put( "ecx = ", ecx, nl );
    sub( 1, ecx );

until( ecx = 0 );
```

If the loop body will always execute at least once, then it is more efficient to use a REPEAT..UNTIL loop rather than a WHILE loop.

2.7.6 The BREAK and BREAKIF Statements

The BREAK and BREAKIF statements provide the ability to prematurely exit from a loop. They use the following syntax:

```
break;
```

```
breakif( expression );
```

The expression in the BREAKIF statement has the same restrictions as the IF statement.

Figure 2.10 HLA Break and Breakif Syntax

The BREAK statement exits the loop that immediately contains the break; The BREAKIF statement evaluates the boolean expression and terminates the containing loop if the expression evaluates true.

2.7.7 The FOREVER..ENDFOR Statement

The FOREVER statement uses the following syntax:

```
forever
```

```
sequence  
of one or  
more statements
```

Loop Body

```
endfor;
```

Figure 2.11 HLA Forever Loop Syntax

This statement creates an infinite loop. You may also use the BREAK and BREAKIF statements along with FOREVER..ENDFOR to create a loop that tests for loop termination in the middle of the loop. Indeed, this is probably the most common use of this loop as the following example demonstrates:

```
forever
```

```
    stdout.put( "Enter an integer less than 10: " );  
    stdin.get( i );  
    breakif( i < 10 );  
    stdout.put( "The value needs to be less than 10!", nl );
```

```
endfor;
```

2.7.8 The TRY..EXCEPTION..ENDTRY Statement

The HLA TRY..EXCEPTION..ENDTRY statement provides very powerful *exception handling* capabilities. The syntax for this statement is the following:

Figure 2.12 HLA Try..Except..Endtry Statement Syntax

The TRY..ENDTRY statement protects a block of statements during execution. If these statements, between the TRY clause and the first EXCEPTION clause, execute without incident, control transfers to the first statement after the ENDTRY immediately after executing the last statement in the protected block. If an error (exception) occurs, then the program interrupts control at the point of the exception (that is, the program *raises* an exception). Each exception has an unsigned integer constant associated with it, known as the exception ID. The “excepts.hhf” header file in the HLA Standard Library predefines several exception IDs, although you may create new ones for your own purposes. When an exception occurs, the system compares the exception ID against the values appearing in each of the one or more EXCEPTION clauses following the protected code. If the current exception ID matches one of the EXCEPTION values, control continues with the block of statements immediately following that EXCEPTION. After the exception handling code completes execution, control transfers to the first statement following the ENDTRY.

If an exception occurs and there is no active TRY..ENDTRY statement, or the active TRY..ENDTRY statements do not handle the specific exception, the program will abort with an error message.

The following sample program demonstrates how to use the TRY..ENDTRY statement to protect the program from bad user input:

```

repeat
    mov( false, GoodInteger );    // Note: GoodInteger must be a boolean var.
    try
        stdout.put( "Enter an integer: " );
        stdin.get( i );
        mov( true, GoodInteger );

    exception( ex.ConversionError );

        stdout.put( "Illegal numeric value, please re-enter", nl );

    exception( ex.ValueOutOfRange );

        stdout.put( "Value is out of range, please re-enter", nl );

    endtry;
until( GoodInteger );

```

The REPEAT..UNTIL loop repeats this code as long as there is an error during input. Should an exception occur, control transfers to the EXCEPTION clauses to see if a conversion error (e.g., illegal characters in the number) or a numeric overflow occurs. If either of these exceptions occur, then they print the appropriate message and control falls out of the TRY..ENDTRY statement and the REPEAT..UNTIL loop repeats since *GoodInteger* was never set to true. If a different exception occurs (one that is not handled in this code), then the program aborts with the specified error message.

Please see the “excepts.hhf” header file that accompanies the HLA release for a complete list of all the exception ID codes. The HLA documentation will describe the purpose of each of these exception codes.

2.8 Introduction to the HLA Standard Library

There are two reasons HLA is much easier to learn and use than standard assembly language. The first reason is HLA’s high level syntax for declarations and control structures. This HLA feature leverages your high level language knowledge, reducing the need to learn arcane syntax, thus allowing you to learn assembly language more efficiently. The other half of the equation is the HLA Standard Library. The HLA Standard Library provides lot of commonly needed, easy to use, assembly language routines that you can call without having to write this code yourself (or even learn how to write yourself). This eliminates one of the larger stumbling blocks many people have when learning assembly language: the need for sophisticated I/O and support code in order to write basic statements. Prior to the advent of a standardized assembly language library, it often took weeks of study before a new assembly language programmer could do as much as print a string to the display. With the HLA Standard Library, this roadblock is removed and you can concentrate on learning assembly language concepts rather than learning low-level I/O details that are specific to a given operating system.

A wide variety of library routines is only part of HLA’s support. After all, assembly language libraries have been around for quite some time¹⁰. HLA’s Standard Library continues the HLA tradition by providing a high level language interface to these routines. Indeed, the HLA language itself was originally designed specifically to allow the creation of a high-level accessible set of library routines¹¹. This high level interface, combined with the high level nature of many of the routines in the library, packs a surprising amount of power in an easy to use package.

The HLA Standard Library consists of several modules organized by category. The following table lists many of the modules that are available¹²:

10. E.g., the UCR Standard Library for 80x86 Assembly Language Programmers.

11. HLA was created because MASM was insufficient to support the creation of the UCR StdLib v2.0.

Table 3: HLA Standard Library Modules

| Name | Description |
|-----------|--|
| args | Command line parameter parsing support routines. |
| conv | Various conversions between strings and other values. |
| cset | Character set functions. |
| DateTime | Calendar, date, and time functions. |
| excepts | Exception handling routines. |
| fileio | File input and output routines |
| hla | Special HLA constants and other values. |
| math | Transcendental and other mathematical functions. |
| memory | Memory allocation, deallocation, and support code. |
| misctypes | Miscellaneous data types. |
| patterns | The HLA pattern matching library. |
| rand | Pseudo-random number generators and support code. |
| stdin | User input routines |
| stdout | Provides user output and several other support routines. |
| stdlib | A special include file that links in all HLA standard library modules. |
| strings | HLA's powerful string library. |
| tables | Table (associative array) support routines. |
| win32 | Constants used in Windows calls (HLA Win32 version, only) |
| x86 | Constants and other items specific to the 80x86 CPU. |

Later sections of this text will explain many of these modules in greater detail. This section will concentrate on the most important routines (at least to beginning HLA programmers), the *stdio* library.

2.8.1 Predefined Constants in the STDIO Module

Perhaps the first place to start is with a description of some common constants that the *STDIO* module defines for you. One constant you've seen already in code examples appearing in this chapter. Consider the following (typical) example:

```
stdout.put( "Hello World", nl );
```

12. Since the HLA Standard Library is expanding, this list is probably out of date. Please see the HLA documentation for a current list of Standard Library modules.

The *nl* appearing at the end of this statement stands for *newline*. The *nl* identifier is not a special HLA reserved word, nor is it specific to the *stdout.put* statement. Instead, it's simply a predefined constant that corresponds to the string containing two characters, a carriage return followed by a line feed (the standard Windows end of line sequence).

In addition to the *nl* constant, the HLA standard I/O library module defines several other useful character constants. They are

- `stdio.bell` The ASCII bell character. Beeps the speaker when printed.
- `stdio.bs` The ASCII backspace character.
- `stdio.tab` The ASCII tab character.
- `stdio.eoln` A linefeed character.
- `stdio.lf` The ASCII linefeed character.
- `stdio.cr` The ASCII carriage return character.

Except for *nl*, these characters appear in the *stdio* namespace (and, therefore, require the “stdio.” prefix). The placement of these ASCII constants within the *stdio* namespace is to help avoid naming conflicts with your own variables. The *nl* name does not appear within a namespace because you will use it very often and typing *stdio.nl* would get tiresome very quickly.

2.8.2 Standard In and Standard Out

Many of the HLA I/O routines have a *stdin* or *stdout* prefix. Technically, this means that the standard library defines these names in a *namespace*¹³. In practice, this prefix suggests where the input is coming from (the Windows' *standard input* device) or going to (the Windows' *standard output* device). By default, the standard input device is the system keyboard. Likewise, the default standard output device is the command window display. So, in general, statements that have *stdin* or *stdout* prefixes will read and write data on the console device.

When you run a program from the command line window, you have the option of *redirecting* the standard input and/or standard output devices. A command line parameter of the form “>outfile” redirects the standard output device to the specified file (outfile). A command line parameter of the form “<infile” redirects the standard input so that its data comes from the specified input file (infile). The following examples demonstrate how to use these parameters when running a program named “testpgm” in the command window:

```
testpgm <input.data
testpgm >output.txt
testpgm <in.txt >output.txt
```

2.8.3 The `stdout.newln` Routine

The *stdout.newln* procedure prints a newline sequence to the standard output device. This is functionally equivalent to saying “`stdout.put(nl);`” Of course, the call to *stdout.newln* is sometimes a little more convenient. Example of call:

```
stdout.newln( );
```

2.8.4 The `stdout.putiX` Routines

The *stdout.puti8*, *stdout.puti16*, and *stdout.puti32* library routines print a single parameter (one byte, two bytes, or four bytes, respectively) as a signed integer value. The parameter may be a constant, a register,

13. Namespaces will be the subject of a later chapter.

or a memory variable, as long as the size of the actual parameter is the same as the size of the formal parameter.

These routines print the value of their specified parameter to the standard output device. These routines will print the value using the minimum number of print positions possible. If the number is negative, these routines will print a leading minus sign. Here are some examples of calls to these routines:

```
stdout.puti8( 123 );
stdout.puti16( DX );
stdout.puti32( i32Var );
```

2.8.5 The `stdout.putiXSize` Routines

The `stdout.puti8Size`, `stdout.puti16Size`, and `stdout.puti32Size` routines output signed integer values to the standard output, just like the `stdout.putiX` routines. These routines, however, provide more control over the output; they let you specify the (minimum) number of print positions the value will require on output. These routines also let you specify a padding character should the print field be larger than the minimum needed to display the value. These routines require the following parameters:

```
stdout.puti8Size( Value8, width, padchar );
stdout.puti16Size( Value16,width, padchar );
stdout.puti32Size( Value32, width, padchar );
```

The *ValueX* parameter can be a constant, a register, or a memory location of the specified size. The *width* parameter can be any signed integer constant that is between -256 and +256; this parameter may be a constant, register (32-bit), or memory location (32-bit). The *padchar* parameter should be a single character value (in HLA, a character constant is a single character surrounding by apostrophes).

Like the `stdout.putiX` routines, these routines print the specified value as a signed integer constant to the standard output device. These routines, however, let you specify the *field width* for the value. The field width is the minimum number of print positions these routines will use when printing the value. The *width* parameter specifies the minimum field width. If the number would require more print positions (e.g., if you attempt to print "1234" with a field width of two), then these routines will print however many characters are necessary to properly display the value. On the other hand, if the *width* parameter is greater than the number of character positions required to display the value, then these routines will print some extra padding characters to ensure that the output has at least *width* character positions. If the *width* value is negative, the number is left justified in the print field; if the *width* value is positive, the number is right justified in the print field.

If the absolute value of the *width* parameter is greater than the minimum number of print positions, then these `stdout.putiXSize` routines will print a padding character before or after the number. The *padchar* parameter specifies which character these routines will print. Most of the time you would specify a space as the pad character; for special cases, you might specify some other character. Remember, the *padchar* parameter is a character value; in HLA character constants are surrounded by apostrophes, not quotation marks. You may also specify an eight-bit register as this parameter.

Here is a short HLA program that demonstrates the use of the `puti32Size` routine to display a list of values in tabular form:

```
program NumsInColumns;

#include( "stdlib.hhf" );

var
    i32: int32;
    ColCnt: int8;

begin NumsInColumns;
```

```

mov( 96, i32 );
mov( 0, ColCnt );
while( i32 > 0 ) do

    if( ColCnt = 8 ) then

        stdout.newln();
        mov( 0, ColCnt );

    endif;
    stdout.puti32Size( i32, 5, ' ' );
    sub( 1, i32 );
    add( 1, ColCnt );

endwhile;
stdout.newln();

end NumsInColumns;

```

Program 2.4 Columnar Output Demonstration Using `stdio.Puti32Size`

2.8.6 The `stdout.put` Routine

The `stdout.put` routine¹⁴ is the one of the most flexible output routines in the standard output library module. It combines most of the other output routines into a single, easy to use, procedure.

The generic form for the `stdout.put` routine is the following:

```
stdout.put( list_of_values_to_output );
```

The `stdout.put` parameter list consists of one or more constants, registers, or memory variables, each separated by a comma. This routine displays the value associated with each parameter appearing in the list. Since we've already been using this routine throughout this chapter, you've already seen lots of examples of this routine's basic form. It is worth pointing out that this routine has several additional features not apparent in the examples appearing in this chapter. In particular, each parameter can take one of the following two forms:

```

value
value:width

```

The *value* may be any legal constant, register, or memory variable object. In this chapter, you've seen string constants and memory variables appearing in the `stdout.put` parameter list. These parameters correspond to the first form above. The second parameter form above lets you specify a minimum field width, similar to the `stdout.putiXSize` routines¹⁵. The following sample program produces the same output as the previous program; however, it uses `stdout.put` rather than `stdout.puti32Size`:

```

program NumsInColumns2;

#include( "stdlib.hhf" );

```

14. `Stdout.put` is actually a macro, not a procedure. The distinction between the two is beyond the scope of this chapter. However, this text will describe their differences a little later.

15. Note that you cannot specify a padding character when using the `stdout.put` routine; the padding character defaults to the space character. If you need to use a different padding character, call the `stdout.putiXSize` routines.

```

var
  i32:   int32;
  ColCnt: int8;

begin NumsInColumns2;

  mov( 96, i32 );
  mov( 0, ColCnt );
  while( i32 > 0 ) do

    if( ColCnt = 8 ) then

      stdout.newln();
      mov( 0, ColCnt );

    endif;
    stdout.put( i32:5 );
    sub( 1, i32 );
    add( 1, ColCnt );

  endwhile;
  stdout.put( nl );

end NumsInColumns2;

```

Program 2.5 Demonstration of stdout.put Field Width Specification

The *stdout.put* routine is capable of much more than the few attributes this section describes. This text will introduce those additional capabilities as appropriate.

2.8.7 The stdin.getc Routine.

The *stdin.getc* routine reads the next available character from the standard input device's input buffer¹⁶. It returns this character in the CPU's AL register. The following example program demonstrates a simple use of this routine:

```

program charInput;

#include( "stdlib.hhf" );

var
  counter: int32;

begin charInput;

  // The following repeats as long as the user
  // confirms the repetition.

  repeat

    // Print out 14 values.

    mov( 14, counter );

```

16. "Buffer" is just a fancy term for an array.

```

while( counter > 0 ) do

    stdout.put( counter:3 );
    sub( 1, counter );

endwhile;

// Wait until the user enters 'y' or 'n'.

stdout.put( nl, nl, "Do you wish to see it again? (Y/N):" );
forever

    stdin.readLine();
    stdin.getc();
    breakif( al = 'n' );
    breakif( al = 'y' );
    stdout.put( "Error, please enter only 'y' or 'n': " );

Program 2.6 Demonstration of the `stdin.getc()` Routine

This program uses the `stdin.ReadLine` routine to force a new line of input from the user. A description of `stdin.ReadLine` appears just a little later in this chapter.

2.8.8 The `stdin.getiX` Routines

The `stdin.geti8`, `stdin.geti16`, and `stdin.geti32` routines read eight, 16, and 32-bit signed integer values from the standard input device. These routines return their values in the AL, AX, or EAX register, respectively. They provide the standard mechanism for reading signed integer values from the user in HLA.

Like the `stdin.getc` routine, these routines read a sequence of characters from the standard input buffer. They begin by skipping over any white space characters (spaces, tabs, etc.) and then convert the following stream of decimal digits (with an optional, leading, minus sign) into the corresponding integer. These routines raise an exception (that you can trap with the `TRY..ENDTRY` statement) if the input sequence is not a valid integer string or if the user input is too large to fit in the specified integer size. Note that values read by `stdin.geti8` must be in the range -128..+127; values read by `stdin.geti16` must be in the range -32,768..+32,767; and values read by `stdin.geti32` must be in the range -2,147,483,648..+2,147,483,647.

The following sample program demonstrates the use of these routines:

```

program intInput;

#include( "stdlib.hhf" );

var
    i8:int8;
    i16:int16;
    i32:int32;

```

```

begin intInput;

    // Read integers of varying sizes from the user:

    stdout.put( "Enter a small integer between -128 and +127: " );
    stdin.geti8();
    mov( al, i8 );

    stdout.put( "Enter a small integer between -32768 and +32767: " );
    stdin.geti16();
    mov( ax, i16 );

    stdout.put( "Enter an integer between +/- 2 billion: " );
    stdin.geti32();
    mov( eax, i32 );

    // Display the input values.

    stdout.put
    (
        nl,
        "Here are the numbers you entered:", nl, nl,
        "Eight-bit integer: ", i8:i2, nl,
        "16-bit integer:    ", i16:i2, nl,
        "32-bit integer:     ", i32:i2, nl
    );

end intInput;

```

Program 2.7 `stdin.getiX` Example Code

You should compile and run this program and test what happens when you enter a value that is out of range or enter an illegal string of characters.

2.8.9 The `stdin.readLine` and `stdin.flushInput` Routines

Whenever you call an input routine like `stdin.getc` or `stdin.geti32`, the program does not necessarily read the value from the user at that particular call. Instead, the HLA Standard Library buffers the input by reading a whole line of text from the user. Calls to input routines will fetch data from this input buffer until the buffer is empty. While this buffering scheme is efficient and convenient, sometimes it can be confusing. Consider the following code sequence:

```

stdout.put( "Enter a small integer between -128 and +127: " );
stdin.geti8();
mov( al, i8 );

stdout.put( "Enter a small integer between -32768 and +32767: " );
stdin.geti16();
mov( ax, i16 );

```

Intuitively, you would expect the program to print the first prompt message, wait for user input, print the second prompt message, and wait for the second user input. However, this isn't exactly what happens. For example if you run this code (from the sample program in the previous section) and enter the text "123 456" in response to the first prompt, the program will not stop for additional user input at the second prompt.

Instead, it will read the second integer (456) from the input buffer read during the execution of the *stdin.geti8* call.

In general, the *stdin* routines only read text from the user when the input buffer is empty. As long as the input buffer contains additional characters, the input routines will attempt to read their data from the buffer. You may take advantage of this behavior by writing code sequences such as the following:

```
stdout.put( "Enter two integer values: " );
stdin.geti32();
mov( eax, intval );
stdin.geti32();
mov( eax, AnotherIntVal );
```

This sequence allows the user to enter both values on the same line (separated by one or more white space characters) thus preserving space on the screen. So the input buffer behavior is desirable every now and then.

Unfortunately, the buffered behavior of the input routines is definitely counter-intuitive at other times. Fortunately, the HLA Standard Library provides two routines, *stdin.readLine* and *stdin.flushInput*, that let you control the standard input buffer. The *stdin.readLine* routine discards everything that is in the input buffer and immediately requires the user to enter a new line of text. The *stdin.flushInput* routine simply discards everything that is in the buffer. The next time an input routine executes, the system will require a new line of input from the user. You would typically call *stdin.readLine* immediately before some standard input routine; you would normally call *stdin.flushInput* immediately after a call to a standard input routine.

Note: If you are calling *stdin.readLine* and you find that you are having to input your data twice, this is a good indication that you should be calling *stdin.flushInput* rather than *stdin.readLine*. In general, you should always be able to call *stdin.flushInput* to flush the input buffer and read a new line of data on the next input call. The *stdin.readLine* routine is rarely necessary, so you should use *stdin.flushInput* unless you really need to immediately force the input of a new line of text.

2.8.10 The *stdin.get* Macro

The *stdin.get* macro combines many of the standard input routines into a single call, in much the same way that *stdout.put* combines all of the output routines into a single call. Actually, *stdin.get* is much easier to use than *stdout.put* since the only parameters to this routine are a list of variable names.

Let's rewrite the example given in the previous section:

```
stdout.put( "Enter two integer values: " );
stdin.geti32();
mov( eax, intval );
stdin.geti32();
mov( eax, AnotherIntVal );
```

Using the *stdin.get* macro, we could rewrite this code as:

```
stdout.put( "Enter two integer values: " );
stdin.get( intval, AnotherIntVal );
```

As you can see, the *stdin.get* routine is a little more convenient to use.

Note that *stdin.get* stores the input values directly into the memory variables you specify in the parameter list; it does not return the values in a register unless you actually specify a register as a parameter. The *stdin.get* parameters must all be variables or registers¹⁷.

17. Note that register input is always in hexadecimal or base 16. The next chapter will discuss hexadecimal numbers.

2.9 Putting It All Together

This chapter has covered a lot of ground! While you've still got a lot to learn about assembly language programming, this chapter, combined with your knowledge of high level languages, provides just enough information to let you start writing real assembly language programs.

In this chapter, you've seen the basic format for an HLA program. You've seen how to declare integer, character, and boolean variables. You have taken a look at the internal organization of the Intel 80x86 CPU family and learned about the MOV, ADD, and SUB instructions. You've looked at the basic HLA high level language control structures (IF, WHILE, REPEAT, FOR, BREAK, BREAKIF, FOREVER, and TRY) as well as what constitutes a legal boolean expression in these statements. Finally, this chapter has introduced several commonly-used routines in the HLA Standard Library.

You might think that knowing only three machine instructions is hardly sufficient to write meaningful programs. However, those three instructions (*mov*, *add*, and *sub*), combined with the HLA high level control structures and the HLA Standard Library routines are actually equivalent to knowing several dozen machine instructions. Certainly enough to write simple programs. Indeed, with only a few more arithmetic instructions plus the ability to write your own procedures, you'll be able to write almost any program. Of course, your journey into the world of assembly language has only just begun; you'll learn some more instructions, and how to use them, starting in the next chapter.

2.10 Sample Programs

This section contains several little HLA programs that demonstrate some of HLA's features appearing in this chapter. These short examples also demonstrate that it is possible to write meaningful (if simple) programs in HLA using nothing more than the information appearing in this chapter. You may find all of the sample programs appearing in this section in the VOLUME1\CH02 subdirectory of the software that accompanies this text.

2.10.1 Powers of Two Table Generation

The following sample program generates a table listing all the powers of two between 2**0 and 2**30.

```
// PowersOfTwo-
//
// This program generates a nicely-formatted
// "Powers of Two" table. It computes the
// various powers of two by successively
// doubling the value in the pwrOf2 variable.

program PowersOfTwo;
#include( "stdlib.hhf" );

static

    pwrOf2:int32;
    LoopCntr:int32;

begin PowersOfTwo;

    // Print a start up banner.

    stdout.put( "Powers of two: ", nl, nl );
```

```

// Initialize "pwrOf2" with 2**0 (two raised to the zero power).

mov( 1, pwrOf2 );

// Because of the limitations of 32-bit signed integers,
// we can only display 2**0..2**30.

mov( 0, LoopCntr );
while( LoopCntr < 31 ) do

    stdout.put( "2**(", LoopCntr:2, ") = ", pwrOf2:10, nl );

    // Double the value in pwrOf2 to compute the
    // next power of two.

    mov( pwrOf2, eax );
    add( eax, eax );
    mov( eax, pwrOf2 );

    // Move on to the next loop iteration.

    inc( LoopCntr );

endwhile;
stdout.newln();

end PowersOfTwo;

```

2.10.2 Checkerboard Program

This short little program demonstrates how to generate a checkerboard pattern with HLA.

```

// CheckerBoard-
//
// This program demonstrates how to draw a
// checkerboard using a set of nested while
// loops.

program CheckerBoard;
#include( "stdlib.hhf" );

static

    xCoord:int8;// Counts off eight squares in each row.
    yCoord:int8;// Counts off four pairs of squares in each column.
    ColCntr:int8;// Counts off four rows in each square.

begin CheckerBoard;

    mov( 0, yCoord );
    while( yCoord < 4 ) do

        // Display a row that begins with black.

```

```
mov( 4, ColCntr );
repeat

    // Each square is a 4x4 group of
    // spaces (white) or asterisks (black).
    // Print out one row of asterisks/spaces
    // for the current row of squares:

    mov( 0, xCoord );
    while( xCoord < 4 ) do

        stdout.put( "****  " );
        add( 1, xCoord );

    endwhile;
    stdout.newln();
    sub( 1, ColCntr );

until( ColCntr = 0 );

// Display a row that begins with white.

mov( 4, ColCntr );
repeat

    // Print out a single row of
    // spaces/asterisks for this
    // row of squares:

    mov( 0, xCoord );
    while( xCoord < 4 ) do

        stdout.put( "  ****" );
        add( 1, xCoord );

    endwhile;
    stdout.newln();
    sub( 1, ColCntr );

until( ColCntr = 0 );

add( 1, yCoord );

endwhile;

end CheckerBoard;
```

2.10.3 Fibonacci Number Generation

The Fibonacci sequence is very important to certain algorithms in Computer Science and other fields. The following sample program generates a sequence of Fibonacci numbers for $n=1..40$.

```
// This program generates the fibonacci
// sequence for n=1..40.
//
// The fibonacci sequence is defined recursively
// for positive integers as follows:
//
// fib(1) = 1;
// fib(2) = 1;
// fib( n ) = fib( n-1 ) + fib( n-2 ).
//
// This program provides an iterative solution.

program fib;
#include( "stdlib.hhf" );

static

    FibCntr:int32;
    CurFib:int32;
    LastFib:int32;
    TwoFibsAgo:int32;

begin fib;

    // Some simple initialization:

    mov( 1, LastFib );
    mov( 1, TwoFibsAgo );

    // Print fib(1) and fib(2) as a special case:

    stdout.put
    (
        "fib( 1) =          1", nl
        "fib( 2) =          1", nl
    );

    // Use a loop to compute the remaining fib values:

    mov( 3, FibCntr );
    while( FibCntr <= 40 ) do

        // Get the last two computed fibonacci values
        // and add them together:

        mov( LastFib, ebx );
        mov( TwoFibsAgo, eax );
        add( ebx, eax );

        // Save the result and print it:

        mov( eax, CurFib );
```

```
stdout.put( "fib(",FibCntr:2, ") =", CurFib:10, nl );

// Recycle current LastFib (in ebx) as TwoFibsAgo,
// and recycle CurFib as LastFib.

mov( eax, LastFib );
mov( ebx, TwoFibsAgo );

// Bump up our loop counter:

add( 1, FibCntr );

endwhile;

end fib;
```

Data Representation

Chapter Three

A major stumbling block many beginners encounter when attempting to learn assembly language is the common use of the binary and hexadecimal numbering systems. Many programmers think that hexadecimal (or hex¹) numbers represent absolute proof that God never intended anyone to work in assembly language. While it is true that hexadecimal numbers are a little different from what you may be used to, their advantages outweigh their disadvantages by a large margin. Nevertheless, understanding these numbering systems is important because their use simplifies other complex topics including boolean algebra and logic design, signed numeric representation, character codes, and packed data.

3.1 Chapter Overview

This chapter discusses several important concepts including the binary and hexadecimal numbering systems, binary data organization (bits, nibbles, bytes, words, and double words), signed and unsigned numbering systems, arithmetic, logical, shift, and rotate operations on binary values, bit fields and packed data. This is basic material and the remainder of this text depends upon your understanding of these concepts. If you are already familiar with these terms from other courses or study, you should at least skim this material before proceeding to the next chapter. If you are unfamiliar with this material, or only vaguely familiar with it, you should study it carefully before proceeding. *All of the material in this chapter is important!* Do not skip over any material. In addition to the basic material, this chapter also introduces some new HLA statements and HLA Standard Library routines.

3.2 Numbering Systems

Most modern computer systems do not represent numeric values using the decimal system. Instead, they typically use a binary or two's complement numbering system. To understand the limitations of computer arithmetic, you must understand how computers represent numbers.

3.2.1 A Review of the Decimal System

You've been using the decimal (base 10) numbering system for so long that you probably take it for granted. When you see a number like "123", you don't think about the value 123; rather, you generate a mental image of how many items this value represents. In reality, however, the number 123 represents:

$$1 \cdot 10^2 + 2 \cdot 10^1 + 3 \cdot 10^0$$

or

$$100 + 20 + 3$$

In the positional numbering system, each digit appearing to the left of the decimal point represents a value between zero and nine times an increasing power of ten. Digits appearing to the right of the decimal point represent a value between zero and nine times an increasing negative power of ten. For example, the value 123.456 means:

$$1 \cdot 10^2 + 2 \cdot 10^1 + 3 \cdot 10^0 + 4 \cdot 10^{-1} + 5 \cdot 10^{-2} + 6 \cdot 10^{-3}$$

or

$$100 + 20 + 3 + 0.4 + 0.05 + 0.006$$

1. Hexadecimal is often abbreviated as *hex* even though, technically speaking, hex means base six, not base sixteen.

3.2.2 The Binary Numbering System

Most modern computer systems (including PCs) operate using binary logic. The computer represents values using two voltage levels (usually 0v and +2.4..5v). With two such levels we can represent exactly two different values. These could be any two different values, but they typically represent the values zero and one. These two values, coincidentally, correspond to the two digits used by the binary numbering system. Since there is a correspondence between the logic levels used by the 80x86 and the two digits used in the binary numbering system, it should come as no surprise that the PC employs the binary numbering system.

The binary numbering system works just like the decimal numbering system, with two exceptions: binary only allows the digits 0 and 1 (rather than 0-9), and binary uses powers of two rather than powers of ten. Therefore, it is very easy to convert a binary number to decimal. For each “1” in the binary string, add in 2^n where “n” is the zero-based position of the binary digit. For example, the binary value 11001010_2 represents:

$$\begin{aligned} 1*2^7 + 1*2^6 + 0*2^5 + 0*2^4 + 1*2^3 + 0*2^2 + 1*2^1 + 0*2^0 \\ = \\ 128 + 64 + 8 + 2 \\ = \\ 202_{10} \end{aligned}$$

To convert decimal to binary is slightly more difficult. You must find those powers of two which, when added together, produce the decimal result. One method is to work from a large power of two down to 2^0 . Consider the decimal value 1359:

- $2^{10}=1024$, $2^{11}=2048$. So 1024 is the largest power of two less than 1359. Subtract 1024 from 1359 and begin the binary value on the left with a “1” digit. Binary = “1”, Decimal result is $1359 - 1024 = 335$.
- The next lower power of two ($2^9 = 512$) is greater than the result from above, so add a “0” to the end of the binary string. Binary = “10”, Decimal result is still 335.
- The next lower power of two is 256 (2^8). Subtract this from 335 and add a “1” digit to the end of the binary number. Binary = “101”, Decimal result is 79.
- $128 (2^7)$ is greater than 79, so tack a “0” to the end of the binary string. Binary = “1010”, Decimal result remains 79.
- The next lower power of two ($2^6 = 64$) is less than 79, so subtract 64 and append a “1” to the end of the binary string. Binary = “10101”, Decimal result is 15.
- 15 is less than the next power of two ($2^5 = 32$) so simply add a “0” to the end of the binary string. Binary = “101010”, Decimal result is still 15.
- $16 (2^4)$ is greater than the remainder so far, so append a “0” to the end of the binary string. Binary = “1010100”, Decimal result is 15.
- 2^3 (eight) is less than 15, so stick another “1” digit on the end of the binary string. Binary = “10101001”, Decimal result is 7.
- 2^2 is less than seven, so subtract four from seven and append another one to the binary string. Binary = “101010011”, decimal result is 3.
- 2^1 is less than three, so append a one to the end of the binary string and subtract two from the decimal value. Binary = “1010100111”, Decimal result is now 1.
- Finally, the decimal result is one, which is 2^0 , so add a final “1” to the end of the binary string. The final binary result is “10101001111”

If you actually have to convert a decimal number to binary by hand, the algorithm above probably isn’t the easiest to master. A simpler solution is the “even/odd – divide by two” algorithm. This algorithm uses the following steps:

- If the number is even, emit a zero. If the number is odd, emit a one.
- Divide the number by two and throw away any fractional component or remainder.

- If the quotient is zero, the algorithm is complete.
- If the quotient is not zero and is odd, prefix the current string you've got with a one; if the number is even prefix your binary string with zero ("prefix" means add the new digit to the left of the string you've produced thus far).
- Go back to step two above and repeat.

Fortunately, you'll rarely need to convert decimal numbers directly to binary strings, so neither of these algorithms is particularly important in real life.

Binary numbers, although they have little importance in high level languages, appear everywhere in assembly language programs (even if you don't convert between decimal and binary). So you should be somewhat comfortable with them.

3.2.3 Binary Formats

In the purest sense, every binary number contains an infinite number of digits (or *bits* which is short for binary digits). For example, we can represent the number five by:

101 00000101 0000000000101 ... 000000000000101

Any number of leading zero bits may precede the binary number without changing its value.

We will adopt the convention of ignoring any leading zeros if present in a value. For example, 101_2 represents the number five but since the 80x86 works with groups of eight bits, we'll find it much easier to zero extend all binary numbers to some multiple of four or eight bits. Therefore, following this convention, we'd represent the number five as 0101_2 or 00000101_2 .

In the United States, most people separate every three digits with a comma to make larger numbers easier to read. For example, 1,023,435,208 is much easier to read and comprehend than 1023435208. We'll adopt a similar convention in this text for binary numbers. We will separate each group of four binary bits with an underscore. For example, we will write the binary value 1010111110110010 as 1010_1111_1011_0010.

We often pack several values together into the same binary number. One form of the 80x86 MOV instruction uses the binary encoding 1011 0rrr dddd dddd to pack three items into 16 bits: a five-bit operation code (1_0110), a three-bit register field (rrr), and an eight-bit immediate value (dddd_ddd). For convenience, we'll assign a numeric value to each bit position. We'll number each bit as follows:

- 1) The rightmost bit in a binary number is bit position zero.
- 2) Each bit to the left is given the next successive bit number.

An eight-bit binary value uses bits zero through seven:

$X_7 X_6 X_5 X_4 X_3 X_2 X_1 X_0$

A 16-bit binary value uses bit positions zero through fifteen:

$X_{15} X_{14} X_{13} X_{12} X_{11} X_{10} X_9 X_8 X_7 X_6 X_5 X_4 X_3 X_2 X_1 X_0$

A 32-bit binary value uses bit positions zero through 31, etc.

Bit zero is usually referred to as the *low order* (L.O.) bit (some refer to this as the *least significant bit*). The left-most bit is typically called the *high order* (H.O.) bit (or the *most significant bit*). We'll refer to the intermediate bits by their respective bit numbers.

3.3 Data Organization

In pure mathematics a value may take an arbitrary number of bits. Computers, on the other hand, generally work with some specific number of bits. Common collections are single bits, groups of four bits (called *nibbles*), groups of eight bits (*bytes*), groups of 16 bits (*words*), groups of 32 bits (double words or *dwords*), groups of 64-bits (quad words or *qwords*), and more. The sizes are not arbitrary. There is a good reason for these particular values. This section will describe the bit groups commonly used on the Intel 80x86 chips.

3.3.1 Bits

The smallest “unit” of data on a binary computer is a single *bit*. Since a single bit is capable of representing only two different values (typically zero or one) you may get the impression that there are a very small number of items you can represent with a single bit. Not true! There are an infinite number of items you can represent with a single bit.

With a single bit, you can represent any two distinct items. Examples include zero or one, true or false, on or off, male or female, and right or wrong. However, you are *not* limited to representing binary data types (that is, those objects which have only two distinct values). You could use a single bit to represent the numbers 723 and 1,245. Or perhaps 6,254 and 5. You could also use a single bit to represent the colors red and blue. You could even represent two unrelated objects with a single bit. For example, you could represent the color red and the number 3,256 with a single bit. You can represent *any* two different values with a single bit. However, you can represent *only two* different values with a single bit.

To confuse things even more, different bits can represent different things. For example, one bit might be used to represent the values zero and one, while an adjacent bit might be used to represent the values true and false. How can you tell by looking at the bits? The answer, of course, is that you can't. But this illustrates the whole idea behind computer data structures: *data is what you define it to be*. If you use a bit to represent a boolean (true/false) value then that bit (by your definition) represents true or false. For the bit to have any real meaning, you must be consistent. That is, if you're using a bit to represent true or false at one point in your program, you shouldn't use the true/false value stored in that bit to represent red or blue later.

Since most items you'll be trying to model require more than two different values, single bit values aren't the most popular data type you'll use. However, since everything else consists of groups of bits, bits will play an important role in your programs. Of course, there are several data types that require two distinct values, so it would seem that bits are important by themselves. However, you will soon see that individual bits are difficult to manipulate, so we'll often use other data types to represent boolean values.

3.3.2 Nibbles

A *nibble* is a collection of four bits. It wouldn't be a particularly interesting data structure except for two items: BCD (*binary coded decimal*) numbers² and hexadecimal numbers. It takes four bits to represent a single BCD or hexadecimal digit. With a nibble, we can represent up to 16 distinct values since there are 16 unique combinations of a string of four bits:

```
0000
0001
0010
0011
0100
0101
0110
0111
1000
```

2. Binary coded decimal is a numeric scheme used to represent decimal numbers using four bits for each decimal digit.

```

1001
1010
1011
1100
1101
1110
1111

```

In the case of hexadecimal numbers, the values 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, and F are represented with four bits (see “The Hexadecimal Numbering System” on page 50). BCD uses ten different digits (0, 1, 2, 3, 4, 5, 6, 7, 8, 9) and requires four bits. In fact, any sixteen distinct values can be represented with a nibble, but hexadecimal and BCD digits are the primary items we can represent with a single nibble.

3.3.3 Bytes

Without question, the most important data structure used by the 80x86 microprocessor is the byte. A byte consists of eight bits and is the smallest addressable datum (data item) on the 80x86 microprocessor. Main memory and I/O addresses on the 80x86 are all byte addresses. This means that the smallest item that can be individually accessed by an 80x86 program is an eight-bit value. To access anything smaller requires that you read the byte containing the data and mask out the unwanted bits. The bits in a byte are normally numbered from zero to seven as shown in Figure 3.1.

Figure 3.1 Bit Numbering

Bit 0 is the *low order bit* or *least significant bit*, bit 7 is the *high order bit* or *most significant bit* of the byte. We'll refer to all other bits by their number.

Note that a byte also contains exactly two nibbles (see Figure 3.2).

Figure 3.2 The Two Nibbles in a Byte

Bits 0..3 comprise the *low order nibble*, bits 4..7 form the *high order nibble*. Since a byte contains exactly two nibbles, byte values require two hexadecimal digits.

Since a byte contains eight bits, it can represent 2^8 , or 256, different values. Generally, we'll use a byte to represent numeric values in the range 0..255, signed numbers in the range -128..+127 (see “Signed and Unsigned Numbers” on page 59), ASCII/IBM character codes, and other special data types requiring no more than 256 different values. Many data types have fewer than 256 items so eight bits is usually sufficient.

Since the 80x86 is a byte addressable machine (see the next volume), it turns out to be more efficient to manipulate a whole byte than an individual bit or nibble. For this reason, most programmers use a whole byte to represent data types that require no more than 256 items, even if fewer than eight bits would suffice. For example, we'll often represent the boolean values true and false by 00000001_2 and 00000000_2 (respectively).

Probably the most important use for a byte is holding a character code. Characters typed at the keyboard, displayed on the screen, and printed on the printer all have numeric values. To allow it to communicate with the rest of the world, the IBM PC uses a variant of the ASCII character set (see "The ASCII Character Encoding" on page 87). There are 128 defined codes in the ASCII character set. IBM uses the remaining 128 possible values for extended character codes including European characters, graphic symbols, Greek letters, and math symbols.

Because bytes are the smallest unit of storage in the 80x86 memory space, bytes also happen to be the smallest variable you can create in an HLA program. As you saw in the last chapter, you can declare an eight-bit signed integer variable using the *int8* data type. Since *int8* objects are signed, you can represent values in the range -128..+127 using an *int8* variable (see "Signed and Unsigned Numbers" on page 59 for a discussion of signed number formats). You should only store signed values into *int8* variables; if you want to create an arbitrary byte variable, you should use the *byte* data type, as follows:

```
static
    byteVar: byte;
```

The *byte* data type is a partially untyped data type. The only type information associated with *byte* objects is their size (one byte). You may store any one-byte object (small signed integers, small unsigned integers, characters, etc.) into a byte variable. It is up to you to keep track of the type of object you've put into a byte variable.

3.3.4 Words

A word is a group of 16 bits. We'll number the bits in a word starting from zero on up to fifteen. The bit numbering appears in Figure 3.3.

Figure 3.3 Bit Numbers in a Word

Like the byte, bit 0 is the low order bit. For words, bit 15 is the high order bit. When referencing the other bits in a word use their bit position number.

Notice that a word contains exactly two bytes. Bits 0 through 7 form the low order byte, bits 8 through 15 form the high order byte (see Figure 3.4).

Figure 3.6 Bit Numbers in a Double Word

Naturally, this double word can be divided into a high order word and a low order word, four different bytes, or eight different nibbles (see Figure 3.7).

Figure 3.7 Nibbles, Bytes, and Words in a Double Word

Double words can represent all kinds of different things. A common item you will represent with a double word is a 32-bit integer value (which allows unsigned numbers in the range 0..4,294,967,295 or signed numbers in the range -2,147,483,648..2,147,483,647). 32-bit floating point values also fit into a double word. Another common use for dword objects is to store pointer variables.

In the previous chapter, you saw how to create 32-bit (dword) signed integer variables using the *int32* data type. You can also create an arbitrary double word variable using the *dword* data type as the following example suggests:

```
static
    d: dword;
```

3.4 The Hexadecimal Numbering System

A big problem with the binary system is verbosity. To represent the value 202_{10} requires eight binary digits. The decimal version requires only three decimal digits and, thus, represents numbers much more compactly than does the binary numbering system. This fact was not lost on the engineers who designed binary computer systems. When dealing with large values, binary numbers quickly become too unwieldy. Unfortunately, the computer thinks in binary, so most of the time it is convenient to use the binary numbering system. Although we can convert between decimal and binary, the conversion is not a trivial task. The

hexadecimal (base 16) numbering system solves these problems. Hexadecimal numbers offer the two features we're looking for: they're very compact, and it's simple to convert them to binary and vice versa. Because of this, most computer systems engineers use the hexadecimal numbering system. Since the radix (base) of a hexadecimal number is 16, each hexadecimal digit to the left of the hexadecimal point represents some value times a successive power of 16. For example, the number 1234_{16} is equal to:

$$1 * 16^3 + 2 * 16^2 + 3 * 16^1 + 4 * 16^0$$

or

$$4096 + 512 + 48 + 4 = 4660_{10}.$$

Each hexadecimal digit can represent one of sixteen values between 0 and 15_{10} . Since there are only ten decimal digits, we need to invent six additional digits to represent the values in the range 10_{10} through 15_{10} . Rather than create new symbols for these digits, we'll use the letters A through F. The following are all examples of valid hexadecimal numbers:

1234_{16} $DEAD_{16}$ $BEEF_{16}$ $0AFB_{16}$ $FEED_{16}$ $DEAF_{16}$

Since we'll often need to enter hexadecimal numbers into the computer system, we'll need a different mechanism for representing hexadecimal numbers. After all, on most computer systems you cannot enter a subscript to denote the radix of the associated value. We'll adopt the following conventions:

- All hexadecimal values begin with a "\$" character, e.g., \$123A4.
- All binary values begin with a percent sign ("%").
- Decimal numbers do not have a prefix character.
- If the radix is clear from the context, this text may drop the leading "\$" or "%" character.

Examples of valid hexadecimal numbers:

\$1234 \$DEAD \$BEEF \$AFB \$FEED \$DEAF

As you can see, hexadecimal numbers are compact and easy to read. In addition, you can easily convert between hexadecimal and binary. Consider the following table:

Table 4: Binary/Hex Conversion

| Binary | Hexadecimal |
|--------|-------------|
| %0000 | \$0 |
| %0001 | \$1 |
| %0010 | \$2 |
| %0011 | \$3 |
| %0100 | \$4 |
| %0101 | \$5 |
| %0110 | \$6 |
| %0111 | \$7 |
| %1000 | \$8 |
| %1001 | \$9 |
| %1010 | \$A |
| %1011 | \$B |

Table 4: Binary/Hex Conversion

| Binary | Hexadecimal |
|--------|-------------|
| %1100 | \$C |
| %1101 | \$D |
| %1110 | \$E |
| %1111 | \$F |

This table provides all the information you'll ever need to convert any hexadecimal number into a binary number or vice versa.

To convert a hexadecimal number into a binary number, simply substitute the corresponding four bits for each hexadecimal digit in the number. For example, to convert \$ABCD into a binary value, simply convert each hexadecimal digit according to the table above:

| 0 | A | B | C | D | Hexadecimal |
|------|------|------|------|------|-------------|
| 0000 | 1010 | 1011 | 1100 | 1101 | Binary |

To convert a binary number into hexadecimal format is almost as easy. The first step is to pad the binary number with zeros to make sure that there is a multiple of four bits in the number. For example, given the binary number 1011001010, the first step would be to add two bits to the left of the number so that it contains 12 bits. The converted binary value is 001011001010. The next step is to separate the binary value into groups of four bits, e.g., 0010_1100_1010. Finally, look up these binary values in the table above and substitute the appropriate hexadecimal digits, i.e., \$2CA. Contrast this with the difficulty of conversion between decimal and binary or decimal and hexadecimal!

Since converting between hexadecimal and binary is an operation you will need to perform over and over again, you should take a few minutes and memorize the table above. Even if you have a calculator that will do the conversion for you, you'll find manual conversion to be a lot faster and more convenient when converting between binary and hex.

3.5 Arithmetic Operations on Binary and Hexadecimal Numbers

There are several operations we can perform on binary and hexadecimal numbers. For example, we can add, subtract, multiply, divide, and perform other arithmetic operations. Although you needn't become an expert at it, you should be able to, in a pinch, perform these operations manually using a piece of paper and a pencil. Having just said that you should be able to perform these operations manually, the correct way to perform such arithmetic operations is to have a calculator that does them for you. There are several such calculators on the market; the following table lists some of the manufacturers who produce such devices:

Manufacturers of Hexadecimal Calculators:

- Casio
- Hewlett-Packard
- Sharp
- Texas Instruments

This list is by no means exhaustive. Other calculator manufacturers probably produce these devices as well. The Hewlett-Packard devices are arguably the best of the bunch. However, they are more expensive than the others. Sharp and Casio produce units which sell for well under \$50. If you plan on doing any assembly language programming at all, owning one of these calculators is essential.

To understand why you should spend the money on a calculator, consider the following arithmetic problem:

```

  $9
+ $1
----

```

You're probably tempted to write in the answer "\$10" as the solution to this problem. But that is not correct! The correct answer is ten, which is "\$A", not sixteen which is "\$10". A similar problem exists with the arithmetic problem:

```

  $10
- $1
----

```

You're probably tempted to answer "\$9" even though the true answer is "\$F". Remember, this problem is asking "what is the difference between sixteen and one?" The answer, of course, is fifteen which is "\$F".

Even if the two problems above don't bother you, in a stressful situation your brain will switch back into decimal mode while you're thinking about something else and you'll produce the incorrect result. Moral of the story – if you must do an arithmetic computation using hexadecimal numbers by hand, take your time and be careful about it. Either that, or convert the numbers to decimal, perform the operation in decimal, and convert them back to hexadecimal.

3.6 A Note About Numbers vs. Representation

Many people confuse numbers and their representation. A common question beginning assembly language students have is "I've got a binary number in the EAX register, how do I convert that to a hexadecimal number in the EAX register?" The answer is "you don't." Although a strong argument could be made that numbers in memory or in registers are represented in binary, it's best to view values in memory or in a register as *abstract numeric quantities*. Strings of symbols like 128, \$80, or %1000_0000 are not different numbers; they are simply different representations for the same abstract quantity that we often refer to as "one hundred twenty-eight." Inside the computer, a number is a number regardless of representation; the only time representation matters is when you input or output the value in a human readable form.

Human readable forms of numeric quantities are always strings of characters. To print the value 128 in human readable form, you must convert the numeric value 128 to the three-character sequence '1' followed by '2' followed by '8'. This would provide the decimal representation of the numeric quantity. If you prefer, you could convert the numeric value 128 to the three character sequence "\$80". It's the same number, but we've converted it to a different sequence of characters because (presumably) we wanted to view the number in hexadecimal rather than decimal. Likewise, if we want to see the number in binary, then we must convert this numeric value to a string containing a one followed by seven zeros.

By default, HLA displays all byte, word, and dword variables using the hexadecimal numbering system when you use the *stdout.put* routine. Likewise, HLA's *stdout.put* routine will display all register values in hex. Consider the following program that converts values input as decimal numbers to their hexadecimal equivalents:

```

program ConvertToHex;
#include( "stdlib.hhf" );
static
  value: int32;
begin ConvertToHex;

  stdout.put( "Input a decimal value:" );
  stdin.get( value );
  mov( value, eax );
  stdout.put( "The value ", value, " converted to hex is $", eax, nl );

end ConvertToHex;

```

Program 3.1 Decimal to Hexadecimal Conversion Program

In a similar fashion, the default input base is also hexadecimal for registers and byte, word, or dword variables. The following program is the converse of the one above- it inputs a hexadecimal value and outputs it as decimal:

```

program ConvertToDecimal;
#include( "stdlib.hhf" );
static
    value: int32;
begin ConvertToDecimal;

    stdout.put( "Input a hexadecimal value: " );
    stdin.get( ebx );
    mov( ebx, value );
    stdout.put( "The value $", ebx, " converted to decimal is ", value, nl );

end ConvertToDecimal;

```

Program 3.2 Hexadecimal to Decimal Conversion Program

Just because the HLA *stdout.put* routine chooses decimal as the default output base for *int8*, *int16*, and *int32* variables doesn't mean that these variables hold "decimal" numbers. Remember, memory and registers hold numeric values, not hexadecimal or decimal values. The *stdout.put* routine converts these numeric values to strings and prints the resulting strings. The choice of hexadecimal vs. decimal output was a design choice in the HLA language, nothing more. You could very easily modify HLA so that it outputs registers and *byte*, *word*, or *dword* variables as decimal values rather than as hexadecimal. If you need to print the value of a register or *byte*, *word*, or *dword* variable as a decimal value, simply call one of the *putiX* routines to do this. The *stdout.puti8* routine will output its parameter as an eight-bit signed integer. Any eight-bit parameter will work. So you could pass an eight-bit register, an *int8* variable, or a *byte* variable as the parameter to *stdout.puti8* and the result will always be decimal. The *stdout.puti16* and *stdout.puti32* provide the same capabilities for 16-bit and 32-bit objects. The following program demonstrates the decimal conversion program (Program 3.2 above) using only the EAX register (i.e., it does not use the variable *iValue*):

```

program ConvertToDecimal2;
#include( "stdlib.hhf" );
begin ConvertToDecimal2;

    stdout.put( "Input a hexadecimal value: " );
    stdin.get( ebx );
    stdout.put( "The value $", ebx, " converted to decimal is " );
    stdout.puti32( ebx );
    stdout.newln();

end ConvertToDecimal2;

```

Program 3.3 Variable-less Hexadecimal to Decimal Converter

Note that HLA's *stdin.get* routine uses the same default base for input as *stdout.put* uses for output. That is, if you attempt to read an *int8*, *int16*, or *int32* variable, the default input base is decimal. If you attempt to read a register or *byte*, *word*, or *dword* variable, the default input base is hexadecimal. If you want to change the default input base to decimal when reading a register or a *byte*, *word*, or *dword* variable, then you can use *stdin.geti8*, *stdin.geti16*, or *stdin.geti32*.

If you want to go in the opposite direction, that is you want to input or output an *int8*, *int16*, or *int32* variable as a hexadecimal value, you can call the *stdout.putb*, *stdout.putw*, *stdout.putd*, *stdin.getb*, *stdin.getw*, or *stdin.getd* routines. The *stdout.putb*, *stdout.putw*, and *stdout.putd* routines write eight-bit, 16-bit, or 32-bit objects as hexadecimal values. The *stdin.getb*, *stdin.getw*, and *stdin.getd* routines read eight-bit, 16-bit, and 32-bit values respectively; they return their results in the AL, AX, or EAX registers. The following program demonstrates the use of a few of these routines:

```

program HexIO;

#include( "stdlib.hhf" );

static
    i32: int32;

begin HexIO;

    stdout.put( "Enter a hexadecimal value: " );
    stdin.getdw();
    mov( eax, i32 );
    stdout.put( "The value you entered was $" );
    stdout.putdw( i32 );
    stdout.newln();

end HexIO;

```

3.7 Logical Operations on Bits

There are four main logical operations we'll need to perform on hexadecimal and binary numbers: AND, OR, XOR (exclusive-or), and NOT. Unlike the arithmetic operations, a hexadecimal calculator isn't necessary to perform these operations. It is often easier to do them by hand than to use an electronic device to compute them. The logical AND operation is a dyadic³ operation (meaning it accepts exactly two operands). These operands are single binary (base 2) bits. The AND operation is:

$$0 \text{ and } 0 = 0$$

$$0 \text{ and } 1 = 0$$

$$1 \text{ and } 0 = 0$$

$$1 \text{ and } 1 = 1$$

A compact way to represent the logical AND operation is with a truth table. A truth table takes the following form:

3. Many texts call this a binary operation. The term dyadic means the same thing and avoids the confusion with the binary numbering system.

Table 5: AND Truth Table

| AND | 0 | 1 |
|-----|---|---|
| 0 | 0 | 0 |
| 1 | 0 | 1 |

This is just like the multiplication tables you encountered in elementary school. The values in the left column correspond to the leftmost operand of the AND operation. The values in the top row correspond to the rightmost operand of the AND operation. The value located at the intersection of the row and column (for a particular pair of input values) is the result of logically ANDing those two values together. In English, the logical AND operation is, “If the first operand is one and the second operand is one, the result is one; otherwise the result is zero.”

One important fact to note about the logical AND operation is that you can use it to force a zero result. If one of the operands is zero, the result is always zero regardless of the other operand. In the truth table above, for example, the row labelled with a zero input contains only zeros and the column labelled with a zero only contains zero results. Conversely, if one operand contains a one, the result is exactly the value of the second operand. These features of the AND operation are very important, particularly when we want to force individual bits in a bit string to zero. We will investigate these uses of the logical AND operation in the next section.

The logical OR operation is also a dyadic operation. Its definition is:

$$0 \text{ or } 0 = 0$$

$$0 \text{ or } 1 = 1$$

$$1 \text{ or } 0 = 1$$

$$1 \text{ or } 1 = 1$$

The truth table for the OR operation takes the following form:

Table 6: OR Truth Table

| OR | 0 | 1 |
|----|---|---|
| 0 | 0 | 1 |
| 1 | 1 | 1 |

Colloquially, the logical OR operation is, “If the first operand or the second operand (or both) is one, the result is one; otherwise the result is zero.” This is also known as the *inclusive-OR* operation.

If one of the operands to the logical-OR operation is a one, the result is always one regardless of the second operand’s value. If one operand is zero, the result is always the value of the second operand. Like the logical AND operation, this is an important side-effect of the logical-OR operation that will prove quite useful when working with bit strings since it lets you force individual bits to one.

Note that there is a difference between this form of the inclusive logical OR operation and the standard English meaning. Consider the phrase “I am going to the store *or* I am going to the park.” Such a statement implies that the speaker is going to the store or to the park but not to both places. Therefore, the English version of logical OR is slightly different than the inclusive-OR operation; indeed, it is closer to the *exclusive-OR* operation.

The logical XOR (exclusive-or) operation is also a dyadic operation. It is defined as follows:

$$0 \text{ xor } 0 = 0$$

$$0 \text{ xor } 1 = 1$$

$$1 \text{ xor } 0 = 1$$

$$1 \text{ xor } 1 = 0$$

The truth table for the XOR operation takes the following form:

Table 7: XOR Truth Table

| XOR | 0 | 1 |
|-----|---|---|
| 0 | 0 | 1 |
| 1 | 1 | 0 |

In English, the logical XOR operation is, “If the first operand or the second operand, but not both, is one, the result is one; otherwise the result is zero.” Note that the exclusive-or operation is closer to the English meaning of the word “or” than is the logical OR operation.

If one of the operands to the logical exclusive-OR operation is a one, the result is always the *inverse* of the other operand; that is, if one operand is one, the result is zero if the other operand is one and the result is one if the other operand is zero. If the first operand contains a zero, then the result is exactly the value of the second operand. This feature lets you selectively invert bits in a bit string.

The logical NOT operation is a monadic operation (meaning it accepts only one operand). It is:

$$\text{NOT } 0 = 1$$

$$\text{NOT } 1 = 0$$

The truth table for the NOT operation takes the following form:

Table 8: NOT Truth Table

| NOT | 0 | 1 |
|-----|---|---|
| | 1 | 0 |

3.8 Logical Operations on Binary Numbers and Bit Strings

As described in the previous section, the logical functions work only with single bit operands. Since the 80x86 uses groups of eight, sixteen, or thirty-two bits, we need to extend the definition of these functions to deal with more than two bits. Logical functions on the 80x86 operate on a *bit-by-bit* (or *bitwise*) basis. Given two values, these functions operate on bit zero producing bit zero of the result. They operate on bit one of the input values producing bit one of the result, etc. For example, if you want to compute the logical AND of the following two eight-bit numbers, you would perform the logical AND operation on each column independently of the others:

```
%1011_0101
%1110_1110
-----
%1010_0100
```

This bit-by-bit form of execution can be easily applied to the other logical operations as well.

Since we've defined logical operations in terms of binary values, you'll find it much easier to perform logical operations on binary values than on values in other bases. Therefore, if you want to perform a logical operation on two hexadecimal numbers, you should convert them to binary first. This applies to most of the basic logical operations on binary numbers (e.g., AND, OR, XOR, etc.).

The ability to force bits to zero or one using the logical AND/OR operations and the ability to invert bits using the logical XOR operation is very important when working with strings of bits (e.g., binary numbers). These operations let you selectively manipulate certain bits within some value while leaving other bits unaffected. For example, if you have an eight-bit binary value X and you want to guarantee that bits four through seven contain zeros, you could logically AND the value X with the binary value `%0000_1111`. This bitwise logical AND operation would force the H.O. four bits to zero and pass the L.O. four bits of X through unchanged. Likewise, you could force the L.O. bit of X to one and invert bit number two of X by logically ORing X with `%0000_0001` and logically exclusive-ORing X with `%0000_0100`, respectively. Using the logical AND, OR, and XOR operations to manipulate bit strings in this fashion is known as *masking* bit strings. We use the term *masking* because we can use certain values (one for AND, zero for OR/XOR) to 'mask out' or 'mask in' certain bits from the operation when forcing bits to zero, one, or their inverse.

The 80x86 CPUs support four instructions that apply these bitwise logical operations to their operands. The instructions are AND, OR, XOR, and NOT. The AND, OR, and XOR instructions use the same syntax as the ADD and SUB instructions, that is,

```
and( source, dest );
or( source, dest );
xor( source, dest );
```

These operands have the same limitations as the ADD operands. Specifically, the *source* operand has to be a constant, memory, or register operand and the *dest* operand must be a memory or register operand. Also, the operands must be the same size and they cannot both be memory operands. These instructions compute the obvious bitwise logical operation via the equation:

$$dest = dest \text{ operator } source$$

The 80x86 logical NOT instruction, since it has only a single operand, uses a slightly different syntax. This instruction takes the following form:

```
not( dest );
```

Note that this instruction has a single operand. It computes the following result:

$$dest = \text{NOT}(dest)$$

The *dest* operand (for *not*) must be a register or memory operand. This instruction inverts all the bits in the specified destination operand.

The following program inputs two hexadecimal values from the user and calculates their logical AND, OR, XOR, and NOT:

```
program LogicalOp;
#include( "stdlib.hhf" );
begin LogicalOp;

    stdout.put( "Input left operand: " );
    stdin.get( eax );
    stdout.put( "Input right operand: " );
    stdin.get( ebx );

    mov( eax, ecx );
    and( ebx, ecx );
    stdout.put( "$", eax, " AND $", ebx, " = $", ecx, nl );
```

```

mov( eax, ecx );
or( ebx, ecx );
stdout.put( "$", eax, " OR $", ebx, " = $", ecx, nl );

mov( eax, ecx );
xor( ebx, ecx );
stdout.put( "$", eax, " XOR $", ebx, " = $", ecx, nl );

mov( eax, ecx );
not( ecx );
stdout.put( "NOT $", eax, " = $", ecx, nl );

mov( ebx, ecx );
not( ecx );
stdout.put( "NOT $", ebx, " = $", ecx, nl );

end LogicalOp;

```

3.9 Signed and Unsigned Numbers

So far, we've treated binary numbers as unsigned values. The binary number ...00000 represents zero, ...00001 represents one, ...00010 represents two, and so on toward infinity. What about negative numbers? Signed values have been tossed around in previous sections and we've mentioned the two's complement numbering system, but we haven't discussed how to represent negative numbers using the binary numbering system. That is what this section is all about!

To represent signed numbers using the binary numbering system we have to place a restriction on our numbers: they must have a finite and fixed number of bits. For our purposes, we're going to severely limit the number of bits to eight, 16, 32, or some other small number of bits.

With a fixed number of bits we can only represent a certain number of objects. For example, with eight bits we can only represent 256 different values. Negative values are objects in their own right, just like positive numbers; therefore, we'll have to use some of the 256 different eight-bit values to represent negative numbers. In other words, we've got to use up some of the (unsigned) positive numbers to represent negative numbers. To make things fair, we'll assign half of the possible combinations to the negative values and half to the positive values and zero. So we can represent the negative values -128..-1 and the non-negative values 0..127 with a single eight bit byte. With a 16-bit word we can represent values in the range -32,768..+32,767. With a 32-bit double word we can represent values in the range -2,147,483,648..+2,147,483,647. In general, with n bits we can represent the signed values in the range -2^{n-1} to $+2^{n-1}-1$.

Okay, so we can represent negative values. Exactly how do we do it? Well, there are many ways, but the 80x86 microprocessor uses the two's complement notation. In the two's complement system, the H.O. bit of a number is a *sign bit*. If the H.O. bit is zero, the number is positive; if the H.O. bit is one, the number is negative. Examples:

For 16-bit numbers:

\$8000 is negative because the H.O. bit is one.

\$100 is positive because the H.O. bit is zero.

\$7FFF is positive.

\$FFFF is negative.

\$FFF is positive.

If the H.O. bit is zero, then the number is positive and is stored as a standard binary value. If the H.O. bit is one, then the number is negative and is stored in the two's complement form. To convert a positive number to its negative, two's complement form, you use the following algorithm:

- 1) Invert all the bits in the number, i.e., apply the logical NOT function.
- 2) Add one to the inverted result.

For example, to compute the eight-bit equivalent of -5:

```
%0000_0101    Five (in binary).
%1111_1010    Invert all the bits.
%1111_1011    Add one to obtain result.
```

If we take minus five and perform the two's complement operation on it, we get our original value, %0000_0101, back again, just as we expect:

```
%1111_1011    Two's complement for -5.
%0000_0100    Invert all the bits.
%0000_0101    Add one to obtain result (+5).
```

The following examples provide some positive and negative 16-bit signed values:

```
$7FFF: +32767, the largest 16-bit positive number.
$8000: -32768, the smallest 16-bit negative number.
$4000: +16,384.
```

To convert the numbers above to their negative counterpart (i.e., to negate them), do the following:

```
$7FFF:    %0111_1111_1111_1111    +32,767
          %1000_0000_0000_0000    Invert all the bits (8000h)
          %1000_0000_0000_0001    Add one (8001h or -32,767)

4000h:    %0100_0000_0000_0000    16,384
          %1011_1111_1111_1111    Invert all the bits ($BFFF)
          %1100_0000_0000_0000    Add one ($C000 or -16,384)

$8000:    %1000_0000_0000_0000    -32,768
          %0111_1111_1111_1111    Invert all the bits ($7FFF)
          %1000_0000_0000_0000    Add one (8000h or -32768)
```

\$8000 inverted becomes \$7FFF. After adding one we obtain \$8000! Wait, what's going on here? -(-32,768) is -32,768? Of course not. But the value +32,768 cannot be represented with a 16-bit signed number, so we cannot negate the smallest negative value.

Why bother with such a miserable numbering system? Why not use the H.O. bit as a sign flag, storing the positive equivalent of the number in the remaining bits? The answer lies in the hardware. As it turns out, negating values is the only tedious job. With the two's complement system, most other operations are as easy as the binary system. For example, suppose you were to perform the addition $5+(-5)$. The result is zero. Consider what happens when we add these two values in the two's complement system:

```
% 0000_0101
% 1111_1011
-----
%1_0000_0000
```

We end up with a carry into the ninth bit and all other bits are zero. As it turns out, if we ignore the carry out of the H.O. bit, adding two signed values always produces the correct result when using the two's complement numbering system. This means we can use the same hardware for signed and unsigned addition and subtraction. This wouldn't be the case with some other numbering systems.

Except for the questions at the end of this chapter, you will not need to perform the two's complement operation by hand. The 80x86 microprocessor provides an instruction, NEG (negate), which performs this operation for you. Furthermore, all the hexadecimal calculators will perform this operation by pressing the change sign key (+/- or CHS). Nevertheless, performing a two's complement by hand is easy, and you should know how to do it.

Once again, you should note that the data represented by a set of binary bits depends entirely on the context. The eight bit binary value %1100_0000 could represent an IBM/ASCII character, it could represent the unsigned decimal value 192, or it could represent the signed decimal value -64, etc. As the programmer, it is your responsibility to use this data consistently.

The 80x86 negate instruction, NEG, uses the same syntax as the NOT instruction; that is, it takes a single destination operand:

```
neg( dest );
```

This instruction computes “dest = -dest;” and the operand has the usual limitation (it must be a memory location or a register). NEG operates on byte, word, and dword-sized objects. Of course, since this is a signed integer operation, it only makes sense to operate on signed integer values. The following program demonstrates the two's complement operation by using the NEG instruction:

```
program twosComplement;
#include( "stdlib.hhf" );

static
    PosValue:int8;
    NegValue:int8;

begin twosComplement;

    stdout.put( "Enter an integer between 0 and 127: " );
    stdin.get( PosValue );

    stdout.put( nl, "Value in hexadecimal: $" );
    stdout.putb( PosValue );

    mov( PosValue, al );
    not( al );
    stdout.put( nl, "Invert all the bits: $", al, nl );
    add( 1, al );
    stdout.put( "Add one: $", al, nl );
    mov( al, NegValue );
    stdout.put( "Result in decimal: ", NegValue, nl );

    stdout.put
    (
        nl,
        "Now do the same thing with the NEG instruction: ",
        nl
    );
    mov( PosValue, al );
    neg( al );
    mov( al, NegValue );
    stdout.put( "Hex result = $", al, nl );
```

```

        stdout.put( "Decimal result = ", NegValue, nl );

end twosComplement;

```

Program 3.6 The Two's Complement Operation

As you saw in the previous chapters, you use the *int8*, *int16*, and *int32* data types to reserve storage for signed integer variables. Those chapters also introduced routines like *stdout.puti8* and *stdin.geti32* that read and write signed integer values. Since this section has made it abundantly clear that you must differentiate signed and unsigned calculations in your programs, you should probably be asking yourself about now “how do I declare and use unsigned integer variables?”

The first part of the question, “how do you declare unsigned integer variables,” is the easiest to answer. You simply use the *uns8*, *uns16*, and *uns32* data types when declaring the variables, for example:

```

static
    u8:    uns8;
    u16:   uns16;
    u32:   uns32;

```

As for using these unsigned variables, the HLA Standard Library provides a complementary set of input/output routines for reading and displaying unsigned variables. As you can probably guess, these routines include *stdout.putu8*, *stdout.putu16*, *stdout.putu32*, *stdout.putu8Size*, *stdout.putu16Size*, *stdout.putu32Size*, *stdin.getu8*, *stdin.getu16*, and *stdin.getu32*. You use these routines just as you would use their signed integer counterparts except, of course, you get to use the full range of the unsigned values with these routines. The following source code demonstrates unsigned I/O as well as demonstrating what can happen if you mix signed and unsigned operations in the same calculation:

```

program UnsExample;
#include( "stdlib.hhf" );

static
    UnsValue:uns16;

begin UnsExample;

    stdout.put( "Enter an integer between 32,768 and 65,535: " );
    stdin.getu16();
    mov( ax, UnsValue );

    stdout.put
    (
        "You entered ",
        UnsValue,
        ". If you treat this as a signed integer, it is "
    );
    stdout.puti16( UnsValue );
    stdout.newln();

end UnsExample;

```

Program 3.7 Unsigned I/O

3.10 Sign Extension, Zero Extension, Contraction, and Saturation

Since two's complement format integers have a fixed length, a small problem develops. What happens if you need to convert an eight bit two's complement value to 16 bits? This problem, and its converse (converting a 16 bit value to eight bits) can be accomplished via *sign extension* and *contraction* operations. Likewise, the 80x86 works with fixed length values, even when processing unsigned binary numbers. *Zero extension* lets you convert small unsigned values to larger unsigned values.

Consider the value “-64”. The eight bit two's complement value for this number is \$C0. The 16-bit equivalent of this number is \$FFC0. Now consider the value “+64”. The eight and 16 bit versions of this value are \$40 and \$0040, respectively. The difference between the eight and 16 bit numbers can be described by the rule: “If the number is negative, the H.O. byte of the 16 bit number contains \$FF; if the number is positive, the H.O. byte of the 16 bit quantity is zero.”

To sign extend a value from some number of bits to a greater number of bits is easy, just copy the sign bit into all the additional bits in the new format. For example, to sign extend an eight bit number to a 16 bit number, simply copy bit seven of the eight bit number into bits 8..15 of the 16 bit number. To sign extend a 16 bit number to a double word, simply copy bit 15 into bits 16..31 of the double word.

Sign extension is required when manipulating signed values of varying lengths. Often you'll need to add a byte quantity to a word quantity. You must sign extend the byte quantity to a word before the operation takes place. Other operations (multiplication and division, in particular) may require a sign extension to 32-bits. You must not sign extend unsigned values.

Sign Extension:

| Eight Bits | Sixteen Bits | Thirty-two Bits |
|------------|--------------|-----------------|
| \$80 | \$FF80 | \$FFFF_FF80 |
| \$28 | \$0028 | \$0000_0028 |
| \$9A | \$FF9A | \$FFFF_FF9A |
| \$7F | \$007F | \$0000_007F |
| --- | \$1020 | \$0000_1020 |
| --- | \$8086 | \$FFFF_8086 |

To extend an unsigned byte you must zero extend the value. Zero extension is very easy – just store a zero into the H.O. byte(s) of the larger operand. For example, to zero extend the value \$82 to 16-bits you simply add a zero to the H.O. byte yielding \$0082.

Zero Extension:

| Eight Bits | Sixteen Bits | Thirty-two Bits |
|------------|--------------|-----------------|
| \$80 | \$0080 | \$0000_0080 |
| \$28 | \$0028 | \$0000_0028 |
| \$9A | \$009A | \$0000_009A |
| \$7F | \$007F | \$0000_007F |
| --- | \$1020 | \$0000_1020 |
| --- | \$8086 | \$0000_8086 |

Sign contraction, converting a value with some number of bits to the identical value with a fewer number of bits, is a little more troublesome. Sign extension never fails. Given an m -bit signed value you can always convert it to an n -bit number (where $n > m$) using sign extension. Unfortunately, given an n -bit number, you cannot always convert it to an m -bit number if $m < n$. For example, consider the value -448. As a 16-bit hexadecimal number, its representation is \$FE40. Unfortunately, the magnitude of this number is too great to fit into an eight bit value, so you cannot sign contract it to eight bits. This is an example of an overflow condition that occurs upon conversion.

To properly sign contract one value to another, you must look at the H.O. byte(s) that you want to discard. The H.O. bytes you wish to remove must all contain either zero or \$FF. If you encounter any other val-

ues, you cannot contract it without overflow. Finally, the H.O. bit of your resulting value must match *every* bit you've removed from the number. Examples (16 bits to eight bits):

```
$FF80 can be sign contracted to $80.
$0040 can be sign contracted to $40.
$FE40 cannot be sign contracted to 8 bits.
$0100 cannot be sign contracted to 8 bits.
```

The 80x86 provides several instructions that will let you sign or zero extend a smaller number to a larger number. The first group of instructions we will look at will sign extend the AL, AX, or EAX register. These instructions are

- `cbw();` // Converts the byte in AL to a word in AX via sign extension.
- `cwd();` // Converts the word in AX to a double word in DX:AX
- `cdq();` // Converts the double word in EAX to the quad word in EDX:EAX
- `cwde();` // Converts the word in AX to a doubleword in EAX.

Note that the CWD (convert word to doubleword) instruction does not sign extend the word in AX to the doubleword in EAX. Instead, it stores the H.O. doubleword of the sign extension into the DX register (the notation "DX:AX" tells you that you have a double word value with DX containing the upper 16 bits and AX containing the lower 16 bits of the value). If you want the sign extension of AX to go into EAX, you should use the CWDE (convert word to doubleword, extended) instruction.

The four instructions above are unusual in the sense that these are the first instructions you've seen that do not have any operands. These instructions' operands are *implied* by the instructions themselves.

Within a few chapters you will discover just how important these instructions are, and why the CWD and CDQ instructions involve the DX and EDX registers. However, for simple sign extension operations, these instructions have a few major drawbacks - you do not get to specify the source and destination operands and the operands must be registers.

For general sign extension operations, the 80x86 provides an extension of the MOV instruction, MOVSX (move with sign extension), that copies data and sign extends the data while copying it. The MOVSX instruction's syntax is very similar to the MOV instruction:

```
movsx( source, dest );
```

The big difference in syntax between this instruction and the MOV instruction is the fact that the destination operand must be larger than the source operand. That is, if the source operand is a byte, the destination operand must be a word or a double word. Likewise, if the source operand is a word, the destination operand must be a double word. Another difference is that the destination operand has to be a register; the source operand, however, can be a memory location⁴.

To zero extend a value, you can use the MOVZX instruction. It has the same syntax and restrictions as the MOVSX instruction. Zero extending certain eight-bit registers (AL, BL, CL, and DL) into their corresponding 16-bit registers is easily accomplished without using MOVZX by loading the complementary H.O. register (AH, BH, CH, or DH) with zero. Obviously, to zero extend AX into DX:AX or EAX into EDX:EAX, all you need to do is load DX or EDX with zero⁵.

The following sample program demonstrates the use of the sign extension instructions:

```
program signExtension;
#include( "stdlib.hhf" );
```

4. This doesn't turn out to be much of a limitation because sign extension almost always precedes an arithmetic operation which must take place in a register.

5. Zero extending into DX:AX or EDX:EAX is just as necessary as the CWD and CDQ instructions, as you will eventually see.

```

static
    i8:    int8;
    i16:   int16;
    i32:   int32;

begin signExtension;

    stdout.put( "Enter a small negative number: " );
    stdin.get( i8 );

    stdout.put( nl, "Sign extension using CBW and CWDE:", nl, nl );

    mov( i8, al );
    stdout.put( "You entered ", i8, " ($", al, ")", nl );

    cbw();
    mov( ax, i16 );
    stdout.put( "16-bit sign extension: ", i16, " ($", ax, ")", nl );

    cwde();
    mov( eax, i32 );
    stdout.put( "32-bit sign extension: ", i32, " ($", eax, ")", nl );

    stdout.put( nl, "Sign extension using MOVSX:", nl, nl );

    movsx( i8, ax );
    mov( ax, i16 );
    stdout.put( "16-bit sign extension: ", i16, " ($", ax, ")", nl );

    movsx( i8, eax );
    mov( eax, i32 );
    stdout.put( "32-bit sign extension: ", i32, " ($", eax, ")", nl );

end signExtension;

```

Program 3.8 Sign Extension Instructions

Another way to reduce the size of an integer is through saturation. Saturation is useful in situations where you must convert a larger object to a smaller object and you're willing to live with possible loss of precision. To convert a value via saturation you simply copy the larger value to the smaller value if it is not outside the range of the smaller object. If the larger value is outside the range of the smaller value, then you *clip* the value by setting it to the largest (or smallest) value within the range of the smaller object.

For example, when converting a 16-bit signed integer to an eight-bit signed integer, if the 16-bit value is in the range -128..+127 you simply copy the L.O. byte of the 16-bit object to the eight-bit object. If the 16-bit signed value is greater than +127, then you clip the value to +127 and store +127 into the eight-bit object. Likewise, if the value is less than -128, you clip the final eight bit object to -128. Saturation works the same way when clipping 32-bit values to smaller values. If the larger value is outside the range of the smaller value, then you simply set the smaller value to the value closest to the out of range value that you can represent with the smaller value.

Obviously, if the larger value is outside the range of the smaller value, then there will be a loss of precision during the conversion. While clipping the value to the limits the smaller object imposes is never desirable, sometimes this is acceptable as the alternative is to raise an exception or otherwise reject the calculation. For many applications, such as audio or video processing, the clipped result is still recognizable, so this is a reasonable conversion to use.

3.11 Shifts and Rotates

Another set of logical operations which apply to bit strings are the *shift* and *rotate* operations. These two categories can be further broken down into *left shifts*, *left rotates*, *right shifts*, and *right rotates*. These operations turn out to be extremely useful to assembly language programmers.

The left shift operation moves each bit in a bit string one position to the left (see Figure 3.8).

Figure 3.8 Shift Left Operation

Bit zero moves into bit position one, the previous value in bit position one moves into bit position two, etc. There are, of course, two questions that naturally arise: “What goes into bit zero?” and “Where does bit seven wind up?” We’ll shift a zero into bit zero and the previous value of bit seven will be the *carry* out of this operation.

The 80x86 provides a shift left instruction, SHL, that performs this useful operation. The syntax for the SHL instruction is the following:

```
shl ( count, dest );
```

The count operand is either “CL” or a constant in the range 0..n, where n is one less than the number of bits in the destination operand (i.e., n=7 for eight-bit operands, n=15 for 16-bit operands, and n=31 for 32-bit operands). The dest operand is a typical dest operand, it can be either a memory location or a register.

When the count operand is the constant one, the SHL instruction does the following:

Figure 3.9 Operation of the SHL(1, Dest) Instruction

In Figure 3.9, the “C” represents the carry flag. That is, the bit shifted out of the H.O. bit of the operand is moved into the carry flag. Therefore, you can test for overflow after a SHL(1, dest) instruction by testing the carry flag immediately after executing the instruction (e.g., by using “if(@c) then...” or “if(@nc) then...”).

Intel’s literature suggests that the state of the carry flag is undefined if the shift count is a value other than one. Usually, the carry flag contains the last bit shifted out of the destination operand, but Intel doesn’t seem to guarantee this. If you need to shift more than one bit out of an operand and you need to capture all the bits you shift out, you should take a look at the SHLD and SHRD instructions in the appendices.

Note that shifting a value to the left is the same thing as multiplying it by its radix. For example, shifting a decimal number one position to the left (adding a zero to the right of the number) effectively multiplies it by ten (the radix):

```
1234 shl 1 = 12340 (shl 1 means shift one position to the left)
```

Since the radix of a binary number is two, shifting it left multiplies it by two. If you shift a binary value to the left twice, you multiply it by two twice (i.e., you multiply it by four). If you shift a binary value to the left three times, you multiply it by eight ($2 \times 2 \times 2$). In general, if you shift a value to the left n times, you multiply that value by 2^n .

A right shift operation works the same way, except we're moving the data in the opposite direction. Bit seven moves into bit six, bit six moves into bit five, bit five moves into bit four, etc. During a right shift, we'll move a zero into bit seven, and bit zero will be the carry out of the operation (see Figure 3.10).

Figure 3.10 Shift Right Operation

As you would probably expect by now, the 80x86 provides a SHR instruction that will shift the bits to the right in a destination operand. The syntax is the same as the SHL instruction except, of course, you specify SHR rather than SHL:

```
SHR ( count, dest );
```

This instruction shifts a zero into the H.O. bit of the destination operand, it shifts all the other bits one place to the right (that is, from a higher bit number to a lower bit number). Finally, bit zero is shifted into the carry flag. If you specify a count of one, the SHR instruction does the following:

Figure 3.11 SHR(1, Dest) Operation

Once again, Intel's documents suggest that shifts of more than one bit leave the carry in an undefined state.

Since a left shift is equivalent to a multiplication by two, it should come as no surprise that a right shift is roughly comparable to a division by two (or, in general, a division by the radix of the number). If you perform n right shifts, you will divide that number by 2^n .

There is one problem with shift rights with respect to division: as described above a shift right is only equivalent to an *unsigned* division by two. For example, if you shift the unsigned representation of 254 (0FEh) one place to the right, you get 127 (07Fh), exactly what you would expect. However, if you shift the binary representation of -2 (0FEh) to the right one position, you get 127 (07Fh), which is *not* correct. This problem occurs because we're shifting a zero into bit seven. If bit seven previously contained a one, we're changing it from a negative to a positive number. Not a good thing when dividing by two.

To use the shift right as a division operator, we must define a third shift operation: *arithmetic shift right*⁶. An arithmetic shift right works just like the normal shift right operation (a *logical shift right*) with one

exception: instead of shifting a zero into bit seven, an arithmetic shift right operation leaves bit seven alone, that is, during the shift operation it does not modify the value of bit seven as Figure 3.12 shows.

Figure 3.12 Arithmetic Shift Right Operation

This generally produces the result you expect. For example, if you perform the arithmetic shift right operation on -2 (0FEh) you get -1 (0FFh). Keep one thing in mind about arithmetic shift right, however. This operation always rounds the numbers to the closest integer *which is less than or equal to the actual result*. Based on experiences with high level programming languages and the standard rules of integer truncation, most people assume this means that a division always truncates towards zero. But this simply isn't the case. For example, if you apply the arithmetic shift right operation on -1 (0FFh), the result is -1, not zero. -1 is less than zero so the arithmetic shift right operation rounds towards minus one. This is not a "bug" in the arithmetic shift right operation, it's just uses a different (though valid) definition of division.

The 80x86 provides an arithmetic shift right instruction, SAR (shift arithmetic right). This instruction's syntax is nearly identical to SHL and SHR. The syntax is

```
SAR( count, dest );
```

The usual limitations on the count and destination operands apply. This instruction does the following if the count is one:

Figure 3.13 SAR(1, dest) Operation

Another pair of useful operations are *rotate left* and *rotate right*. These operations behave like the shift left and shift right operations with one major difference: the bit shifted out from one end is shifted back in at the other end.

6. There is no need for an arithmetic shift left. The standard shift left operation works for both signed and unsigned numbers, assuming no overflow occurs.

Figure 3.14 Rotate Left Operation

Figure 3.15 Rotate Right Operation

The 80x86 provides ROL (rotate left) and ROR (rotate right) instructions that do these basic operations on their operands. The syntax for these two instructions is similar to the shift instructions:

```
rol ( count, dest );
ror ( count, dest );
```

Once again, these instructions provide a special behavior if the shift count is one. Under this condition these two instructions also copy the bit shifted out of the destination operand into the carry flag as the following two figures show:

Figure 3.16 ROL(1, Dest) Operation

Figure 3.17 ROR(1, Dest) Operation

It will turn out that it is often more convenient for the rotate operation to shift the output bit through the carry and shift the previous carry value back into the input bit of the shift operation. The 80x86 RCL (rotate through carry left) and RCR (rotate through carry right) instructions achieve this for you. These instructions use the following syntax:

```
RCL( count, dest );
RCR( count, dest );
```

As for the other shift and rotate instructions, the count operand is either a constant or the CL register and the destination operand is a memory location or register. The count operand must be a value that is less than the number of bits in the destination operand. For a count value of one, these two instructions do the following:

Figure 3.18 RCL(1, Dest) Operation

Figure 3.19 RCR(1, Dest) Operation

3.12 Bit Fields and Packed Data

Although the 80x86 operates most efficiently on byte, word, and double word data types, occasionally you'll need to work with a data type that uses some number of bits other than eight, 16, or 32. For example, consider a date of the form "04/02/01". It takes three numeric values to represent this date: a month, day, and year value. Months, of course, take on the values 1..12. It will require at least four bits (maximum of sixteen different values) to represent the month. Days range between 1..31. So it will take five bits (maximum of 32 different values) to represent the day entry. The year value, assuming that we're working with values in the range 0..99, requires seven bits (which can be used to represent up to 128 different values). Four plus five plus seven is 16 bits, or two bytes. In other words, we can pack our date data into two bytes rather than the three that would be required if we used a separate byte for each of the month, day, and year values. This saves one byte of memory for each date stored, which could be a substantial saving if you need to store a lot of dates. The bits could be arranged as shown in the following figure:

Figure 3.20 Short Packed Date Format (Two Bytes)

MMMM represents the four bits making up the month value, DDDDD represents the five bits making up the day, and YYYYYYY is the seven bits comprising the year. Each collection of bits representing a data item is a *bit field*. April 2nd, 2001 would be represented as \$4101:

```
0100  00010 0000001 = %0100_0001_0000_0001 or $4101
 4      2      01
```

Although packed values are *space efficient* (that is, very efficient in terms of memory usage), they are computationally *inefficient* (slow!). The reason? It takes extra instructions to unpack the data packed into the various bit fields. These extra instructions take additional time to execute (and additional bytes to hold the instructions); hence, you must carefully consider whether packed data fields will save you anything. The following sample program demonstrates the effort that must go into packing and unpacking this 16-bit date format:

```
program dateDemo;

#include( "stdlib.hhf" );

static
  day:   uns8;
  month: uns8;
  year:  uns8;

  packedDate: word;

begin dateDemo;

  stdout.put( "Enter the current month, day, and year: " );
  stdin.get( month, day, year );

  // Pack the data into the following bits:
  //
```

```

// 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0
//  m m m m d d d d d y y y y y y y

mov( 0, ax );
mov( ax, packedDate );//Just in case there is an error.
if( month > 12 ) then

    stdout.put( "Month value is too large", nl );

elseif( month = 0 ) then

    stdout.put( "Month value must be in the range 1..12", nl );

elseif( day > 31 ) then

    stdout.put( "Day value is too large", nl );

elseif( day = 0 ) then

Program 3.9 Packing and Unpacking Date Data

Of course, having gone through the problems with Y2K, using a date format that limits you to 100 years (or even 127 years) would be quite foolish at this time. If you're concerned about your software running 100 years from now, perhaps it would be wise to use a three-byte date format rather than a two-byte format. As you will see in the chapter on arrays, however, you should always try to create data objects whose length is an even power of two (one byte, two bytes, four bytes, eight bytes, etc.) or you will pay a performance penalty. Hence, it is probably wise to go ahead and use four bytes and pack this data into a dword variable. Figure 3.21 shows a possible data organization for a four-byte date.

Figure 3.21 Long Packed Date Format (Four Bytes)

In this long packed data format several changes were made beyond simply extending the number of bits associated with the year. First, since there are lots of extra bits in a 32-bit dword variable, this format allots extra bits to the month and day fields. Since these two fields consist of eight bits each, they can be easily extracted as a byte object from the dword. This leaves fewer bits for the year, but 65,536 years is probably sufficient; you can probably assume without too much concern that your software will not still be in use 63 thousand years from now when this date format will wrap around.

Of course, you could argue that this is no longer a packed date format. After all, we needed three numeric values, two of which fit just nicely into one byte each and one that should probably have at least two bytes. Since this “packed” date format consumes the same four bytes as the unpacked version, what is so special about this format? Well, another difference you will note between this long packed date format and the short date format appearing in Figure 3.20 is the fact that this long date format rearranges the bits so the *Year* is in the H.O. bit positions, the *Month* field is in the middle bit positions, and the *Day* field is in the L.O. bit positions. This is important because it allows you to very easily compare two dates to see if one date is less than, equal to, or greater than another date. Consider the following code:

```
mov( Date1, eax );           // Assume Date1 and Date2 are dword variables
if( eax > Date2 ) then      // using the Long Packed Date format.

    << do something if Date1 > Date2 >>

endif;
```

Had you kept the different date fields in separate variables, or organized the fields differently, you would not have been able to compare *Date1* and *Date2* in such a straight-forward fashion. Therefore, this example demonstrates another reason for packing data even if you don't realize any space savings- it can make certain computations more convenient or even more efficient (contrary to what normally happens when you pack data).

Examples of practical packed data types abound. You could pack eight boolean values into a single byte, you could pack two BCD digits into a byte, etc. Of course, a classic example of packed data is the FLAGS register (see Figure 3.22). This register packs nine important boolean objects (along with seven important system flags) into a single 16-bit register. You will commonly need to access many of these flags. For this reason, the 80x86 instruction set provides many ways to manipulate the individual bits in the FLAGS regis-

ter. Of course, you can test many of the condition code flags using the HLA `@c`, `@nc`, `@z`, `@nz`, etc., pseudo-boolean variables in an IF statement or other statement using a boolean expression.

In addition to the condition codes, the 80x86 provides instructions that directly affect certain flags. These instructions include the following:

- `cld()`; Clears (sets to zero) the direction flag.
- `std()`; Sets (to one) the direction flag.
- `cli()`; Clears the interrupt disable flag.
- `sti()`; Sets the interrupt disable flag.
- `clc()`; Clears the carry flag.
- `stc()`; Sets the carry flag.
- `cmc()`; Complements (inverts) the carry flag.
- `sahf()`; Stores the AH register into the L.O. eight bits of the FLAGS register.
- `lahf()`; Loads AH from the L.O. eight bits of the FLAGS register.

There are other instructions that affect the FLAGS register as well; these, however, demonstrate how to access several of the packed boolean values in the FLAGS register. The LAHF and SAHF instructions, in particular, provide a convenient way to access the L.O. eight bits of the FLAGS register as an eight-bit byte (rather than as eight separate one-bit values).

Figure 3.22 The FLAGS Register as a Packed Data Type

The LAHF (load AH with the L.O. eight bits of the FLAGS register) and the SAHF (store AH into the L.O. byte of the FLAGS register) use the following syntax:

```
lahf ();
sahf ();
```

3.13 Putting It All Together

In this chapter you've seen how we represent numeric values inside the computer. You've seen how to represent values using the decimal, binary, and hexadecimal numbering systems as well as the difference between signed and unsigned numeric representation. Since we represent nearly everything else inside a computer using numeric values, the material in this chapter is very important. Along with the base representation of numeric values, this chapter discusses the finite bit-string organization of data on typical computer systems, specifically bytes, words, and doublewords. Next, this chapter discusses arithmetic and logical operations on the numbers and presents some new 80x86 instructions to apply these operations to values

inside the CPU. Finally, this chapter concludes by showing how you can pack several different numeric values into a fixed-length object (like a byte, word, or doubleword).

Absent from this chapter is any discussion of non-integer data. For example, how do we represent real numbers as well as integers? How do we represent characters, strings, and other non-numeric data? Well, that's the subject of the next chapter, so keep in reading...

More Data Representation

Chapter Four

4.1 Chapter Overview

Although the basic machine data objects (bytes, words, and double words) appear to represent nothing more than signed or unsigned numeric values, we can employ these data types to represent many other types of objects. This chapter discusses some of the other objects and their internal computer representation.

This chapter begins by discussing floating point (real) numeric format. After integer representation, floating point representation is the second most popular numeric format in use on modern computer systems¹. Although the floating point format is somewhat complex, the necessity to handle non-integer calculations in modern programs requires that you understand this numeric format and its limitations.

Binary Coded Decimal (BCD) is another numeric data representation that is useful in certain contexts. Although BCD is not suitable for general purpose arithmetic, it is useful in some embedded applications. The principle benefit of the BCD format is the ease with which you can convert between string and BCD format. When we look at the BCD format a little later in this chapter, you'll see why this is the case.

Computers can represent all kinds of different objects, not just numeric values. Characters are, unquestionably, one of the more popular data types a computer manipulates. In this chapter you will take a look at a couple of different ways we can represent individual characters on a computer system. This chapter discusses two of the more common character sets in use today: the ASCII character set and the Unicode character set.

This chapter concludes by discussing some common non-numeric data types like pixel colors on a video display, audio data, video data, and so on. Of course, there are lots of different representations for any kind of standard data you could envision; there is no way two chapters in a textbook can cover them all. (And that's not even considering specialized data types you could create). Nevertheless, this chapter (and the last) should give you the basic idea behind representing data on a computer system.

4.2 An Introduction to Floating Point Arithmetic

Integer arithmetic does not let you represent fractional numeric values. Therefore, modern CPUs support an approximation of *real* arithmetic: floating point arithmetic. A big problem with floating point arithmetic is that it does not follow the standard rules of algebra. Nevertheless, many programmers apply normal algebraic rules when using floating point arithmetic. This is a source of defects in many programs. One of the primary goals of this section is to describe the limitations of floating point arithmetic so you will understand how to use it properly.

Normal algebraic rules apply only to *infinite precision* arithmetic. Consider the simple statement “ $x:=x+1$,” x is an integer. On any modern computer this statement follows the normal rules of algebra *as long as overflow does not occur*. That is, this statement is valid only for certain values of x ($minint \leq x < maxint$). Most programmers do not have a problem with this because they are well aware of the fact that integers in a program do not follow the standard algebraic rules (e.g., $5/2 \neq 2.5$).

Integers do not follow the standard rules of algebra because the computer represents them with a finite number of bits. You cannot represent any of the (integer) values above the maximum integer or below the minimum integer. Floating point values suffer from this same problem, only worse. After all, the integers are a subset of the real numbers. Therefore, the floating point values must represent the same infinite set of integers. However, there are an infinite number of values between any two real values, so this problem is infinitely worse. Therefore, as well as having to limit your values between a maximum and minimum range, you cannot represent all the values between those two ranges, either.

1. There are other numeric formats, such as fixed point formats and binary coded decimal format.

To represent real numbers, most floating point formats employ scientific notation and use some number of bits to represent a *mantissa* and a smaller number of bits to represent an *exponent*. The end result is that floating point numbers can only represent numbers with a specific number of *significant* digits. This has a big impact on how floating point arithmetic operates. To easily see the impact of limited precision arithmetic, we will adopt a simplified decimal floating point format for our examples. Our floating point format will provide a mantissa with three significant digits and a decimal exponent with two digits. The mantissa and exponents are both signed values as shown in Figure 4.1

Figure 4.1 Simple Floating Point Format

When adding and subtracting two numbers in scientific notation, you must adjust the two values so that their exponents are the same. For example, when adding $1.23e1$ and $4.56e0$, you must adjust the values so they have the same exponent. One way to do this is to convert $4.56e0$ to $0.456e1$ and then add. This produces $1.686e1$. Unfortunately, the result does not fit into three significant digits, so we must either *round* or *truncate* the result to three significant digits. Rounding generally produces the most accurate result, so let's round the result to obtain $1.69e1$. As you can see, the lack of *precision* (the number of digits or bits we maintain in a computation) affects the accuracy (the correctness of the computation).

In the previous example, we were able to round the result because we maintained *four* significant digits *during* the calculation. If our floating point calculation is limited to three significant digits *during* computation, we would have had to truncate the last digit of the smaller number, obtaining $1.68e1$ which is even less correct. To improve the accuracy of floating point calculations, it is necessary to add extra digits for use during the calculation. Extra digits available during a computation are known as *guard digits* (or *guard bits* in the case of a binary format). They greatly enhance accuracy during a long chain of computations.

The accuracy loss during a single computation usually isn't enough to worry about unless you are greatly concerned about the accuracy of your computations. However, if you compute a value which is the result of a sequence of floating point operations, the error can *accumulate* and greatly affect the computation itself. For example, suppose we were to add $1.23e3$ with $1.00e0$. Adjusting the numbers so their exponents are the same before the addition produces $1.23e3 + 0.001e3$. The sum of these two values, even after rounding, is $1.23e3$. This might seem perfectly reasonable to you; after all, we can only maintain three significant digits, adding in a small value shouldn't affect the result at all. However, suppose we were to add $1.00e0$ to $1.23e3$ *ten times*. The first time we add $1.00e0$ to $1.23e3$ we get $1.23e3$. Likewise, we get this same result the second, third, fourth, ..., and tenth time we add $1.00e0$ to $1.23e3$. On the other hand, had we added $1.00e0$ to itself ten times, then added the result ($1.00e1$) to $1.23e3$, we would have gotten a different result, $1.24e3$. This is an important thing to know about limited precision arithmetic:

- The order of evaluation can effect the accuracy of the result.

You will get more accurate results if the relative magnitudes (that is, the exponents) are close to one another. If you are performing a chain calculation involving addition and subtraction, you should attempt to group the values appropriately.

Another problem with addition and subtraction is that you can wind up with *false precision*. Consider the computation $1.23e0 - 1.22e0$. This produces $0.01e0$. Although this is mathematically equivalent to $1.00e-2$, this latter form suggests that the last two digits are exactly zero. Unfortunately, we've only got a single significant digit at this time. Indeed, some FPUs or floating point software packages might actually insert random digits (or bits) into the L.O. positions. This brings up a second important rule concerning limited precision arithmetic:

- Whenever subtracting two numbers with the same signs or adding two numbers with different signs, the accuracy of the result may be less than the precision available in the floating point format.

Multiplication and division do not suffer from the same problems as addition and subtraction since you do not have to adjust the exponents before the operation; all you need to do is add the exponents and multiply the mantissas (or subtract the exponents and divide the mantissas). By themselves, multiplication and division do not produce particularly poor results. However, they tend to multiply any error that already exists in a value. For example, if you multiply 1.23e0 by two, when you should be multiplying 1.24e0 by two, the result is even less accurate. This brings up a third important rule when working with limited precision arithmetic:

- When performing a chain of calculations involving addition, subtraction, multiplication, and division, try to perform the multiplication and division operations first.

Often, by applying normal algebraic transformations, you can arrange a calculation so the multiply and divide operations occur first. For example, suppose you want to compute $x*(y+z)$. Normally you would add y and z together and multiply their sum by x . However, you will get a little more accuracy if you transform $x*(y+z)$ to get $x*y+x*z$ and compute the result by performing the multiplications first.

Multiplication and division are not without their own problems. When multiplying two very large or very small numbers, it is quite possible for *overflow* or *underflow* to occur. The same situation occurs when dividing a small number by a large number or dividing a large number by a small number. This brings up a fourth rule you should attempt to follow when multiplying or dividing values:

- When multiplying and dividing sets of numbers, try to arrange the multiplications so that they multiply large and small numbers together; likewise, try to divide numbers that have the same relative magnitudes.

Comparing floating point numbers is very dangerous. Given the inaccuracies present in any computation (including converting an input string to a floating point value), you should *never* compare two floating point values to see if they are equal. In a binary floating point format, different computations which produce the same (mathematical) result may differ in their least significant bits. For example, adding 1.31e0+1.69e0 should produce 3.00e0. Likewise, adding 1.50e0+1.50e0 should produce 3.00e0. However, were you to compare (1.31e0+1.69e0) against (1.50e0+1.50e0) you might find out that these sums are *not* equal to one another. The test for equality succeeds if and only if all bits (or digits) in the two operands are exactly the same. Since this is not necessarily true after two different floating point computations which should produce the same result, a straight test for equality may not work.

The standard way to test for equality between floating point numbers is to determine how much error (or tolerance) you will allow in a comparison and check to see if one value is within this error range of the other. The straight-forward way to do this is to use a test like the following:

```
if Value1 >= (Value2-error) and Value1 <= (Value2+error) then ...
```

Another common way to handle this same comparison is to use a statement of the form:

```
if abs(Value1-Value2) <= error then ...
```

Most texts, when discussing floating point comparisons, stop immediately after discussing the problem with floating point equality, assuming that other forms of comparison are perfectly okay with floating point numbers. This isn't true! If we are assuming that $x=y$ if x is within $y\pm error$, then a simple bitwise comparison of x and y will claim that $x<y$ if y is greater than x but less than $y+error$. However, in such a case x should really be treated as equal to y , not less than y . Therefore, we must always compare two floating point numbers using ranges, regardless of the actual comparison we want to perform. Trying to compare two floating point numbers directly can lead to an error. To compare two floating point numbers, x and y , against one another, you should use one of the following forms:

```
= if abs(x-y) <= error then ...
≠ if abs(x-y) > error then ...
< if (x-y) < error then ...
≤ if (x-y) <= error then ...
> if (x-y) > error then ...
≥ if (x-y) >= error then ...
```

Although there are an infinite number of values between one and two, we can only represent eight million of them because we use a 23 bit mantissa (the 24th bit is always one). This is the reason for inaccuracy in floating point arithmetic – we are limited to 23 bits of precision in computations involving single precision floating point values.

The mantissa uses a *one's complement* format rather than two's complement. This means that the 24 bit value of the mantissa is simply an unsigned binary number and the sign bit determines whether that value is positive or negative. One's complement numbers have the unusual property that there are two representations for zero (with the sign bit set or clear). Generally, this is important only to the person designing the floating point software or hardware system. We will assume that the value zero always has the sign bit clear.

To represent values outside the range 1.0 to just under 2.0, the exponent portion of the floating point format comes into play. The floating point format raise two to the power specified by the exponent and then multiplies the mantissa by this value. The exponent is eight bits and is stored in an *excess-127* format. In excess-127 format, the exponent 2^0 is represented by the value 127 (\$7f). Therefore, to convert an exponent to excess-127 format simply add 127 to the exponent value. The use of excess-127 format makes it easier to compare floating point values. The single precision floating point format takes the form shown in Figure 4.2.

Figure 4.2 Single Precision (32-bit) Floating Point Format

With a 24 bit mantissa, you will get approximately $6\frac{1}{2}$ digits of precision (one half digit of precision means that the first six digits can all be in the range 0..9 but the seventh digit can only be in the range 0..x where $x < 9$ and is generally close to five). With an eight bit excess-127 exponent, the dynamic range of single precision floating point numbers is approximately $2^{\pm 128}$ or about $10^{\pm 38}$.

Although single precision floating point numbers are perfectly suitable for many applications, the dynamic range is somewhat limited for many scientific applications and the very limited precision is unsuitable for many financial, scientific, and other applications. Furthermore, in long chains of computations, the limited precision of the single precision format may introduce serious error.

The double precision format helps overcome the problems of single precision floating point. Using twice the space, the double precision format has an 11-bit excess-1023 exponent and a 53 bit mantissa (with an implied H.O. bit of one) plus a sign bit. This provides a dynamic range of about $10^{\pm 308}$ and $14\frac{1}{2}$ digits of precision, sufficient for most applications. Double precision floating point values take the form shown in Figure 4.3.

Figure 4.3 64-Bit Double Precision Floating Point Format

malized values allows IEEE floating point computations to produce better results than if underflow occurred, keep in mind that denormalized values offer less bits of precision.

Since the FPU always converts single and double precision values to extended precision, extended precision arithmetic is actually *faster* than single or double precision. Therefore, the expected performance benefit of using the smaller formats is not present on these chips. However, when designing the Pentium/586 CPU, Intel redesigned the built-in floating point unit to better compete with RISC chips. Most RISC chips support a native 64 bit double precision format which is faster than Intel's extended precision format. Therefore, Intel provided native 64 bit operations on the Pentium to better compete against the RISC chips. Therefore, the double precision format is the fastest on the Pentium and later chips.

4.2.2 HLA Support for Floating Point Values

HLA provides several data types and library routines to support the use of floating point data in your assembly language programs. These include built-in types to declare floating point variables as well as routines that provide floating point input, output, and conversion.

Perhaps the best place to start when discussing HLA's floating point facilities is with a description of floating point literal constants. HLA floating point constants allow the following syntax:

- An optional “+” or “-” symbol, denoting the sign of the mantissa (if this is not present, HLA assumes that the mantissa is positive),
- Followed by one or more decimal digits,
- Optionally followed by a decimal point and one or more decimal digits,
- Optionally followed by an “e” or “E”, optionally followed by a sign (“+” or “-”) and one or more decimal digits.

Note: the decimal point or the “e”/“E” must be present in order to differentiate this value from an integer or unsigned literal constant. Here are some examples of legal literal floating point constants:

```
1.234      3.75e2      -1.0      1.1e-1      1e+4      0.1      -123.456e+789      +25e0
```

Notice that a floating point literal constant cannot begin with a decimal point; it must begin with a decimal digit so you must use “0.1” to represent “.1” in your programs.

HLA also allows you to place an underscore character (“_”) between any two consecutive decimal digits in a floating point literal constant. You may use the underscore character in place of a comma (or other language-specific separator character) to help make your large floating point numbers easier to read. Here are some examples:

```
1_234_837.25      1_000.00      789_934.99      9_999.99
```

To declare a floating point variable you use the *real32*, *real64*, or *real80* data types. Like their integer and unsigned brethren, the number at the end of these data type declarations specifies the number of bits used for each type's binary representation. Therefore, you use *real32* to declare single precision real values, *real64* to declare double precision floating point values, and *real80* to declare extended precision floating point values. Other than the fact that you use these types to declare floating point variables rather than integers, their use is nearly identical to that for *int8*, *int16*, *int32*, etc. The following examples demonstrate these declarations and their syntax:

```
static

    fltVar1:  real32;
    fltVar1a: real32 := 2.7;
    pi:      real32 := 3.14159;
    DblVar:  real64;
    DblVar2: real64 := 1.23456789e+10;
    XPVar:   real80;
    XPVar2:  real80 := -1.0e-104;
```

To output a floating point variable in ASCII form, you would use one of the *stdout.putr32*, *stdout.putr64*, or *stdout.putr80* routines. These procedures display a number in decimal notation, that is, a string of digits, an optional decimal point and a closing string of digits. Other than their names, these three routines use exactly the same calling sequence. Here are the calls and parameters for each of these routines:

```
stdout.putr80( r:real80; width:uns32; decpts:uns32 );
stdout.putr64( r:real64; width:uns32; decpts:uns32 );
stdout.putr32( r:real32; width:uns32; decpts:uns32 );
```

The first parameter to these procedures is the floating point value you wish to print. The size of this parameter must match the procedure's name (e.g., the *r* parameter must be an 80-bit extended precision floating point variable when calling the *stdout.putr80* routine). The second parameter specifies the field width for the output text; this is the number of print positions the number will require when the procedure displays it. Note that this width must include print positions for the sign of the number and the decimal point. The third parameter specifies the number of print positions after the decimal point. For example,

```
stdout.putr32( pi, 10, 4 );
```

displays the value

```
_ _ _ _ 3.1416
```

(the underscores represent leading spaces in this example).

Of course, if the number is very large or very small, you will want to use scientific notation rather than decimal notation for your floating point numeric output. The HLA Standard Library *stdout.pute32*, *stdout.pute64*, and *stdout.pute80* routines provide this facility. These routines use the following procedure prototypes:

```
stdout.pute80( r:real80; width:uns32 );
stdout.pute64( r:real64; width:uns32 );
stdout.pute32( r:real32; width:uns32 );
```

Unlike the decimal output routines, these scientific notation output routines do not require a third parameter specifying the number of digits after the decimal point to display. The width parameter, indirectly, specifies this value since all but one of the mantissa digits always appears to the right of the decimal point. These routines output their values in decimal notation, similar to the following:

```
1.23456789e+10    -1.0e-104    1e+2
```

You can also output floating point values using the HLA Standard Library *stdout.put* routine. If you specify the name of a floating point variable in the *stdout.put* parameter list, the *stdout.put* code will output the value using scientific notation. The actual field width varies depending on the size of the floating point variable (the *stdout.put* routine attempts to output as many significant digits as possible, in this case). Example:

```
stdout.put( "XPVar2 = ", XPVar2 );
```

If you specify a field width specification, by using a colon followed by a signed integer value, then the *stdout.put* routine will use the appropriate *stdout.puteXX* routine to display the value. That is, the number will still appear in scientific notation, but you get to control the field width of the output value. Like the field width for integer and unsigned values, a positive field width right justifies the number in the specified field, a negative number left justifies the value. Here is an example that prints the *XPVar2* variable using ten print positions:

```
stdout.put( "XPVar2 = ", XPVar2:10 );
```

If you wish to use *stdout.put* to print a floating point value in decimal notation, you need to use the following syntax:

Variable_Name : Width : DecPts

Note that the *DecPts* field must be a non-negative integer value.

When *stdout.put* contains a parameter of this form, it calls the corresponding *stdout.putrXX* routine to display the specified floating point value. As an example, consider the following call:

```
stdout.put( "Pi = ", pi:5:3 );
```

The corresponding output is

3.142

The HLA Standard Library provides several other useful routines you can use when outputting floating point values. Consult the HLA Standard Library reference manual for more information on these routines.

The HLA Standard Library provides several routines to let you display floating point values in a wide variety of formats. In contrast, the HLA Standard Library only provides two routines to support floating point input: *stdin.getf()* and *stdin.get()*. The *stdin.getf()* routine requires the use of the 80x86 FPU stack, a hardware component that this chapter is not going to cover. Therefore, this chapter will defer the discussion of the *stdin.getf()* routine until the chapter on arithmetic, later in this text. Since the *stdin.get()* routine provides all the capabilities of the *stdin.getf()* routine, this deference will not prove to be a problem.

You've already seen the syntax for the *stdin.get()* routine; its parameter list simply contains a list of variable names. *Stdin.get()* reads appropriate values for the user for each of the variables appearing in the parameter list. If you specify the name of a floating point variable, the *stdin.get()* routine automatically reads a floating point value from the user and stores the result into the specified variable. The following example demonstrates the use of this routine:

```
stdout.put( "Input a double precision floating point value: " );
stdin.get( DblVar );
```

Warning: This section has discussed how you would declare floating point variables and how you would input and output them. It did not discuss arithmetic. Floating point arithmetic is different than integer arithmetic; you cannot use the 80x86 ADD and SUB instructions to operating on floating point values. Floating point arithmetic will be the subject of a later chapter in this text.

4.3 Binary Coded Decimal (BCD) Representation

Although the integer and floating point formats cover most of the numeric needs of an average program, there are some special cases where other numeric representations are convenient. In this section we'll discuss the Binary Coded Decimal (BCD) format since the 80x86 CPU provides a small amount of hardware support for this data representation.

BCD values are a sequence of nibbles with each nibble representing a value in the range zero through nine. Of course you can represent values in the range 0..15 using a nibble; the BCD format, however, uses only 10 of the possible 16 different values for each nibble.

Each nibble in a BCD value represents a single decimal digit. Therefore, with a single byte (i.e., two digits) we can represent values containing two decimal digits, or values in the range 0..99. With a word, we can represent values having four decimal digits, or values in the range 0..9999. Likewise, with a double word we can represent values with up to eight decimal digits (since there are eight nibbles in a double word value).

Figure 4.5 BCD Data Representation in Memory

As you can see, BCD storage isn't particularly memory efficient. For example, an eight-bit BCD variable can represent values in the range 0..99 while that same eight bits, when holding a binary value, can represent values in the range 0..255. Likewise, a 16-bit binary value can represent values in the range 0..65535 while a 16-bit BCD value can only represent about $\frac{1}{6}$ of those values (0..9999). Inefficient storage isn't the only problem. BCD calculations tend to be slower than binary calculations.

At this point, you're probably wondering why anyone would ever use the BCD format. The BCD format does have two saving graces: it's very easy to convert BCD values between the internal numeric representation and their string representation; also, it's very easy to encode multi-digit decimal values in hardware (e.g., using a "thumb wheel" or dial) using BCD than it is using binary. For these two reasons, you're likely to see people using BCD in embedded systems (e.g., toaster ovens and alarm clocks) but rarely in general purpose computer software.

A few decades ago people mistakenly thought that calculations involving BCD (or just 'decimal') arithmetic was more accurate than binary calculations. Therefore, they would often perform 'important' calculations, like those involving dollars and cents (or other monetary units) using decimal-based arithmetic. While it is true that certain calculations can produce more accurate results in BCD, this statement is not true in general. Indeed, for most calculations (even those involving fixed point decimal arithmetic), the binary representation is more accurate. For this reason, most modern computer programs represent all values in a binary form. For example, the Intel x86 floating point unit (FPU) supports a pair of instructions for loading and storing BCD values. Internally, however, the FPU converts these BCD values to binary and performs all calculations in binary. It only uses BCD as an external data format (external to the FPU, that is). This generally produces more accurate results and requires far less silicon than having a separate coprocessor that supports decimal arithmetic.

This text will take up the subject of BCD arithmetic in a later chapter (See "Decimal Arithmetic" on page 870.) Until then, you can safely ignore BCD unless you find yourself converting a COBOL program to assembly language (which is quite unlikely).

4.4 Characters

Perhaps the most important data type on a personal computer is the character data type. The term "character" refers to a human or machine readable symbol that is typically a non-numeric entity. In general, the term "character" refers to any symbol that you can normally type on a keyboard (including some symbols that may require multiple key presses to produce) or display on a video display. Many beginners often confuse the terms "character" and "alphabetic character." These terms are not the same. Punctuation symbols, numeric digits, spaces, tabs, carriage returns (enter), other control characters, and other special symbols are also characters. When this text uses the term "character" it refers to any of these characters, not just the alphabetic characters. When this text refers to alphabetic characters, it will use phrases like "alphabetic characters," "upper case characters," or "lower case characters."⁶

6. Upper and lower case characters are always alphabetic characters within this text.

Another common problem beginners have when they first encounter the character data type is differentiating between numeric characters and numbers. The character '1' is distinct and different from the value one. The computer (generally) uses two different internal, binary, representations for numeric characters ('0', '1', ..., '9') versus the numeric values zero through nine. You must take care not to confuse the two.

Most computer systems use a one or two byte sequence to encode the various characters in binary form. Windows certainly falls into this category, using either the ASCII or Unicode encodings for characters. This section will discuss the ASCII character set and the character declaration facilities that HLA provides.

4.4.1 The ASCII Character Encoding

The ASCII (American Standard Code for Information Interchange) Character set maps 128 textual characters to the unsigned integer values 0..127 (0..\$7F). Internally, of course, the computer represents everything using binary numbers; so it should come as no surprise that the computer also uses binary values to represent non-numeric entities such as characters. Although the exact mapping of characters to numeric values is arbitrary and unimportant, it is important to use a standardized code for this mapping since you will need to communicate with other programs and peripheral devices and you need to talk the same "language" as these other programs and devices. This is where the ASCII code comes into play; it is a standardized code that nearly everyone has agreed upon. Therefore, if you use the ASCII code 65 to represent the character "A" then you know that some peripheral device (such as a printer) will correctly interpret this value as the character "A" whenever you transmit data to that device.

You should not get the impression that ASCII is the only character set in use on computer systems. IBM uses the EBCDIC character set family on many of its mainframe computer systems. Another common character set in use is the Unicode character set. Unicode is an extension to the ASCII character set that uses 16 bits rather than seven to represent characters. This allows the use of 65,536 different characters in the character set, allowing the inclusion of most symbols in the world's different languages into a single unified character set.

Since the ASCII character set provides only 128 different characters and a byte can represent 256 different values, an interesting question arises: "what do we do with the values 128..255 that one could store into a byte value when working with character data?" One answer is to ignore those extra values. That will be the primary approach of this text. Another possibility is to extend the ASCII character set and add an additional 128 characters to the character set. Of course, this would tend to defeat the whole purpose of having a standardized character set unless you could get everyone to agree upon the extensions. That is a difficult task.

When IBM first created their IBM-PC, they defined these extra 128 character codes to contain various non-English alphabetic characters, some line drawing graphics characters, some mathematical symbols, and several other special characters. Since IBM's PC was the foundation for what we typically call a PC today, that character set has become a pseudo-standard on all IBM-PC compatible machines. Even on modern Windows machines, which are not IBM-PC compatible and cannot run early PC software, the IBM extended character set still survives. Note, however, that this PC character set (an extension of the ASCII character set) is not universal. Most printers will not print the extended characters when using native fonts and many programs (particularly in non-English countries) do not use those characters for the upper 128 codes in an eight-bit value. For these reasons, this text will generally stick to the standard 128 character ASCII character set. However, a few examples and programs in this text will use the IBM PC extended character set, particularly the line drawing graphic characters (see Appendix B).

Should you need to exchange data with other machines which are not PC-compatible, you have only two alternatives: stick to standard ASCII or ensure that the target machine supports the extended IBM-PC character set. Some machines, like the Apple Macintosh, do not provide native support for the extended IBM-PC character set; however you may obtain a PC font which lets you display the extended character set. Other machines have similar capabilities. However, the 128 characters in the standard ASCII character set are the only ones you should count on transferring from system to system.

Despite the fact that it is a "standard", simply encoding your data using standard ASCII characters does not guarantee compatibility across systems. While it's true that an "A" on one machine is most likely an "A"

on another machine, there is very little standardization across machines with respect to the use of the control characters. Indeed, of the 32 control codes plus delete, there are only four control codes commonly supported – backspace (BS), tab, carriage return (CR), and line feed (LF). Worse still, different machines often use these control codes in different ways. End of line is a particularly troublesome example. Windows, MS-DOS, CP/M, and other systems mark end of line by the two-character sequence CR/LF. Apple Macintosh, and many other systems mark the end of line by a single CR character. Linux, BeOS, and other UNIX systems mark the end of a line with a single LF character. Needless to say, attempting to exchange simple text files between such systems can be an experience in frustration. Even if you use standard ASCII characters in all your files on these systems, you will still need to convert the data when exchanging files between them. Fortunately, such conversions are rather simple.

Despite some major shortcomings, ASCII data is *the* standard for data interchange across computer systems and programs. Most programs can accept ASCII data; likewise most programs can produce ASCII data. Since you will be dealing with ASCII characters in assembly language, it would be wise to study the layout of the character set and memorize a few key ASCII codes (e.g., “0”, “A”, “a”, etc.).

The ASCII character set (excluding the extended characters defined by IBM) is divided into four groups of 32 characters. The first 32 characters, ASCII codes 0 through 1F (31), form a special set of non-printing characters called the control characters. We call them control characters because they perform various printer/display control operations rather than displaying symbols. Examples include *carriage return*, which positions the cursor to the left side of the current line of characters⁷, line feed (which moves the cursor down one line on the output device), and back space (which moves the cursor back one position to the left). Unfortunately, different control characters perform different operations on different output devices. There is very little standardization among output devices. To find out exactly how a control character affects a particular device, you will need to consult its manual.

The second group of 32 ASCII character codes comprise various punctuation symbols, special characters, and the numeric digits. The most notable characters in this group include the space character (ASCII code 20) and the numeric digits (ASCII codes 30..39). Note that the numeric digits differ from their numeric values only in the H.O. nibble. By subtracting 30 from the ASCII code for any particular digit you can obtain the numeric equivalent of that digit.

The third group of 32 ASCII characters is reserved for the upper case alphabetic characters. The ASCII codes for the characters “A”..”Z” lie in the range 41..5A (65..90). Since there are only 26 different alphabetic characters, the remaining six codes hold various special symbols.

The fourth, and final, group of 32 ASCII character codes are reserved for the lower case alphabetic symbols, five additional special symbols, and another control character (delete). Note that the lower case character symbols use the ASCII codes 61..7A. If you convert the codes for the upper and lower case characters to binary, you will notice that the upper case symbols differ from their lower case equivalents in exactly one bit position. For example, consider the character code for “E” and “e” in the following figure:

7. Historically, carriage return refers to the *paper carriage* used on typewriters. A carriage return consisted of physically moving the carriage all the way to the right so that the next character typed would appear at the left hand side of the paper.

Figure 4.6 ASCII Codes for “E” and “e”

The only place these two codes differ is in bit five. Upper case characters always contain a zero in bit five; lower case alphabetic characters always contain a one in bit five. You can use this fact to quickly convert between upper and lower case. If you have an upper case character you can force it to lower case by setting bit five to one. If you have a lower case character and you wish to force it to upper case, you can do so by setting bit five to zero. You can toggle an alphabetic character between upper and lower case by simply inverting bit five.

Indeed, bits five and six determine which of the four groups in the ASCII character set you’re in:

Table 9: ASCII Groups

| Bit 6 | Bit 5 | Group |
|-------|-------|----------------------|
| 0 | 0 | Control Characters |
| 0 | 1 | Digits & Punctuation |
| 1 | 0 | Upper Case & Special |
| 1 | 1 | Lower Case & Special |

So you could, for instance, convert any upper or lower case (or corresponding special) character to its equivalent control character by setting bits five and six to zero.

Consider, for a moment, the ASCII codes of the numeric digit characters:

Table 10: ASCII Codes for Numeric Digits

| Character | Decimal | Hexadecimal |
|-----------|---------|-------------|
| “0” | 48 | \$30 |
| “1” | 49 | \$31 |
| “2” | 50 | \$32 |
| “3” | 51 | \$33 |
| “4” | 52 | \$34 |

Table 10: ASCII Codes for Numeric Digits

| Character | Decimal | Hexadecimal |
|-----------|---------|-------------|
| "5" | 53 | \$35 |
| "6" | 54 | \$36 |
| "7" | 55 | \$37 |
| "8" | 56 | \$38 |
| "9" | 57 | \$39 |

The decimal representations of these ASCII codes are not very enlightening. However, the hexadecimal representation of these ASCII codes reveals something very important – the L.O. nibble of the ASCII code is the binary equivalent of the represented number. By stripping away (i.e., setting to zero) the H.O. nibble of a numeric character, you can convert that character code to the corresponding binary representation. Conversely, you can convert a binary value in the range 0..9 to its ASCII character representation by simply setting the H.O. nibble to three. Note that you can use the logical-AND operation to force the H.O. bits to zero; likewise, you can use the logical-OR operation to force the H.O. bits to %0011 (three).

Note that you *cannot* convert a string of numeric characters to their equivalent binary representation by simply stripping the H.O. nibble from each digit in the string. Converting 123 (\$31 \$32 \$33) in this fashion yields three bytes: \$010203, not the correct value which is \$7B. Converting a string of digits to an integer requires more sophistication than this; the conversion above works only for single digits.

4.4.2 HLA Support for ASCII Characters

Although you could easily store character values in *byte* variables and use the corresponding numeric equivalent ASCII code when using a character literal in your program, such agony is unnecessary - HLA provides good support for character variables and literals in your assembly language programs.

Character literal constants in HLA take one of two forms: a single character surrounded by apostrophes or a pound symbol (“#”) followed by a numeric constant in the range 0..127 specifying the ASCII code of the character. Here are some examples:

```
'A'      #65      #$41      %#0100_0001
```

Note that these examples all represent the same character ('A') since the ASCII code of 'A' is 65.

With a single exception, only a single character may appear between the apostrophes in a literal character constant. That single exception is the apostrophe character itself. If you wish to create an apostrophe literal constant, place four apostrophes in a row (i.e., double up the apostrophe inside the surrounding apostrophes), i.e.,

```
''''
```

The pound sign operator (“#”) must precede a legal HLA numeric constant (either decimal, hexadecimal or binary as the examples above indicate). In particular, the pound sign is not a generic character conversion function; it cannot precede registers or variable names, only constants. As a general rule, you should always use the apostrophe form of the character literal constant for graphic characters (that is, those that are printable or displayable). Use the pound sign form of character literal constants for control characters (that are invisible, or do funny things when you print them) or for extended ASCII characters that may not display or print properly within your source code.

Notice the difference between a character literal constant and a string literal constant in your programs. Strings are sequences of zero or more characters surrounded by quotation marks, characters are surrounded by apostrophes. It is especially important to realize that

```
'A' ≠ "A"
```

The character constant 'A' and the string containing the single character "A" have two completely different internal representations. If you attempt to use a string containing a single character where HLA expects a character constant, HLA will report an error. Strings and string constants will be the subject of a later chapter.

To declare a character variable in an HLA program, you use the *char* data type. The following declaration, for example, demonstrates how to declare a variable named *UserInput*:

```
static
    UserInput:    char;
```

This declaration reserves one byte of storage that you could use to store any character value (including eight-bit extended ASCII characters). You can also initialize character variables as the following example demonstrates:

```
static

    TheCharA:    char := 'A';
    ExtendedChar char := #128;
```

Since character variables are eight-bit objects, you can manipulate them using eight-bit registers. You can move character variables into eight-bit registers and you can store the value of an eight-bit register into a character variable.

The HLA Standard Library provides a handful of routines that you can use for character I/O and manipulation; these include *stdout.putc*, *stdout.putcSize*, *stdout.put*, *stdin.getc*, and *stdin.get*.

The *stdout.putc* routine uses the following calling sequence:

```
stdout.putc( chvar );
```

This procedure outputs the single character parameter passed to it as a character to the standard output device. The parameter may be any *char* constant or variable, or a *byte* variable or register⁸.

The *stdout.putcSize* routine provides output width control when displaying character variables. The calling sequence for this procedure is

```
stdout.putcSize( charvar, widthInt32, fillchar );
```

This routine prints the specified character (parameter *c*) using at least *width* print positions⁹. If the absolute value of *width* is greater than one, then *stdout.putcSize* prints the *fill* character as padding. If the value of *width* is positive, then *stdout.putcSize* prints the character right justified in the print field; if *width* is negative, then *stdout.putcSize* prints the character left justified in the print field. Since character output is usually left justified in a field, the *width* value will normally be negative for this call. The space character is the most common value used for the *fill* character.

You can also print character values using the generic *stdout.put* routine. If a character variable appears in the *stdout.put* parameter list, then *stdout.put* will automatically print it as a character value, e.g.,

```
stdout.put( "Character c = ", c, "", nl );
```

You can read characters from the standard input using the *stdin.getc* and *stdin.get* routines. The *stdin.getc* routine does not have any parameters. It reads a single character from the standard input buffer and returns this character in the AL register. You may then store the character value away or otherwise manipulate the character in the AL register. The following program reads a single character from the user, converts it to upper case if it is a lower case character, and then displays the character:

8. If you specify a byte variable or a byte-sized register as the parameter, the *stdout.putc* routine will output the character whose ASCII code appears in the variable or register.

9. The only time *stdout.putcSize* uses more print positions than you specify is when you specify zero as the width; then this routine uses exactly one print position.

```

program charInputDemo;
#include( "stdlib.hhf" );
static
    c:char;

begin charInputDemo;

    stdout.put( "Enter a character: " );
    stdin.getc();
    if( al >= 'a' ) then

        if( al <= 'z' ) then

            and( $5f, al );

        endif;

    endif;
    stdout.put
    (
        "The character you entered, possibly ", nl,
        "converted to upper case, was '"
    );
    stdout.putc( al );
    stdout.put( "'", nl );

end charInputDemo;

```

Program 4.1 Character Input Sample

You can also use the generic *stdin.get* routine to read character variables from the user. If a *stdin.get* parameter is a character variable, then the *stdin.get* routine will read a character from the user and store the character value into the specified variable. Here is the program above rewritten to use the *stdin.get* routine:

```

program charInputDemo2;
#include( "stdlib.hhf" );
static
    c:char;

begin charInputDemo2;

    stdout.put( "Enter a character: " );
    stdin.get(c);
    if( c >= 'a' ) then

        if( c <= 'z' ) then

            and( $5f, c );

        endif;

    endif;
    stdout.put
    (
        "The character you entered, possibly ", nl,
        "converted to upper case, was '",
        c,

```

```

        "", nl
    );
end charInputDemo2;

```

Program 4.2 Stdin.get Character Input Sample

As you may recall from the last chapter, the HLA Standard Library buffers its input. Whenever you read a character from the standard input using *stdin.getc* or *stdin.get*, the library routines read the next available character from the buffer; if the buffer is empty, then the program reads a new line of text from the user and returns the first character from that line. If you want to guarantee that the program reads a new line of text from the user when you read a character variable, you should call the *stdin.flushInput* routine before attempting to read the character. This will flush the current input buffer and force the input of a new line of text on the next input (which should be your *stdin.getc* or *stdin.get* call).

The end of line is problematic. Different operating systems handle the end of line differently on output versus input. From the console device, pressing the ENTER key signals the end of a line; however, when reading data from a file you get an end of line sequence which is typically a line feed or a carriage return/line feed pair. To help solve this problem, HLA's Standard Library provides an "end of line" function. This procedure returns true (one) in the AL register if all the current input characters have been exhausted, it returns false (zero) otherwise. The following sample program is a rewrite of the above code using the *stdin.eoln* function.

```

program eolnDemo2;
#include( "stdlib.hhf" );
begin eolnDemo2;

    stdout.put( "Enter a short line of text: " );
    stdin.flushInput();
    repeat

        stdin.getc();
        stdout.putc( al );
        stdout.put( "=$", al, nl );

    until( stdin.eoln() );

end eolnDemo2;

```

Program 4.3 Testing for End of Line Using Stdin.eoln

The HLA language and the HLA Standard Library provide many other procedures and additional support for character objects. Later chapters in this textbook, as well as the HLA reference documentation, describe how to use these features.

4.4.3 The ASCII Character Set

The following table lists the binary, hexadecimal, and decimal representations for each of the 128 ASCII character codes.

4.5 The UNICODE Character Set

Although the ASCII character set is, unquestionably, the most popular character representation on computers, it is certainly not the only format around. For example, IBM uses the EBCDIC code on many of its mainframe and minicomputer lines. Since EBCDIC appears mainly on IBM's big iron and you'll rarely encounter it on personal computer systems, we will not consider that character set in this text. Another character representation that is becoming popular on small computer systems (and large ones, for that matter) is the Unicode character set. Unicode overcomes two of ASCII's greatest limitations: the limited character space (i.e., a maximum of 128/256 characters in an eight-bit byte) and the lack of international (beyond the USA) characters.

Unicode uses a 16-bit word to represent a single character. Therefore, Unicode supports up to 65,536 different character codes. This is obviously a huge advance over the 256 possible codes we can represent with an eight-bit byte. Unicode is upwards compatible from ASCII. Specifically, if the H.O. 17 bits of a Unicode character contain zero, then the L.O. seven bits represent the same character as the ASCII character with the same character code. If the H.O. 17 bits contain some non-zero value, then the character represents some other value. If you're wondering why so many different character codes are necessary, simply note that certain Asian character sets contain 4096 characters (at least, their Unicode subset).

This text will stick to the ASCII character set except for a few brief mentions of Unicode here and there. Eventually, this text may have to eliminate the discussion of ASCII in favor of Unicode since all new versions of Windows use Unicode internally (and convert to ASCII as necessary). Unfortunately, many string algorithms are not as conveniently written for Unicode as for ASCII (especially character set functions) so we'll stick with ASCII in this text as long as possible.

4.6 Other Data Representations

Of course, we can represent many different objects other than numbers and characters in a computer system. The following subsections provide a brief description of the different real-world data types you might encounter.

4.6.1 Representing Colors on a Video Display

As you're probably aware, color images on a computer display are made up of a series of dots known as *pixels* (which is short for "picture elements."). Different display modes (depending on the capability of the display adapter) use different data representations for each of these pixels. The one thing in common between these data types is that they control the mixture of the three additive primary colors (red, green, and blue) to form a specific color on the display. The question, of course, is how much of each of these colors do they mix together?

Color depth is the term video card manufacturers use to describe how much red, green, and blue they mix together for each pixel. Modern video cards generally provides three color depths of eight, sixteen, or twenty-four bits, allowing 256, 65536, or over 16 million colors per pixel on the display. This produces images that are somewhat coarse and grainy (eight-bit images) to “Polaroid quality” (16-bit images), on up to “photographic quality” (24-bit images)¹⁰.

One problem with these color depths is that two of the three formats do not contain a number of bits that is evenly divisible by three. Therefore, in each of these formats at least one of the three primary colors will have fewer bits than the others. For example, with an eight-bit color depth, two of the colors can have three bits (or eight different shades) associated with them while one of the colors must have only two bits (or four shades). Therefore, when distributing the bits there are three formats possible: 2-3-3 (two bits red, three bits green, and three bits blue), 3-2-3, or 3-3-2. Likewise, with a 16 bit color depth, two of the three colors can have five bits while the third color can have six bits. This lets us generate three different palettes using the bit values 5-5-6, 5-6-5, or 6-5-5. For 24-bit displays, each primary color can have eight bits, so there is an even distribution of the colors for each pixel.

A 24-bit display produces amazingly good results. A 16-bit display produces okay images. Eight-bit displays, to put it bluntly, produce horrible photographic images (they do produce good synthetic images like those you would manipulate with a draw program). To produce better images when using an eight-bit display, most cards provide a hardware *palette*. A palette is nothing more than an array of 24-bit values containing 256 elements¹¹. The system uses the eight-bit pixel value as an index into this array of 256 values and displays the color associated with the 24-bit entry in the palette table. Although the display can still display only 256 different colors at one time, the palette mechanism lets users select exactly which colors they want to display. For example, they could display 250 shades of blue and six shades of purple if such a mixture produces a better image for them.

10. Some graphic artists would argue that 24 bit images are not of a sufficient quality. There are some display/printer/scanner devices capable of working with 33-bit, 36-bit, and even 48-bit images; if, of course, you're willing to pay for them.

11. Actually, the color depth of each palette entry is not necessarily fixed at 24 bits. Some display devices, for example, use 18-bit entries in their palette.

Figure 4.7 Extending the Number of Colors Using a Palette

Unfortunately, the palette scheme only works for displays with minimal color depths. For example, attempting to use a palette with 16-bit images would require a lookup table with 65,536 different three-byte entries – a bit much for today’s operating systems (since they may have to reload the palette every time you select a window on the display). Fortunately, the higher bit depths don’t require the palette concept as much as the eight-bit color depth.

Obviously, we could dream up other schemes for representing pixel color on the display. Some display systems, for example, use the subtractive primary colors (Cyan, Yellow, and Magenta, plus Black, the so-called CMYK color space). Other display system use fewer or more bits to represent the values. Some distribute the bits between various shades. Monochrome displays typically use one, four, or eight bit pixels to display various gray scales (e.g., two, sixteen, or 256 shades of gray). However, the bit organizations of this section are among the more popular in use by display adapters.

4.6.2 Representing Audio Information

Another real-world quantity you’ll often find in digital form on a computer is audio information. WAV files, MP3 files, and other audio formats are quite popular on personal computers. An interesting question is “how do we represent audio information inside the computer?” While many sound formats are far too com-

plex to discuss here (e.g., the MP3 format), it is relatively easy to represent sound using a simple sound data format (something similar to the WAV file format). In this section we'll explore a couple of possible ways to represent audio information; but before we take a look at the digital format, perhaps it's a wise idea to study the analog format first.

Figure 4.8 Operation of a Speaker

Sounds you hear are the result of vibrating air molecules. When air molecules quickly vibrate back and forth between 20 and 20,000 times per second, we interpret this as some sort of sound. A speaker (see Figure 4.8) is a device which vibrates air in response to an electrical signal. That is, it converts an electric signal which alternates between 20 and 20,000 times per second (Hz) to an audible tone. Alternating a signal is very easy on a computer, all you have to do is apply a logic one to an output port for some period of time and then write a logic zero to the output port for a short period. Then repeat this over and over again. A plot of this activity over time appears in Figure 4.9.

Note: Frequency is equal to the reciprocal of the clock period. Audible sounds are between 20 and 20,000 Hz.

Figure 4.9 An Audible Sound Wave

Although many humans are capable of hearing tones in the range 20-20Khz, the PC's speaker is not capable of faithfully reproducing the tones in this range. It works pretty good for sounds in the range 100-10Khz, but the volume drops off dramatically outside this range. Fortunately, most modern PCs contain a sound card that is quite capable (with appropriate external speakers) of faithfully representing "CD-Quality" sound. Of course, a good question might be "what is CD-Quality sound, anyway?" Well, to answer

that question, we've got to decide how we're going to represent sound information in a binary format (see "What is "Digital Audio" Anyway?" on page 102).

Take another look at Figure 4.9. This is a graph of amplitude (volume level) over time. If logic one corresponds to a fully extended speaker cone and logic zero corresponds to a fully retracted speaker cone, then the graph in Figure 4.9 suggests that we are constantly pushing the speaker cone in and out as time progresses. This analog data, by the way, produces what is known as a "square wave" which tends to be a very bright sound at high frequencies and a very buzzy sound at low frequencies. One advantage of a square wave tone is that we only need to alternate a single bit of data over time in order to produce a tone. This is very easy to do and very inexpensive. These two reasons are why the PC's built-in speaker (not the sound card) uses exactly this technique for produces beeps and squawks.

To produce different tones with a square wave sound system is very easy. All you've got to do is write a one and a zero to some bit connected to the speaker somewhere between 20 and 20,000 times per second. You can even produce "warbling" sounds by varying the frequency at which you write those zeros and ones to the speaker.

One easy data format we can develop to represent digitized (or, should we say, "binarized") audio data is to create a stream of bits that we feed to the speaker every $\frac{1}{40,000}$ seconds. By alternating ones and zeros in this bit stream, we get a 20 KHz tone (remember, it takes a high and a low section to give us one clock period, hence it will take two bits to produce a single cycle on the output). To get a 20 Hz tone, you would create a bit stream that alternates between 1,000 zeros and 1,000 ones. With 1,000 zeros, the speaker will remain in the retracted position for $\frac{1}{40}$ seconds, following that with 1,000 ones leaves the speaker in the fully extended position for $\frac{1}{40}$ seconds. The end result is that the speaker moves in and out 20 times a second (giving us our 20 Hz frequency). Of course, you don't have to emit a regular pattern of zeros and ones. By varying the positions of the ones and zeros in your data stream you can dramatically affect the type of sound the system will produce.

The length of your data stream will determine how long the sound plays. With 40,000 bits, the sound will play for one second (assuming each bit's duration is $\frac{1}{40,000}$ seconds). As you can see, this sound format will consume 5,000 bytes per second. This may seem like a lot, but it's relatively modest by digital audio standards.

Unfortunately, square waves are very limited with respect to the sounds you can produce with them and they are not very high fidelity (certainly not "CD-Quality"). Real analog audio signals are much more complex and you cannot represent them with two different voltage levels on a speaker. Figure 4.10 provides a

What is "Digital Audio" Anyway?

"Digital Audio" or "digitized audio" is the conventional term the consumer electronics industry uses to describe audio information encoded for use on a computer. What exactly does the term "digital" mean in this case. Historically, the term "digit" refers to a finger. A digital numbering system is one based on counting one's fingers. Traditionally, then, a "digital number" was a base ten number (since the numbering system we most commonly use is based on the ten digits with which God endowed us). In the early days of computer systems the terms "digital computer" and "binary computer" were quite prevalent, with digital computers describing decimal computer systems (i.e., BCD-based systems). Binary computers, of course, were those based on the binary numbering system. Although BCD computers are mainly an artifact in the historical dust bin, the name "digital computer" lives on and is the common term to describe all computer systems, binary or otherwise. Therefore, when people talk about the logic gates computer designers use to create computer systems, they call them "digital logic." Likewise, when they refer to computerized data (like audio data), they refer to it as "digital." Technically, the term "digital" should mean base ten, not base two. Therefore, we should really refer to "digital audio" as "binary audio" to be technically correct. However, it's a little late in the game to change this term, so "digital XXXXX" lives on. Just keep in mind that the two terms "digital audio" and "binary audio" really do mean the same thing, even though they shouldn't.

typical example of an audio waveform. Notice that the frequency and the amplitude (the height of the signal) varies considerably over time. To capture the height of the waveform at any given point in time we will need more than two values; hence, we'll need more than a single bit.

Figure 4.10 A Typical Audio Waveform

An obvious first approximation is to use a byte, rather than a single bit, to represent each point in time on our waveform. We can convert this byte data to an analog signal using a device that is called a “digital to analog converter” (how obvious) or DAC. This accepts some binary number as input and produces an analog voltage on its output. This allows us to represent an impressive 256 different voltage levels in the waveform. By using eight bits, we can produce a far wider range of sounds than are possible with a single bit. Of course, our data stream now consumes 40,000 bytes per second; quite a big step up from the 5,000 bytes/second in the previous example, but still relatively modest in terms of digital audio data rates.

You might think that 256 levels would be sufficient to produce some impressive audio. Unfortunately, our hearing is logarithmic in nature and it takes an order of magnitude difference in signal for a sound to appear just a little bit louder. Therefore, our 256 different analog levels aren't as impressive to our ears. Although you can produce some decent sounds with an eight-bit data stream, it's still not high fidelity and certainly not “CD-Quality” audio.

The next obvious step up the ladder is a 16-bit value for each point of our digital audio stream. With 65,536 different analog levels we finally reach the realm of “CD-Quality” audio. Of course, we're now consuming 80,000 bytes per second to achieve this! For technical reasons, the Compact Disc format actually requires 44,100 16-bit samples per second. For a stereo (rather than monaural) data stream, you need two 16-bit values each $\frac{1}{44,100}$ seconds. This produces a whopping data rate of over 160,000 bytes per second. Now you understand the claim a littler earlier that 5,000 bytes per second is a relatively modest data rate.

Some very high quality digital audio systems use 20 or 24 bits of information and record the data at a higher frequency than 44.1 KHz (48 KHz is popular, for example). Such data formats record a better signal at the expense of a higher data rate. Some sound systems don't require anywhere near the fidelity levels of even a CD-Quality recording. Telephone conversations, for example, require only about 5,000 eight-bit samples per second (this, by the way, is why phone modems are limited to approximately 56,000 bits per second, which is about 5,000 bytes per second plus some overhead). Some common “digitizing” rates for audio include the following:

- Eight-bit samples at 11 KHz
- Eight-bit samples at 22 KHz
- Eight-bit samples at 44.1 KHz
- 16-bit samples at 32 KHz
- 16-bit samples at 44.1 KHz
- 16-bit samples at 48 KHz
- 24-bit samples at 44.1 KHz (generally in professional recording systems)
- 24-bit samples at 48 KHz (generally in professional recording systems)

The fidelity increases as you move down this list.

The exact format for various audio file formats is way beyond the scope of this text since many of the formats incorporate data compression. Some simple audio file formats like WAV and AIFF consist of little more than the digitized byte stream, but other formats are nearly indecipherable in their complexity. The exact nature of a sound data type is highly dependent upon the sound hardware in your system, so we won't delve any farther into this subject. There are several books available on computer audio and sound file formats if you're interested in pursuing this subject farther.

4.6.3 Representing Musical Information

Although it is possible to compress an audio data stream somewhat, high-quality audio will consume a large amount of data. CD-Quality audio consumes just over 160 Kilobytes per second, so a CD at 650 Megabytes holds enough data for just over an hour of audio (in stereo). Earlier, you saw that we could use a palette to allow higher quality color images on an eight-bit display. An interesting question is "can we create a sound palette to let us encode higher quality audio?" Unfortunately, the general answer is no because audio information is much less redundant than video information and you cannot produce good results with rough approximation (which using a sound palette would require). However, if you're trying to produce a specific sound, rather than trying to faithfully reproduce some recording, there are some possibilities open to you.

The advantage to the digitized audio format is that it records *everything*. In a music track, for example, the digital information records all the instruments, the vocalists, the background noise, and, well, *everything*. Sometimes you might not need to retain all this information. For example, if all you want to record is a keyboard player's synthesizer, the ability to record all the other audio information simultaneously is not necessary. In fact, with an appropriate interface to the computer, recording the audio signal from the keyboard is completely unnecessary. A far more cost-effective approach (from a memory usage point of view) is to simply record the notes the keyboardist plays (along with the duration of each note and the velocity at which the keyboardist plays the note) and then simply feed this keyboard information back to the synthesizer to play the music at a later time. Since it only takes a few bytes to record each note the keyboardist plays, and the keyboardist generally plays fewer than 100 notes per second, the amount of data needed to record a complex piece of music is tiny compared to a digitized audio recording of the same performance.

One very popular format for recording musical information in this fashion is the MIDI format (MIDI stands for Musical Instrument Digital Interface and it specifies how to connect musical instructions, computers, and other equipment together). The MIDI protocol uses multi-byte values to record information about a series of instruments (a simple MIDI file can actually control up to 16 or more instruments simultaneously).

Although the internal data format of the MIDI protocol is beyond the scope of this chapter, it is interesting to note that a MIDI command is effectively equivalent to a "palette look-up" for an audio signal. When a musical instrument receives a MIDI command telling it to play back some note, that instrument generally plays back some waveform stored in the synthesizer.

Note that you don't actually need an external keyboard/synthesizer to play back MIDI files. Most sound cards contain software that will interpret MIDI commands and play the accompanying notes. These cards definitely use the MIDI command as an index into a "wave table" (short for waveform lookup table) to play the accompanying sound. Although the quality of the sound these cards reproduce is often inferior to that a professional synthesizer produces, they do let you play MIDI files without purchasing an expensive synthesizer module¹².

If you're interested in the actual data format that MIDI uses, there are dozens of texts available on the MIDI format. Any local music store should carry several of these. You should also be able to find lots of information on MIDI on the Internet (try Roland's web site as a good starting point).

12. For those who would like a better MIDI experience using a sound card, some synthesizer manufacturers produce sound cards with an integrated synthesizer on-board.

4.6.4 Representing Video Information

Recent increases in disk space, computer speed, and network access have allowed an explosion in the popularity of multimedia on personal computers. Although the term “multimedia” suggests that the data format deals with many different types of media, most people use this term to describe digital video recording and playback on a computer system. In fact, most multimedia formats support at least two mediums: video and audio. The more popular formats like Apple’s Quicktime support other concurrent media streams as well (e.g., a separate subtitle track, time codes, and device control). To simplify matters, we limit the discussion in this section to digital video streams.

Fundamentally, a video image is nothing more than a succession of still pictures that the system displays at some rate like 30 images per second. Therefore, if we want to create a digitized video image format, all we really need to do is store 30 or so pictures for each second of video we wish to view. This may not seem like a big deal, but consider that a typical “full screen” video display has 640x480 pixels or a total of 307,200 pixels. If we use a 24-bit RGB color space, then each pixel will require three bytes, raising the total to 921,600 bytes per image. Displaying 30 of these images per second means our video format will consume 27,648,000 bytes per second. Digital audio, at 160 Kilobytes per second is virtually nothing compared to the data requirements for digital video.

Although computer systems and hard disk systems have advanced tremendously over the past decade, maintaining a 30 MByte/second data rate from disk to display is a little too much to expect from all but the most expensive workstations currently available (at least, in the year 2000 as this was written). Therefore, most multimedia systems use various techniques (or combinations of these techniques) to get the data rate down to something more reasonable. In stock computer systems, a common technique is to display a 320x240 quarter screen image rather than a full-screen 640x480 image. This reduces the data rate to about seven megabytes per second.

Another technique digital video formats use is to *compress* the video data. Video data tends to contain lots of redundant information that the system can eliminate through the use of compression. The popular DV format for digital video camcorders, for example, compresses the data stream by almost 90%, requiring only a 3.3 MByte/second data rate for full-screen video. This type of compression is not without cost. There is a detectable, though slight, loss in image quality when employing DV compression on a video image. Nevertheless, this compression makes it possible to deal with digital video data streams on a contemporary computer system. Compressed data formats are a little beyond the scope of this chapter; however, by the time you finish this text you should be well-prepared to deal with compressed data formats. Programmers writing video data compression algorithms often use assembly language because compression and decompression algorithms need to be very fast to process a video stream in real time. Therefore, keep reading this text if you’re interested in working on these types of algorithms.

4.6.5 Where to Get More Information About Data Types

Since there are many ways to represent a particular real-world object inside the computer, and nearly an infinite variety of real-world objects, this text cannot even begin to cover all the possibilities. In fact, one of the most important steps in writing a piece of computer software is to carefully consider what objects the software needs to represent and then choose an appropriate internal representation for that object. For some objects or processes, an internal representation is fairly obvious; for other objects or processes, developing an appropriate data type representation is a difficult task. Although we will continue to look at different data representations throughout this text, if you’re really interested in learning more about data representation of real world objects, activities, and processes, you should consult a good “Data Structures and Algorithms” textbook. This text does not have the space to treat these subjects properly (since it still has to teach assembly language). Most texts on data structures present their material in a high level language. Adopting this material to assembly language is not difficult, especially once you’ve digested a large percentage of this text. For something a little closer to home, you might consider reading Knuth’s “The Art of Computer Programming” that describes data structures and algorithms using a synthetic assembly language called *MIX*. Although *MIX* isn’t the same as HLA or even x86 assembly language, you will probably find it easier to

convert algorithms in this text to x86 than it would be to convert algorithms written in Pascal, Java, or C++ to assembly language.

4.7 Putting It All Together

Perhaps the most important fact this chapter and the last chapter present is that computer programs all use strings of binary bits to represent data internally. It is up to an application program to distinguish between the possible representations. For example, the bit string %0100_0001 could represent the numeric value 65, an ASCII character ('A'), or the mantissa portion of a floating point value (\$41). The CPU cannot and does not distinguish between these different representations, it simply processes this eight-bit value as a bit string and leaves the interpretation of the data to the application.

Beginning assembly language programmers often have trouble comprehending that they are responsible for interpreting the type of data found in memory; after all, one of the most important abstractions that high level languages provide is to associate a data type with a bit string in memory. This allows the compiler to do the interpretation of data representation rather than the programmer. Therefore, an important point this chapter makes is that assembly language programmers must handle this interpretation themselves. The HLA language provides built-in data types that seem to provide these abstractions, but keep in mind that once you've loaded a value into a register, HLA can no longer interpret that data for you, it is your responsibility to use the appropriate machine instructions that operate on the specified data.

One small amount of checking that HLA and the CPU does enforce is size checking - HLA will not allow you to mix sizes of operands within most instructions¹³. That is, you cannot specify a byte operand and a word operand in the same instruction that expects its two operands to be the same size. However, as the following program indicates, you can easily write a program that treats the same value as completely different types.

```

program dataInterpretation;
#include( "stdlib.hhf" );
static
    r: real32 := -1.0;

begin dataInterpretation;

    stdout.put( ``r' interpreted as a real32 value: ", r:5:2, nl );

    stdout.put( ``r' interpreted as an uns32 value: " );
    mov( r, eax );
    stdout.putu32( eax );
    stdout.newln();

    stdout.put( ``r' interpreted as an int32 value: " );
    mov( r, eax );
    stdout.puti32( eax );
    stdout.newln();

    stdout.put( ``r' interpreted as a dword value: $" );
    mov( r, eax );
    stdout.putdw( eax );
    stdout.newln();

end dataInterpretation;

```

13. The sign and zero extension instructions are an obvious exception, though HLA still checks the operand sizes to ensure they are appropriate.

Program 4.4 Interpreting a Single Value as Several Different Data Types

As this sample program demonstrates, you can get completely different results by interpreting your data differently during your program's execution. So always remember, it is your responsibility to interpret the data in your program. HLA helps a little by allowing you to declare data types that are slightly more abstract than bytes, words, or double words; HLA also provides certain support routines, like `stdout.put`, that will automatically interpret these abstract data types for you; however, it is generally your responsibility to use the appropriate machine instructions to consistently manipulate memory objects according to their data type.

 - b) 16-bit general purpose registers.
 - c) 32-bit general purpose registers.
- 4) Which registers overlap with
 - a) ax?
 - b) bx?
 - c) cx?
 - d) dx?
 - e) si?
 - f) di?
 - g) bp?
 - h) sp?
- 5) In what register does the condition codes appear?
- 6) What is the generic syntax of the HLA MOV instruction?
- 7) What are the legal operand formats for the MOV instruction?
- 8) What do the following symbols denote in an HLA boolean expression?
 - a) @c
 - b) @nc
 - c) @z
 - d) @nz
 - e) @o
 - f) @no
 - g) @s
 - h) @ns
- 9) Collectively, what do we call the carry, overflow, zero, and sign flags?
- 10) What high level language control structures does HLA provide?

- 11) What does the *nl* symbol represent?
- 12) What routine would you call, that doesn't require any parameters, to print a new line on the screen?
- 13) If you wanted to print a nicely-formatted column of 32-bit integer values, what standard library routines could you call to achieve this?
- 14) The `stdin.getc()` routine does not allow a parameter. Where does it return the character it reads from the user?
- 15) When reading an integer value from the user via the `stdin.getiX` routines, the program will stop with an exception if the user enters a value that is out of range or enters a value that contains illegal characters. How can you trap this error?
- 16) What is the difference between the `stdin.ReadLn()` and `stdin.FlushInput()` procedures?
- 17) Convert the following decimal values to binary:

| | | | | |
|-----------|-----------|-----------|----------|-----------|
| a) 128 | b) 4096 | c) 256 | d) 65536 | e) 254 |

| u) 0BEAD | v) 0ABE | w) 0DEAF | x) 0DAD | y) 9876 |

Perform the following hex computations (leave the result in hex):

- 21) 1234 + 9876
- 22) 0FFF - 0F34
- 23) 100 - 1
- 24) 0FFE - 1
- 25) What is the importance of a nibble?
- 26) How many hexadecimal digits in:

| | | |
|-----------|-----------|------------------|
| a) a byte | b) a word | c) a double word |
|-----------|-----------|------------------|
- 27) How many bits in a:

| | | | |
|-----------|---------|---------|----------------|
| a) nibble | b) byte | c) word | d) double word |
|-----------|---------|---------|----------------|
- 28) Which bit (number) is the H.O. bit in a:

- a) nibble b) byte c) word d) double word
- 29) What character do we use as a suffix for hexadecimal numbers? Binary numbers? Decimal numbers?
- 30) Assuming a 16-bit two's complement format, determine which of the values in question 4 are positive and which are negative.
- 31) Sign extend all of the values in question two to sixteen bits. Provide your answer in hex.
- 32) Perform the bitwise AND operation on the following pairs of hexadecimal values. Present your answer in hex. (Hint: convert hex values to binary, do the operation, then convert back to hex).
- a) 0FF00, 0FF0b) 0F00F, 1234c) 4321, 1234d) 2341, 3241 e) 0FFFF, 0EDCB
- f) 1111, 5789g) 0FABA, 4322h) 5523, 0F572i) 2355, 7466 j) 4765, 6543
- k) 0ABCD, 0EFDCl) 0DDDD, 1234m) 0CCCC, 0ABCDo) 0BBBB, 1234o) 0AAAA, 1234
- p) 0EEEE, 1248q) 8888, 1248r) 8086, 124Fs) 8086, 0CFA7 t) 8765, 3456
- u) 7089, 0FEDCv) 2435, 0BCDEw) 6355, 0EFDCx) 0CBA, 6884y) 0AC7, 365
- 33) Perform the logical OR operation on the above pairs of numbers.
- 34) Perform the logical XOR operation on the above pairs of numbers.
- 35) Perform the logical NOT operation on all the values in question four. Assume all values are 16 bits.
- 36) Perform the two's complement operation on all the values in question four. Assume 16 bit values.
- 37) Sign extend the following hexadecimal values from eight to sixteen bits. Present your answer in hex.
- a) FF b) 82 c) 12 d) 56 e) 98
- f) BF g) 0F h) 78 i) 7F j) F7
- k) 0E l) AE m) 45 n) 93 o) C0
- p) 8F q) DA r) 1D s) 0D t) DE
- u) 54 v) 45 w) F0 x) AD y) DD
- 38) Sign contract the following values from sixteen bits to eight bits. If you cannot perform the operation, explain why.
- a) FF00 b) FF12 c) FFF0 d) 12 e) 80
- f) FFFF g) FF88 h) FF7F i) 7F j) 2
- k) 8080 l) 80FF m) FF80 n) FF o) 8
- p) F q) 1 r) 834 s) 34 t) 23
- u) 67 v) 89 w) 98 x) FF98 y) F98
- 39) Sign extend the 16-bit values in question 22 to 32 bits.
- 40) Assuming the values in question 22 are 16-bit values, perform the left shift operation on them.
- 41) Assuming the values in question 22 are 16-bit values, perform the logical right shift operation on them.
- 42) Assuming the values in question 22 are 16-bit values, perform the arithmetic right shift operation on them.
- 43) Assuming the values in question 22 are 16-bit values, perform the rotate left operation on them.
- 44) Assuming the values in question 22 are 16-bit values, perform the rotate right operation on them.
- 45) Convert the following dates to the short packed format described in this chapter (see "Bit Fields and Packed Data" on page 71). Present your values as a 16-bit hex number.
- a) 1/1/92b) 2/4/56 c) 6/19/60 d) 6/16/86 e) 1/1/99
- 46) Convert the above dates to the long packed data format described in this chapter.
- 47) Describe how to use the shift and logical operations to *extract* the day field from the packed date record in question 29. That is, wind up with a 16-bit integer value in the range 0..31.

- 48) Assume you've loaded a long packed date (See "Bit Fields and Packed Data" on page 71.) into the EAX register. Explain how you can easily access the day and month fields directly, without any shifting or rotating of the EAX register.
- 49) Suppose you have a value in the range 0..9. Explain how you could convert it to an ASCII character using the basic logical operations.
- 50) The following C++ function locates the first set bit in the *BitMap* parameter starting at bit position *start* and working up to the H.O. bit . If no such bit exists, it returns -1. Explain, in detail, how this function works.

```
int FindFirstSet(unsigned BitMap, unsigned start)
{
    unsigned Mask = (1 << start);

    while (Mask)
    {
        if (BitMap & Mask) return start;
        ++start;
        Mask <<= 1;
    }
    return -1;
}
```

- 51) The C++ programming language does not specify how many bits there are in an unsigned integer. Explain why the code above will work regardless of the number of bits in an unsigned integer.
- 52) The following C++ function is the complement to the function in the questions above. It locates the first zero bit in the *BitMap* parameter. Explain, in detail, how it accomplishes this.

```
int FindFirstClr(unsigned BitMap, unsigned start)
{
    return FindFirstSet(~BitMap, start);
}
```

- 53) The following two functions set or clear (respectively) a particular bit and return the new result. Explain, in detail, how these functions operate.

```
unsigned SetBit(unsigned BitMap, unsigned position)
{
    return BitMap | (1 << position);
}

unsigned ClrBit(unsigned BitMap, unsigned position)
{
    return BitMap & ~(1 << position);
}
```

- 54) In code appearing in the questions above, explain what happens if the start and position parameters contain a value greater than or equal to the number of bits in an unsigned integer.

- 55) Provide an example of HLA variable declarations for the following data types:

- a) Eight-bit byte
- b) 16-bit word
- c) 32-bit dword
- d) Boolean
- e) 32-bit floating point
- f) 64-bit floating point
- g) 80-bit floating point

h) Character

- 56) The long packed date format offers two advantages over the short date format. What are these advantages?
- 57) Convert the following real values to 32-bit single precision floating point format. Provide your answers in hexadecimal, explain your answers.
- | | | | |
|---------|---------|---------|-------------|
| a) 1.0 | b) 2.0 | c) 1.5 | d) 10.0 |
| e) 0.5 | f) 0.25 | g) 0.1 | h) -1.0 |
| i) 1.75 | j) 128 | k) 1e-2 | l) 1.024e+3 |
- 58) Which of the values in question 41 do not have exact representations?
- 59) Show how to declare a character variable that is initialized with the character “*”.
- 60) Show how to declare a character variable that is initialized with the control-A character (See “The ASCII Character Set” on page 93 for the ASCII code for control-A).
- 61) How many characters are present in the standard ASCII character set?
- 62) What is the basic structure of an HLA program?
- 63) Which HLA looping control structure(s) test(s) for loop termination at the beginning of the loop?
- 64) Which HLA looping control structure(s) test(s) for loop termination at the end of the loop?
- 65) Which HLA looping construct lets you create an infinite loop?
- 66) What set of flags are known as the “condition codes?”
- 67) What HLA statement would you use to trap exceptions?
- 68) Explain how the IN operator works in a boolean expression.
- 69) What is the *stdio.bs* constant?
- 70) How do you redirect the standard output of your programs so that the data is written to a text file?

5.2 Programming Projects for Chapter Two

- 1) Write a program to produce an “addition table.” This table should input two small *int8* values from the user. It should verify that the input is correct (i.e., handle the *ex.ConversionError* and *ex.ValueOutOfRange* exceptions) and is positive. The second value must be greater than the first input value. The program will display a row of values between the lower and upper input values. It will also print a column of values between the two values specified. Finally, it will print a matrix of sums. The following is the expected output for the user inputs 15 & 18

```

add    15  16  17  18
15     30  31  32  33
16     31  32  33  34
17     32  33  34  35
18     33  34  35  36

```

- 2) Modify program (1), above, to draw lines between the columns and rows. Use the hyphen ('-'), vertical bar ('|'), and plus sign ('+') characters to draw the lines. E.g.,

```

add  | 15 | 16 | 17 | 18 |
-----+-----+-----+-----+
15   | 30 | 31 | 32 | 33 |
-----+-----+-----+-----+
16   | 31 | 32 | 33 | 34 |
-----+-----+-----+-----+
17   | 32 | 33 | 34 | 35 |
-----+-----+-----+-----+
18   | 33 | 34 | 35 | 36 |
-----+-----+-----+-----+

```

For extra credit, use the line drawing character graphics symbols listed in Appendix B to draw the lines. Note: to print a character constant as an ASCII code, use “#nnn” where “nnn” represents the ASCII code of the character you wish to print. For example, “`stdout.put(#179);`” prints the line drawing vertical bar character.

- 3) Write a program that generates a “Powers of Four” table. Note that you can create the powers of four by loading a register with one and then successively add that register to itself twice for each power of two.
- 4) Write a program that reads a list of positive numbers from a user until that user enters a negative or zero value. Display the sum of those positive integers.
- 5) Write a program that computes $(n)(n-1)/2$. It should read the value “n” from the user. Hint: you can compute this formula by adding up all the numbers between one and n.

5.3 Programming Projects for Chapter Three

Write each of the following programs in HLA. Be sure to fully comment your source code. See Appendix C for style guidelines and rules when writing HLA programs (and follow these rules to the letter!). Include sample output and a short descriptive write up with your program submission(s).

- 1) Write a program that reads a line of characters from the user and displays that entire line after converting any upper case characters to lower case. All non-alphabetic and existing lower case characters should pass through unchanged; you should convert all upper case characters to lower case before printing them.
- 2) Write a program that reads a line of characters from the user and displays that entire line after swapping upper case characters with lower case; that is, convert the incoming lower case characters to upper case and convert the incoming upper case characters to lower case. All non-alphabetic characters should pass through unchanged.
- 3) Write a program that reads three values from the user: a month, a day, and a year. Pack the date into the long date format appearing in this chapter and display the result in hexadecimal. If the date is between 2000 and 2099, also pack the date into the short packed date format and display that 16-bit value in hexadecimal form. If the date is not in the range 2000..2099, then display a short message suggesting that the translation is not possible.
- 4) Write a date validation program that reads a month, day, and year from the user, verifies that the date is correct (ignore leap years for the time being), and then packs the date into the long date format appearing in this chapter.
- 5) Write a “CntBits” program that counts the number of one bits in a 16-bit integer value input from the user. *Do not use any built-in functions in HLA’s library to count these bits for you.* Use the shift or rotate instructions to extract each bit in the value.
- 6) Write a “TestBit” program. This program requires two integer inputs. The first value is a 32-bit integer to test; the second value is an unsigned integer in the range 0..31 describing which bit to test. The program should display true if the corresponding bit (in the test value) contains a one, the program should display false if that bit position contains a zero. The program should always display false if the second value holds a value outside the range 0..31.
- 7) Write a program that reads an eight-bit signed integer and a 32-bit signed integer from the user that computes and displays the sum and difference of these two numbers.
- 8) Write a program that reads an eight-bit unsigned integer and a 16-bit unsigned integer from the user that computes and displays the sum and the absolute value of the difference of these two numbers.
- 9) Write a program that reads a 32-bit unsigned integer from the user and displays this value in binary. Use the SHL instruction to perform the integer to binary conversion.
- 10) Write a program that uses *stdin.getc* to read a sequence of binary digits from the user (that is, a sequence of ‘1’ and ‘0’ characters). Convert this string to an integer using the AND, SHL, and OR instructions. Display the integer result in hexadecimal and decimal.
- 11) Using the LAFH instruction, write a program that will display the current values of the carry, sign, and zero flags as boolean values. Read two integer values from the user, add them together, and then immediately capture the flags’ values using the LAHF instruction and display the result of these three flags as boolean values. Hint: use the SHL or SHR instructions to extract the specific flag bits.

5.4 Programming Projects for Chapter Four

- 1) Write an HLA program that reads a single precision floating point number from the user and prints the internal representation of that value using hexadecimal notation.
- 2) Write a program that reads a single precision floating point value from the user, takes the absolute value of that number, and then displays the result. Hint: this program does not use any arithmetic instructions or comparisons. Take a look at the binary representation for floating point numbers in order to solve this problem.
- 3) Write a program that generates an ASCII character set chart using the following output format:

```

| 00 01 02 03 04 05 06 07 08 09 0A 0B 0C 0D 0E 0F
-----+-----
20|      !  "  #  ...
30|     0  1  2  3  ...
40|    @  A  B  C  ...
50|    P  Q  R  S  ...
60|    `  a  b  c  ...
70|    p  q  r  s  ...

```

Note that the columns in the table represent the L.O. four bits of the ASCII code, the rows in the table represent the H.O. four bits of the ASCII code. Note: for extra consideration, use the line-drawing graphic characters (see Appendix B) to draw the lines in the table.

- 4) Using only five FOR loops, four calls to *stdout.putcSize*, and two calls to *stdout.newln*, write a program that draws a checkerboard pattern. Your checkerboard should look like the following:

```

*****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
*****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****
      *****      *****      *****      *****

```

5.5 Laboratory Exercises for Chapter Two

Before you can write, compile, and run a single HLA program, you will need to install the HLA language system on your computer. If you are using HLA at school or some other institution, the system administrator has probably set up HLA for you. If you are working at home or on some computer on which HLA is not installed, you will need to obtain the HLA distribution package and set it up on your computer. The first section of this set of laboratory exercises deals with obtaining and installing HLA.

Once HLA is installed, the next step is to take stock of what is present in the HLA system. The second part of this laboratory deals with the files that are present in the HLA distribution.

Finally, and probably most important, this set of laboratory exercises discusses how to write, compile, and run some simple HLA programs.

5.5.1 A Short Note on Laboratory Exercises and Lab Reports

Whenever you work on laboratory exercises in this textbook you should always prepare a lab report associated with each exercise. Your instructor may have some specific guidelines concerning the content of the lab report (if your instructor requires that you submit the report). Be sure to check with your instructor concerning the lab report requirements.

At a bare minimum, a lab report should contain the following:

- A title page with the lab title (chapter #), your name and other identification, the current date, and the due date. If you have a course-related computer account, you should also include your login name.
- If you modify or create a program in a lab exercise, the source code for that program should appear in the laboratory report (do not simply reprint source code appearing in this text in order to pad your lab report).
- Output from all programs should also appear in the lab report.
- For each exercise, you should provide a write-up describing the purpose of the exercise, what you learned from the exercise, and any comments about improvements or other work you've done with the exercise.
- If you make any mistakes that require correction, you should include the source code for the incorrect program with your lab report. Hand write on the listing where the error occurs and describe (in handwriting, on the listing) what you did to correct the problem. **Note:** no one is perfect. If you turn in a lab report that has no listings with errors in it, this is a clear indication that you didn't bother to perform this part of the exercise.
- Appropriate diagrams.

The lab report should be prepared with a word processing program. Hand-written reports are unacceptable (although hand-drawn diagrams are acceptable if a suitable drawing package isn't available). The report should be proofread and of finished quality before submission. Only the listings with errors (and hand written annotations) should be in a less than finished quality. See the "HLA Programming Style Guidelines" appendix for important information concerning programming style. Adhere to these guidelines in the HLA programs you submit.

5.5.2 Installing the HLA Distribution Package

The latest version of HLA is available from the Webster web server at

<http://webster.cs.ucr.edu>

Go to this web site and following the HLA links to the "HLA Download" page. From here you should select the latest version of HLA for download to your computer. The HLA distribution is provided in a "Zip

File” compressed format. You will need a decompressor program like PKUNZIP or WinZip in order to extract the HLA files from this zipped archive file. The use of these decompression products is beyond the scope of this manual, please consult the software vendor’s documentation or their web page for information concerning the use of these products.

This text assumes that you have unzipped the HLA distribution into the root directory of your C: drive. You can certainly install HLA anywhere you want, but you will have to adjust the following descriptions if you install HLA somewhere else.

HLA is a command window/console application. In order to run the HLA compiler you must run the command window program (this is “command.com” on Windows 95 and 98, or “cmd.exe” on Windows NT and Windows 2000). Most Windows distributions let you run the command prompt windows from the Start menu or from a submenu hanging off the start menu. Otherwise, you can find the executable in the “C:\Windows” directory or in the “C:\WinNT\System32” directory¹. This text assumes that you are familiar with the Windows command window and you know how to use some basic command window commands (e.g., dir, del, rename, etc.). If you have never before used the Windows command line interpreter, you should consult an appropriate text to learn a few basic commands.

Before you can actually run the HLA compiler, you must set the system execution path and set up various environment variables. Some versions of Windows (e.g., NT) let you permanently set up these values. However, an easy and universal way to set up the path and environment variables is to use a *batch file*. A batch file is a sequence of command window commands that you store into a file (with a “.BAT” extension) to quickly execute by typing the filename (sans extension). This is the method we will use to initialize the system.

The following text provides a suitable “ihla.bat” (initialize HLA) file that sets up the important variables, assuming you’ve installed HLA on your “C:” drive in the “C:\HLA” subdirectory:

```
path=c:\hla;%path%
set lib=c:\hla\hlalib;%lib%
set include=c:\hla\include;%include%
set hlainc=c:\hla\include
set hlalib=c:\hla\hlalib\hlalib.lib
```

Enter these lines of text into a suitable text editor (not a word processor) and save them as “ihla.bat” in the “c:\hla” subdirectory. For your convenience, this batch file also appears in the “AoA_Software” directory of the HLA distribution.

The first line in this batch file tells the system to execute the HLA.EXE and HLPARSE.EXE files directly from the HLA subdirectory without your having to specify the full pathname. That is, you can type “hla” rather than “c:\hla\hla” in order to run the HLA compiler. Obviously, this saves a lot of typing and is quite worthwhile². The second and third lines of this batch file insert the HLA include directory and HLA Standard Library directory into the search list used by compilers on the system. HLA doesn’t actually use these variables, but other tools might, hence their inclusion in the batch file. The last two entries in the batch file set up the HLA-specific environment variables that provide the paths to the HLA include file directory and the HLA standard library file (hlalib.lib). The HLA compiler expects to find these variables in the system environment. **Compilation will probably fail if you haven’t set up these environment variables.**

In addition to the HLA distribution files, you will also need some additional Microsoft tools in order to use the HLA system. Specifically, you will need a copy of Microsoft’s Macro Assembler (MASM) and a copy of the Microsoft Linker in order to use HLA. Fortunately, you may download these programs for free from the internet. Instructions on how to do so are available on the net. The Webster web site (see the “Randall Hyde’s Assembly Page” link) maintains a link to a site that explains how to download MASM and LINK from Microsoft’s web page. You will need to obtain the ml.exe, ml.err, link.exe, and the MspdbX0.dll (x=5, 6, or some other integer) files. Place these files in the HLA directory along with the HLA.EXE and HLPARSE.EXE files³. In addition to these files, you will need a copy of Microsoft’s “kernel32.lib” and

1. Assuming you’ve installed Windows on your “C:” drive. Adjust the drive letter appropriately if you’ve installed Windows on a different drive.

2. Alternately, you can move the HLA.EXE and HLPARSE.EXE files to a subdirectory already in the execution path.

“user32.lib” library packages. These come with Visual C++ and other Microsoft tools and compilers. If this file is not in the current path specified by the “lib” environment variable, put a copy in the “c:\hla\hlalib” subdirectory.

Getting HLA up and running is a complex process because there are so many different files that have to all be located in the right spot. If you are having trouble getting HLA running on your system, be sure that:

- HLA.EXE and HLPARSE.EXE are in the “c:\hla” subdirectory.
- ml.exe, ml.err, and link.exe are in the “c:\hla” subdirectory.
- mspdbX0.dll (x=5, 6, or greater) is in the “c:\hla” subdirectory (win95 and win98 users).
- msvcrt.dll is in the c:\hla” subdirectory (Win NT and Win 2000 users).
- kernel32.lib and user32.lib are in the path specified by the “set lib=...” statement (e.g., the “c:\hla\hlalib” subdirectory).

To verify the proper operation of HLA, open up a command window (i.e., from the START button in Windows), type “c:\hla\ihla” to run the “ihla.bat” file to initialize the path and important environment variables. Then type “hla -?” at the command line. HLA should display the current version number along with a list of legal command line parameters. If you get this display, the system can find the HLA compiler, so go on to the next step. If you do not get this message, then type “SET” at the command line prompt and verify that the path is correct and that the lib, include, hlalib, and hlainc environment variables are set correctly. If not, rerun the ihla.bat file and try again⁴. If you are still having problems, check out the complete installation instructions in the appendices.

Once you’ve verified the proper operation of the HLA compiler, the next step is to verify the proper operation of the MASM assembler. You can do this by typing “ML -?” at the Windows command line prompt. MASM should display its current version number and all the command line parameters it supports. You will not directly run MASM, so you can ignore all this information. The important issue is whether the information appears. If it does not, an HLA compile will fail. If the ML command does not bring up this information, verify that ml.exe and ml.err are in an execution path (e.g., in the “c:\hla” subdirectory).

The next step is to verify that the Microsoft linker is operational. You can do this by typing “link -?” at the Windows command line prompt. The program should display a message like “Microsoft (R) Incremental Linker Version 6.00.xxxx”. If you do not get a linker message at all, verify that the link.exe program is installed in a subdirectory in the execution path (e.g., “c:\hla”). Also make sure that the mspdbX0.dll (X=5 or greater) and msvcrt.dll files appear in this same directory. Warning: depending on where you got your copy of MASM, it may have come with a 16-bit linker. 16-bit linkers are not compatible with HLA. You must use the newer 32-bit linkers that come with Visual C++ and other Microsoft languages.

At this point, you should have successfully installed the HLA system and it should be ready to use. After a description of the HLA distribution in the next section, you’ll get an opportunity to test out your installation.

5.5.3 What’s Included in the HLA Distribution Package

Although HLA is relatively flexible about where you put it on your system, this text assumes you’ve installed HLA on your C: drive under a Win32 operating system (e.g., Windows 95, 98, NT, 2000, and later versions that are 32-bit compatible). This text also assumes the standard directory placement for the HLA files, which has the following layout

- HLA directory
 - Doc directory
 - Examples directory
 - hlalib directory
 - include directory

3. Actually, you may install these files in any directory that is in the execution path. So if you’ve purchased a commercial version of MASM, or have installed the linker via Visual C++, there is no need to move or copy these files to the HLA directory.

4. Be sure the ihla.bat file contains appropriate drive letters in front of the pathnames if you are having problems.

- Tests directory

The “Art of Assembly” software distribution has the following directory tree structure:

- AoA_Software directory
 - Volume1
 - Ch01 directory
 - Ch02 directory
 - etc.
 - Volume2
 - Ch01 directory
 - Ch02 directory
 - etc.
 - etc.

The main *HLA* directory contains the executable code for the compiler. This consists of two files, *HLA.EXE* and *HLAPARSE.EXE*. These two programs must be in the current execution path in order to run the compiler (the “path” command in the *ihla.bat* file sets the execution path). It wouldn’t hurt to put the *ml.exe*, *ml.err*, *link.exe*, *mspdbX0.dll* ($x=5, 6$, or greater), and *msvcrt.dll* files in this directory as well.

The *Doc* directory contains reference material for HLA in PDF and HTML formats. If you have a copy of Adobe Acrobat Reader, you will probably want to read the PDF versions since they are much nicer than the HTML versions. These documents contain the most up-to-date information about the HLA language; you should consult them if you have a question about the HLA language or the HLA Standard Library. Generally, material in this documentation supersedes information appearing in this text since the HLA document is electronic and is probably more up to date.

The *Examples* directory contains a large set of HLA programs that demonstrate various features in the HLA language. If you have a question about an HLA feature, you can probably find an example program that demonstrates that feature in the *Examples* directory. Such examples provide invaluable insight that is often superior to a written description of the feature.

The *hlalib* directory contains the source and object code for the HLA Standard Library. As you become more competent with HLA, you may want to take a look at how HLA implements various library functions. In the meantime, this directory contains the *hlalib.lib* file which you must link with your own programs that make calls to the standard library. Linking instructions appear a little later in this chapter.

The *include* directory contains the HLA Standard Library include files. These special files (that end with a “.hhf” suffix, for HLA Header File) are needed during assembly to provide prototype and other information to your program. The example programs in this chapter all include the HLA header file “*stdlib.hhf*” that, in turn, includes all the other HLA header files in the standard library.

The *Tests* directory contains various test files that test the correct operation of the HLA system. HLA includes these files as part of the distribution package because they provide additional examples of HLA coding.

The *AoA_Software* directory contains the code specific to this textbook. This directory contains all the source code to (complete) programs appearing in this text. It also contains the programs appearing in the Laboratory Exercises section of each chapter. Therefore, this directory is very important to you. Within this subdirectory, the information is further divided up by volume and chapter. The material for Chapter One appears in the *AoA_Software\Volume1\Ch01* subdirectory, the material for Chapter Two appears in the *AoA_Software\Volume1\Ch02* subdirectory, etc..

5.5.4 Using the HLA Compiler

If you've made it through the previous two sections, it's now time to test out your installation and verify that it is correct. In this section you'll also learn how to run the compiler and the executables it produces.

To begin with, open a command prompt window. This is usually accomplished by selecting the "command prompt" program from the Windows Start menu (or one of its submenus). You can also use the "run" command (from the Start button) and type "command" for Windows 95 & 98 or "cmd" for Windows NT & 2000. Once you are faced with the command prompt window, type the following (boldfaced) commands to initialize the HLA system:⁵

```
c:> cd c:\hla
c:\hla> ihla
```

If your command prompt opens up a drive other than C:, you may need to switch to the "C:" drive (or whatever drive contains the HLA subdirectory) before issuing these commands. You can switch the default drive by simply typing the drive letter followed by a colon. For example, to switch to the C: drive, you would use the following command:

```
x:> c:
```

After running the "ihla" batch file to initialize the system, you can test for the presence of the HLA compiler by entering the following command:

```
c:\hla> hla -?
```

This should display some internal information about HLA along with a description of the syntax for the HLA command. If you get an error message complaining about a missing command, you've probably not installed HLA properly or the path hasn't been properly set. If you believe you've installed HLA properly, try running the *ihla.bat* file again, and check to be sure that the batch file contains the correct data.

Warning: every time you start a new command prompt window, you will need to re-run the *ihla.bat* file. Generally, you should only have to open a command prompt window once per programming session. However, if you close the window for some reason, keep in mind that you must rerun *ihla.bat* before you can run HLA⁶.

5.5.5 Compiling Your First Program

Once HLA is operational, the next step is to compile an actual working program. The HLA distribution contains lots of example HLA programs, including the HLA programs appearing in this text. Since these examples are already written, tested, and ready to compile and run, it makes sense to work with one of these example files when compiling your first program.

A good first program is the "Hello World" program appearing earlier in this volume (repeated below):

```
program helloWorld;
#include( "stdlib.hhf" );

begin helloWorld;

    stdout.put( "Hello, World of Assembly Language", nl );
```

5. This text typically displays the entire command line text when showing the execution of a command window command. The non-boldfaced text is printed by the command line processor, the boldfaced text is user input. Note that this text assumes that you are working on the "C:" disk drive. If you're working on a different drive (e.g., a network drive containing your personal account), you will see a slightly different prompt and you will need to adjust the drive letters in the commands presented in this text.

6. This is assuming that you haven't permanently set the path and other environment variables in Windows.

```
end HelloWorld;
```

The source code for this program appears in the “AoA_Software\Volume1\Ch02\HelloWorld.hla” file. Create a new subdirectory in your root directory and name this new directory “lab1”. From the command window prompt, you can create the new subdirectory using the following two commands:

```
c:> cd \  
c:> mkdir lab1
```

The first command above switches you to the root directory (assuming you’re not there already). The second command (mkdir = “make directory”) creates the *lab1* directory⁷.

Copy the “Hello World” program (HelloWorld.hla) to this *lab1* directory using the following command window statement⁸:

```
c:> copy c:\AoA_Software\Volume1\CH02\HelloWorld.hla c:\lab1
```

From the command prompt window, switch to this new directory using the command:

```
c:> cd \lab1
```

To compile this program, type the following at the command prompt:

```
c:\lab1> hla HelloWorld
```

After a few moments, the Windows command prompt (“C:>”) should reappear. At this point, your program has been successfully compiled. To run the executable (HelloWorld.exe) that HLA has produced, you would use the following command:

```
c:\lab1> HelloWorld
```

The program should run, display “Hello World”, and then terminate. At that time the command window should be waiting for another command.

If you have not successfully completed the previous steps, return to the previous section and repeat the steps to verify that HLA is operational on your system. Remember, each time you start a new command window, you must execute the “ihla.bat” file (or otherwise set up the environment) in order to make HLA accessible in that command window.

In your lab report, describe the output of the HLA compiler. For additional compilation information, use the following command to compile this program:

```
c:> hla -v HelloWorld
```

The “-v” option stands for *verbose* compile. This presents more information during the compilation process. Describe the output of this verbose compilation in your lab report. If possible, capture the output and include the captured output with your lab report. To capture the output to a file, use a command like the following:

```
c:> hla -test -v HelloWorld >capture.txt
```

7. Some school’s labs may not allow you to place information on the C: drive. If you want or need to place your personal working directory on a different drive, just substitute the appropriate drive letter for “C:” in these examples.

8. You may need to modify this statement if the AoA_Software directory does not appear in the root directory of the C: drive.

This command sends most of the output normally destined to the screen to the "capture.txt" output file. You can then load this text file into an editor for further processing. Of course, you may choose a different filename than "capture.txt" if you so desire.

5.5.6 Compiling Other Programs Appearing in this Chapter

The "AoA_Software\Volume1\Ch02" subdirectory contains all the sample programs appearing in this chapter. They are

- HelloWorld.hla
- CharInput.hla
- CheckerBoard.hla
- DemoMOVaddSUB.hla
- DemoVars.hla
- fib.hla
- intInput.hla
- NumsInColumns.hla
- NumsInColumns2.hla
- PowersOfTwo.hla

Copy each of these files to your lab1 subdirectory. Compile and run each of these programs. Describe the output of each in your lab report.

5.5.7 Creating and Modifying HLA Programs

In order to create or modify HLA programs you will need to use a *text* editor to manipulate HLA source code. Windows provides two low-end text editors: notepad.exe and edit.exe. Notepad.exe is a windows-based application while edit.exe is a console (command prompt) application. Neither editor is particularly good for editing program source code; if you have an option to use a different text editor (e.g., the Microsoft Visual Studio system that comes with VC++ and other Microsoft languages), you should certainly do so. This text will assume the use of notepad or edit since these two programs come with every copy of windows and will be present on all systems.

Warning: do not use Microsoft Word, wordpad, or any other word processing programs to create or modify HLA programs. Word processing programs insert extra characters into the document that are incompatible with HLA. If you accidentally save a source file from one of these word processors, you will not be able to compile the program⁹.

Edit.exe is probably a better choice for program development than is notepad.exe. One reason edit.exe is better is because it displays line numbers while notepad.exe does not. When HLA reports an error in your program, it provides the line number of the offending statement; if you are using notepad.exe, it will be very difficult to locate the source of your error since notepad does not report the line numbers. Another problem with notepad is that it insists on tacking a ".txt" extension onto the end of your filenames, even if they already have an ".hla" extension. This is rather annoying¹⁰. One advantage to using notepad is that you can run it by simply double-clicking on a (notepad-registered) ".hla" icon.

To run the edit.exe program to edit an HLA program, you would specify a command line like the following:

```
c:> edit HelloWorld.hla
```

9. Note that many word processing programs provide a "save as text" option. If you accidentally destroy a source file by saving it from a word processor, simply reenter the word processor and save the file as text.

10. You can eliminate this problem by registering ".HLA" as a notepad document format by selecting "view>options>File Types" from the view menu in any open directory window.

This example brings up the “Hello World” program into the editor, ready to be modified. This text assumes that you are already familiar with text editing principles. Edit.exe is a very simple editor; if you’ve used any text editor in the past, you should be comfortable using edit.exe (other than the fact that it is quite limited).

For the time being, modify the statement:

```
stdout.put( “Hello, World of Assembly Language”, nl );
```

Change the text ‘World of Assembly Language’ to your name, e.g.,

```
stdout.put( “Hello Randall Hyde”, nl );
```

After you’ve done this, save the file to disk and recompile and run the program. Assuming you haven’t introduced any typographical errors into the program, it should compile and run without incident. After making the modifications to the program, capture the output and include the captured output in your lab report. You can capture the output from this program by using the I/O redirection operator as follows:

```
c:> HelloWorld >out.txt
```

This sends the output (“Hello Randall Hyde”) to the “out.txt” text file rather than to the display. Include the sample output and the modified program in your lab report. Note: don’t forget to include any erroneous source code in your lab report to demonstrate the changes you’ve made during development of the code.

5.5.8 Writing a New Program

To create a brand-new program is relatively easy. Simply specify the name of the new file as a parameter to the edit command line:

```
c:> edit newfile.hla
```

This will bring up the editor with an empty file. Enter the following program into the editor (note: this program is not available in the AoA_Software directory, you must enter this file yourself):

```
program onePlusOne;
#include( "stdlib.hhf" );

static
    One: int32;

begin onePlusOne;

    mov( 1, One );
    mov( One, eax );
    add( One, eax );
    mov( eax, One );
    stdout.put( "One + One = ", One, nl );

end onePlusOne;
```

Program 5.1 OnePlusOne Program

Remember, HLA is very particular about the way you spell names. So be sure that the alphabetic case is correct on all identifiers in this program. Before attempting to compile your program, proof read it to check for any typographical errors.

After entering and saving the program above, exit the editor and compile this program from the command prompt. If there are any errors in the program, reenter the editor, correct the errors, and then compile the program again. Repeat until the program compiles correctly.

Note: If you encounter any errors during compilation, make a printout of the program (with errors) and hand write on the printout where the errors occur and what was necessary to correct the error(s). Include this printout with your lab report.

After the program compiles successfully, run it and verify that it runs correctly. Include a printout of the program and the captured output in your lab report.

5.5.9 Correcting Errors in an HLA Program

The following program (HasAnError.hla in the appropriate AoA_Examples directory) contains a minor syntax error (a missing semicolon). Compile this program:

```
// This program has a syntactical error to
// demonstrate compilation errors in an HLA
// program.

program hasAnError;
#include( "stdlib.hhf" );
begin hasAnError;

    stdout.puts( "This program doesn't compile!" ) // missing ";"

end hasAnError;
```

Program 5.2 Sample Program With a Syntax Error

When you compile this program, you will notice that it doesn't report the error on line nine (the line actually containing the error). Instead, it reports the error on line 11 (the "end" statement) since this is the first point at which the compiler can determine that an error has occurred.

Capture the error output of this program into a text file using the following command:

```
c:> hla -test HasAnError >err1.txt
```

Include this output in your laboratory report.

Correct the syntax error in this program and compile and run the program. Include the source code of the corrected program as well as its output in your lab report.

5.5.10 Write Your Own Sample Program

Conclude this laboratory exercise by writing a simple little program of your own. Include the source code and sample output in your lab report. If you have any syntax errors in your code, be sure to include a printout of the incorrect code with hand-written annotations describing how you fixed the problem(s) in your program.

5.6 Laboratory Exercises for Chapter Three and Chapter Four

Accompanying this text is a significant amount of software. The software can be found in the AoA_Software\Volume1 directory. Inside this directory is a set of directories with names like *Ch03* and *Ch04*, with the names obviously corresponding to chapters in this textbook. All the source code to the example programs in this chapter can be found in the Ch04 subdirectory. The Ch04 subdirectory also contains some executable programs for this chapter's laboratory exercises as well as the (Inprise Delphi) source code for the lab exercises. Please see this directory for more details.

5.6.1 Data Conversion Exercises

In this exercise you will be using the "convert.exe" program found in the Ch04 subdirectory. This program displays and converts 16-bit integers using signed decimal, unsigned decimal, hexadecimal, and binary notation.

When you run this program it opens a window with four *edit boxes*. (one for each data type). Changing a value in one of the edit boxes immediately updates the values in the other boxes so they all display their corresponding representations for the new value. If you make a mistake on data entry, the program beeps and turns the edit box red until you correct the mistake. Note that you can use the mouse, cursor control keys, and the editing keys (e.g., DEL and Backspace) to change individual values in the edit boxes.

For this exercise and your laboratory report, you should explore the relationship between various binary, hexadecimal, unsigned decimal, and signed decimal values. For example, you should enter the unsigned decimal values 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, 4096, 8192, 16384, and 32768 and comment on the values that appear in the other text boxes.

The primary purpose of this exercise is to familiarize yourself with the decimal equivalents of some common binary and hexadecimal values. In your lab report, for example, you should explain what is special about the binary (and hexadecimal) equivalents of the decimal numbers above.

Another set of experiments to try is to choose various binary numbers that have exactly two bits set, e.g., 11, 110, 1100, 1 1000, 11 0000, etc. Be sure to comment on the decimal and hexadecimal results these inputs produce.

Try entering several binary numbers where the L.O. eight bits are all zero. Comment on the results in your lab report. Try the same experiment with hexadecimal numbers using zeros for the L.O. digit or the two L.O. digits.

You should also experiment with negative numbers in the signed decimal text entry box; try using values like -1, -2, -3, -256, -1024, etc. Explain the results you obtain using your knowledge of the two's complement numbering system.

Try entering even and odd numbers in unsigned decimal. Discover and describe the difference between even and odd numbers in their binary representation. Try entering multiples of other values (e.g., for three: 3, 6, 9, 12, 15, 18, 21, ...) and see if you can detect a pattern in the binary results.

Verify the hexadecimal <-> binary conversion this chapter describes. In particular, enter the same hexadecimal digit in each of the four positions of a 16-bit value and comment on the position of the corresponding bits in the binary representation. Try entering several binary values like 1111, 11110, 111100, 1111000, and 11110000. Explain the results you get and describe why you should always extend binary values so their length is an even multiple of four before converting them.

In your lab report, list the experiments above plus several you devise yourself. Explain the results you expect and include the actual results that the convert.exe program produces. Explain any insights you have while using the convert.exe program.

5.6.2 Logical Operations Exercises

The “logical.exe” program is a simple calculator that computes various logical functions. It allows you to enter binary or hexadecimal values and then it computes the result of some logical operation on the inputs. The calculator supports the dyadic logical AND, OR, and XOR. It also supports the monadic NOT, NEG (two’s complement), SHL (shift left), SHR (shift right), ROL (rotate left), and ROR (rotate right).

When you run the logical.exe program it displays a set of buttons on the left hand side of the window. These buttons let you select the calculation. For example, pressing the AND button instructs the calculator to compute the logical AND operation between the two input values. If you select a monadic (unary) operation like NOT, SHL, etc., then you may only enter a single value; for the dyadic operations, both sets of text entry boxes will be active.

The logical.exe program lets you enter values in binary or hexadecimal. Note that this program automatically converts any changes in the binary text entry window to hexadecimal and updates the value in the hex entry edit box. Likewise, any changes in the hexadecimal text entry box are immediately reflected in the binary text box. If you enter an illegal value in a text entry box, the logical.exe program will turn the box red until you correct the problem.

For this laboratory exercise, you should explore each of the bitwise logical operations. Create several experiments by carefully choosing some values, manually compute the result you expect, and then run the experiment using the logical.exe program to verify your results. You should especially experiment with the masking capabilities of the logical AND, OR, and XOR operations. Try logically ANDing, ORing, and XORing different values with values like 000F, 00FF, 00F0, 0FFF, FF00, etc. Report the results and comment on them in your laboratory report.

Some experiments you might want to try, in addition to those you devise yourself, include the following:

- Devise a mask to convert ASCII values ‘0’..’9’ to their binary integer counterparts using the logical AND operation. Try entering the ASCII codes of each of these digits when using this mask. Describe your results. What happens if you enter non-digit ASCII codes?
- Devise a mask to convert integer values in the range 0..9 to their corresponding ASCII codes using the logical OR operation. Enter each of the binary values in the range 0..9 and describe your results. What happens if you enter values outside the range 0..9? In particular, what happens if you enter values outside the range 0h..0fh?
- Devise a mask to determine whether a 16-bit integer value is positive or negative using the logical AND operation. The result should be zero if the number is positive (or zero) and it should be non-zero if the number is negative. Enter several positive and negative values to test your mask. Explain how you could use the AND operation to test *any* single bit to determine if it is zero or one.
- Devise a mask to use with the logical XOR operation that will produce the same result on the second operand as applying the logical NOT operator to that second operand.
- Verify that the SHL and SHR operators correspond to an integer multiplication by two and an integer division by two, respectively. What happens if you shift data out of the H.O. or L.O. bits? What does this correspond to in terms of integer multiplication and division?
- Apply the ROL operation to a set of positive and negative numbers. Based on your observations in Section 5.6.2, what can you say about the result when you rotate left a negative number or a positive number?
- Apply the NEG and NOT operators to a value. Discuss the similarity and the difference in their results. Describe this difference based on your knowledge of the two’s complement numbering system.

5.6.3 Sign and Zero Extension Exercises

The “signext.exe” program accepts eight-bit binary or hexadecimal values then sign and zero extends them to 16 bits. Like the logical.exe program, this program lets you enter a value in either binary or hexadecimal and immediate zero and sign extends that value.

For your laboratory report, provide several eight-bit input values and describe the results you expect. Run these values through the `signext.exe` program and verify the results. For each experiment you run, be sure to list all the results in your lab report. Be sure to try values like \$0, \$7f, \$80, and \$ff.

While running these experiments, discover which hexadecimal digits appearing in the H.O. nibble produce negative 16-bit numbers and which produce positive 16-bit values. Document this set in your lab report.

Enter sets of values like (1,10), (2,20), (3,30), ..., (7,70), (8,80), (9,90), (A,A0), ..., (F,F0). Explain the results you get in your lab report. Why does “F” sign extend with zeros while “F0” sign extends with ones?

Explain in your lab report how one would sign or zero extend 16 bit values to 32 bit values. Explain why zero extension or sign extension is useful.

5.6.4 Packed Data Exercises

The `packdata.exe` program uses the 16-bit Date data type appearing in Chapter Three (see “Bit Fields and Packed Data” on page 71). It lets you input a date value in binary or decimal and it packs that date into a single 16-bit value.

When you run this program, it will give you a window with six data entry boxes: three to enter the date in decimal form (month, day, year) and three text entry boxes that let you enter the date in binary form. The month value should be in the range 1..12, the day value should be in the range 1..31, and the year value should be in the range 0..99. If you enter a value outside this range (or some other illegal value), then the `packdata.exe` program will turn the data entry box red until you correct the problem.

Choose several dates for your experiments and convert these dates to the 16-bit packed binary form by hand (if you have trouble with the decimal to binary conversion, use the conversion program from the first set of exercises in this laboratory). Then run these dates through the `packdata.exe` program to verify your answer. Be sure to include all program output in your lab report.

At a bare minimum, you should include the following dates in your experiments:

2/4/68, 1/1/80, 8/16/64, 7/20/60, 11/2/72, 12/25/99, Today’s Date, a birthday (not necessarily yours), the due date on your lab report.

5.6.5 Running this Chapter’s Sample Programs

The Ch03 and Ch04 subdirectories also contain the source code to each of the sample programs appearing in Chapters Three and Four. Compile and run each of these programs. Capture the output and include a printout of the source code and the output of each program in your laboratory report. Comment on the results produced by each program in your laboratory report.

5.6.6 Write Your Own Sample Program

To conclude your laboratory exercise, design and write a program on your own that demonstrates the use of each of the data types presented in this chapter. Your sample program should also show how you can interpret data values differently, depending on the instructions or HLA Standard Library routines you use to operate on that data. Your sample program should also demonstrate conversions, logical operations, sign and zero extension, and packing or unpacking a packed data type (in other words, your program should demonstrate your understanding of the other components of this laboratory exercise). Include the source code, sample output, and a description of your sample program in your lab report.

This topic, as its title suggests, is primarily targeted towards a machine organization course. Those who wish to study assembly language programming should at least read Chapter Two and possibly Chapter One. Chapter Three is a low-level discussion of digital logic. This information is important to those who are interested in design-

ing CPUs and other system components. Those individuals who are main interested in programming can safely skip this chapter. Chapters Four, Five, and Six provide a more in-depth look at computer systems' architecture. Those wanting to know how things work "under the hood" will want to read these chapters. However, programmers who just want to learn assembly language programming can safely skip these chapters. Chapter Seven discusses I/O on the 80x86. Under Win32 you will not be able to utilize much of this information unless you are writing device drivers. However, those interested in learning how low-level I/O takes place in assembly language will want to read this chapter.

System Organization

Chapter One

To write even a modest 80x86 assembly language program requires considerable familiarity with the 80x86 family. To write *good* assembly language programs requires a strong knowledge of the underlying hardware. Unfortunately, the underlying hardware is not consistent. Techniques that are crucial for 8088 programs may not be useful on Pentium systems. Likewise, programming techniques that provide big performance boosts on the Pentium chip may not help at all on an 80486. Fortunately, some programming techniques work well no matter which microprocessor you're using. This chapter discusses the effect hardware has on the performance of computer software.

1.1 Chapter Overview

This chapter describes the basic components that make up a computer system: the CPU, memory, I/O, and the bus that connects them. Although you can write software that is ignorant of these concepts, high performance software requires a complete understanding of this material. This chapter also discusses the 80x86 memory addressing modes and how you access memory data from your programs.

This chapter begins by discussing bus organization and memory organization. These two hardware components will probably have a bigger performance impact on your software than the CPU's speed. Understanding the organization of the system bus will allow you to design data structures and algorithms that operate at maximum speed. Similarly, knowing about memory performance characteristics, data locality, and cache operation can help you design software that runs as fast as possible. Of course, if you're not interested in writing code that runs as fast as possible, you can skip this discussion; however, most people do care about speed at one point or another, so learning this information is useful.

With the generic hardware issues out of the way, this chapter then discusses the program-visible components of the memory architecture - specifically the 80x86 addressing modes and how a program can access memory. In addition to the addressing modes, this chapter introduces several new 80x86 instructions that are quite useful for manipulating memory. This chapter also presents several new HLA Standard Library calls you can use to allocate and deallocate memory.

Some might argue that this chapter gets too involved with computer architecture. They feel such material should appear in an architectural book, not an assembly language programming book. This couldn't be farther from the truth! Writing *good* assembly language programs requires a strong knowledge of the architecture. Hence the emphasis on computer architecture in this chapter.

1.2 The Basic System Components

The basic operational design of a computer system is called its *architecture*. John Von Neumann, a pioneer in computer design, is given credit for the architecture of most computers in use today. For example, the 80x86 family uses the *Von Neumann architecture* (VNA). A typical Von Neumann system has three major components: the *central processing unit* (or *CPU*), *memory*, and *input/output* (or *I/O*). The way a system designer combines these components impacts system performance (See Figure 1.1).

Figure 1.1 Typical Von Neumann Machine

In VNA machines, like the 80x86 family, the CPU is where all the action takes place. All computations occur inside the CPU. Data and machine instructions reside in memory until required by the CPU. To the CPU, most I/O devices look like memory because the CPU can store data to an output device and read data from an input device. The major difference between memory and I/O locations is the fact that I/O locations are generally associated with external devices in the outside world.

1.2.1 The System Bus

The *system bus* connects the various components of a VNA machine. The 80x86 family has three major busses: the *address bus*, the *data bus*, and the *control bus*. A bus is a collection of wires on which electrical signals pass between components in the system. These busses vary from processor to processor. However, each bus carries comparable information on all processors; e.g., the data bus may have a different implementation on the 80386 than on the 8088, but both carry data between the processor, I/O, and memory.

A typical 80x86 system component uses *standard TTL logic levels*¹. This means each wire on a bus uses a standard voltage level to represent zero and one². We will always specify zero and one rather than the electrical levels because these levels vary on different processors (especially laptops).

1.2.1.1 The Data Bus

The 80x86 processors use the *data bus* to shuffle data between the various components in a computer system. The size of this bus varies widely in the 80x86 family. Indeed, this bus defines the “size” of the processor.

On typical 80x86 systems, the data bus contains eight, 16, 32, or 64 lines. The 8088 and 80188 microprocessors have an eight bit data bus (eight data lines). The 8086, 80186, 80286, and 80386SX processors have a 16 bit data bus. The 80386DX, 80486, and Pentium Overdrive™ processors have a 32 bit data bus.

1. Actually, newer members of the family tend to use lower voltage signals, but these remain compatible with TTL signals.

2. TTL logic represents the value zero with a voltage in the range 0.0-0.8v. It represents a one with a voltage in the range 2.4-5v. If the signal on a bus line is between 0.8v and 2.4v, it's value is indeterminate. Such a condition should only exist when a bus line is changing from one state to the other.

The Pentium™, Pentium Pro, Pentium II, Pentium III, and Pentium IV processors have a 64 bit data bus. Future versions of the chip (e.g., the AMD 86-64) may have a larger bus.

Having an eight bit data bus does not limit the processor to eight bit data types. It simply means that the processor can only access one byte of data per memory cycle (see “The Memory Subsystem” on page 135 for a description of memory cycles). Therefore, the eight bit bus on an 8088 can only transmit half the information per unit time (memory cycle) as the 16 bit bus on the 8086. Therefore, processors with a 16 bit bus are naturally faster than processors with an eight bit bus. Likewise, processors with a 32 bit bus are faster than those with a 16 or eight bit data bus. The size of the data bus affects the performance of the system more than the size of any other bus.

You’ll often hear a processor called an *eight, 16, 32, or 64 bit processor*. While there is a mild controversy concerning the size of a processor, most people now agree that the minimum of either the number of data lines on the processor or the size of the largest general purpose integer register determines the processor size. Since the 80x86 family busses are eight, 16, 32, or 64 bits wide, most data accesses are also eight, 16, 32, or 64 bits. Therefore, the Pentium CPUs are still 32-bit CPUs even though they have a 64-bit data bus.

Although it is possible to process 12 bit data with an 80x86, most programmers process 16 bits since the processor will fetch and manipulate 16 bits anyway. This is because the processor always fetches data in groups of eight bits. To fetch 12 bits requires two eight bit memory operations. Since the processor fetches 16 bits rather than 12, most programmers use all 16 bits. In general, manipulating data which is eight, 16, 32, or 64 bits in length is the most efficient.

Although the 80x86 family members with 16, 32, and 64 bit data busses *can* process data up to the width of the bus, they can also access smaller memory units of eight, 16, or 32 bits. Therefore, anything you can do with a small data bus can be done with a larger data bus as well; the larger data bus, however, may access memory faster and can access larger chunks of data in one memory operation. You’ll read about the exact nature of these memory accesses a little later (see “The Memory Subsystem” on page 135).

1.2.1.2 The Address Bus

The data bus on an 80x86 family processor transfers information between a particular memory location or I/O device and the CPU. The only question is, “Which memory location or I/O device?” The address bus answers that question. To differentiate memory locations and I/O devices, the system designer assigns a unique memory address to each memory element and I/O device. When the software wants to access some particular memory location or I/O device, it places the corresponding address on the address bus. Circuitry associated with the memory or I/O device recognizes this address and instructs the memory or I/O device to

read the data from or place data on to the data bus. In either case, all other memory locations ignore the request. Only the device whose address matches the value on the address bus responds.

With a single address line, a processor could create exactly two unique addresses: zero and one. With n address lines, the processor can provide 2^n unique addresses (since there are 2^n unique values in an n -bit binary number). Therefore, the number of bits on the address bus will determine the *maximum* number of addressable memory and I/O locations. The 8088 and 8086, for example, have 20 bit address busses. Therefore, they can access up to 1,048,576 (or 2^{20}) memory locations. Larger address busses can access more memory. The 8088 and 8086 suffer from an anemic address space³ – their address bus is too small. Intel corrected this in later processors.

Table 13: 80x86 Family Address Bus Sizes

| Processor | Address Bus Size | Max Addressable Memory | In English! |
|-----------------|------------------|------------------------|-------------------|
| 8088 | 20 | 1,048,576 | One Megabyte |
| 8086 | 20 | 1,048,576 | One Megabyte |
| 80188 | 20 | 1,048,576 | One Megabyte |
| 80186 | 20 | 1,048,576 | One Megabyte |
| 80286 | 24 | 16,777,216 | Sixteen Megabytes |
| 80386sx | 24 | 16,777,216 | Sixteen Megabytes |
| 80386dx | 32 | 4,294,976,296 | Four Gigabytes |
| 80486 | 32 | 4,294,976,296 | Four Gigabytes |
| 80586 / Pentium | 32 | 4,294,976,296 | Four Gigabytes |
| Pentium Pro | 36 | 68,719,476,736 | 64 Gigabytes |
| Pentium II | 36 | 68,719,476,736 | 64 Gigabytes |
| Pentium III | 36 | 68,719,476,736 | 64 Gigabytes |

Future 80x86 processors will probably support 40, 48, and 64-bit address busses. The time is coming when most programmers will consider four gigabytes of storage to be too small, much like they consider one megabyte insufficient today. (There was a time when one megabyte was considered far more than anyone would ever need!).

1.2.1.3 The Control Bus

The control bus is an eclectic collection of signals that control how the processor communicates with the rest of the system. Consider for a moment the data bus. The CPU sends data to memory and receives data from memory on the data bus. This prompts the question, “Is it sending or receiving?” There are two lines on the control bus, *read* and *write*, which specify the direction of data flow. Other signals include system clocks, interrupt lines, status lines, and so on. The exact make up of the control bus varies among processors in the 80x86 family. However, some control lines are common to all processors and are worth a brief mention.

The *read* and *write* control lines control the direction of data on the data bus. When both contain a logic one, the CPU and memory-I/O are not communicating with one another. If the read line is low (logic zero), the CPU is reading data from memory (that is, the system is transferring data from memory to the CPU). If the write line is low, the system transfers data from the CPU to memory.

3. The address space is the set of all addressable memory locations.

The *byte enable lines* are another set of important control lines. These control lines allow 16, 32, and 64 bit processors to deal with smaller chunks of data. Additional details appear in the next section.

The 80x86 family, unlike many other processors, provides two distinct address spaces: one for memory and one for I/O. While the memory address busses on various 80x86 processors vary in size, the I/O address bus on all 80x86 CPUs is 16 bits wide. This allows the processor to address up to 65,536 different I/O *locations*. As it turns out, most devices (like the keyboard, printer, disk drives, etc.) require more than one I/O location. Nonetheless, 65,536 I/O locations are more than sufficient for most applications. The original IBM PC design only allowed the use of 1,024 of these.

Although the 80x86 family supports two address spaces, it does not have two address busses (for I/O and memory). Instead, the system shares the address bus for both I/O and memory addresses. Additional control lines decide whether the address is intended for memory or I/O. When such signals are active, the I/O devices use the address on the L.O. 16 bits of the address bus. When inactive, the I/O devices ignore the signals on the address bus (the memory subsystem takes over at that point).

1.2.2 The Memory Subsystem

A typical 80x86 processor addresses a maximum of 2^n different memory locations, where n is the number of bits on the address bus⁴. As you've seen already, 80x86 processors have 20, 24, 32, and 36 bit address busses (with 64 bits on the way).

Of course, the first question you should ask is, "What exactly is a memory location?" The 80x86 supports *byte addressable memory*. Therefore, the basic memory unit is a byte. So with 20, 24, 32, and 36 address lines, the 80x86 processors can address one megabyte, 16 megabytes, four gigabytes, and 64 gigabytes of memory, respectively.

Think of memory as a linear array of bytes. The address of the first byte is zero and the address of the last byte is $2^n - 1$. For an 8088 with a 20 bit address bus, the following pseudo-Pascal array declaration is a good approximation of memory:

Memory: array [0..1048575] of byte;

To execute the equivalent of the Pascal statement "Memory [125] := 0;" the CPU places the value zero on the data bus, the address 125 on the address bus, and asserts the write line (since the CPU is writing data to memory), see Figure 1.2.

Figure 1.2 Memory Write Operation

4. This is the *maximum*. Most computer systems built around 80x86 family do not include the maximum addressable amount of memory.

To execute the equivalent of “CPU := Memory [125];” the CPU places the address 125 on the address bus, asserts the read line (since the CPU is reading data from memory), and then reads the resulting data from the data bus (see Figure 1.3).

Figure 1.3 Memory Read Operation

The above discussion applies *only* when accessing a single byte in memory. So what happens when the processor accesses a word or a double word? Since memory consists of an array of bytes, how can we possibly deal with values larger than eight bits?

Different computer systems have different solutions to this problem. The 80x86 family deals with this problem by storing the L.O. byte of a word at the address specified and the H.O. byte at the next location. Therefore, a word consumes two consecutive memory addresses (as you would expect, since a word consists of two bytes). Similarly, a double word consumes four consecutive memory locations. The address for the double word is the address of its L.O. byte. The remaining three bytes follow this L.O. byte, with the H.O. byte appearing at the address of the double word *plus three* (see Figure 1.4). Bytes, words, and double words may begin at *any* valid address in memory. We will soon see, however, that starting larger objects at an arbitrary address is not a good idea.

Figure 1.4 Byte, Word, and DWord Storage in Memory

Note that it is quite possible for byte, word, and double word values to overlap in memory. For example, in Figure 1.4 you could have a word variable beginning at address 193, a byte variable at address 194, and a double word value beginning at address 192. These variables would all overlap.

The 8088 and 80188 microprocessors have an eight bit data bus. This means that the CPU can transfer eight bits of data at a time. Since each memory address corresponds to an eight bit byte, this turns out to be the most convenient arrangement (from the hardware perspective), see Figure 1.5.

Figure 1.5 Eight-Bit CPU <-> Memory Interface

The term “byte addressable memory array” means that the CPU can address memory in chunks as small as a single byte. It also means that this is the *smallest* unit of memory you can access at once with the processor. That is, if the processor wants to access a four bit value, it must read eight bits and then ignore the extra four bits. Also realize that byte addressability does not imply that the CPU can access eight bits on any arbitrary bit boundary. When you specify address 125 in memory, you get the entire eight bits at that address, nothing less, nothing more. Addresses are integers; you cannot, for example, specify address 125.5 to fetch fewer than eight bits.

The 8088 and 80188 can manipulate word and double word values, even with their eight bit data bus. However, this requires multiple memory operations because these processors can only move eight bits of data at once. To load a word requires two memory operations; to load a double word requires four memory operations.

The 8086, 80186, 80286, and 80386sx processors have a 16 bit data bus. This allows these processors to access twice as much memory in the same amount of time as their eight bit brethren. These processors organize memory into two *banks*: an “even” bank and an “odd” bank (see Figure 1.6). Figure 1.7 illustrates the connection to the CPU (D0-D7 denotes the L.O. byte of the data bus, D8-D15 denotes the H.O. byte of the data bus):

| | Even | Odd |
|--------|------|-----|
| Word 3 | 6 | 7 |
| Word 2 | 4 | 5 |
| Word 1 | 2 | 3 |
| Word 0 | 0 | 1 |

Numbers in cells represent the byte addresses

Figure 1.6 Byte Addressing in Word Memory

Figure 1.7 Sixteen-Bit Processor (8086, 80186, 80286, 80386sx) Memory Organization

The 16 bit members of the 80x86 family can load a word from any arbitrary address. As mentioned earlier, the processor fetches the L.O. byte of the value from the address specified and the H.O. byte from the next consecutive address. This creates a subtle problem if you look closely at the diagram above. What happens when you access a word on an odd address? Suppose you want to read a word from location 125. Okay, the L.O. byte of the word comes from location 125 and the H.O. byte comes from location 126. What's the big deal? It turns out that there are two problems with this approach.

First, look again at Figure 1.7. Data bus lines eight through 15 (the H.O. byte) connect to the odd bank, and data bus lines zero through seven (the L.O. byte) connect to the even bank. Accessing memory location 125 will transfer data to the CPU on the H.O. byte of the data bus; yet we want this data in the L.O. byte! Fortunately, the 80x86 CPUs recognize this situation and automatically transfer the data on D8-D15 to the L.O. byte.

The second problem is even more obscure. When accessing words, we're really accessing two separate bytes, each of which has its own byte address. So the question arises, "What address appears on the address bus?" The 16 bit 80x86 CPUs always place even addresses on the bus. Even bytes always appear on data lines D0-D7 and the odd bytes always appear on data lines D8-D15. If you access a word at an even address, the CPU can bring in the entire 16 bit chunk in one memory operation. Likewise, if you access a single byte, the CPU activates the appropriate bank (using a "byte enable" control line). If the byte appeared at an odd address, the CPU will automatically move it from the H.O. byte on the bus to the L.O. byte.

So what happens when the CPU accesses a *word* at an odd address, like the example given earlier? Well, the CPU cannot place the address 125 onto the address bus and read the 16 bits from memory. There are no odd addresses coming out of a 16 bit 80x86 CPU. The addresses are always even. So if you try to put 125 on the address bus, this will put 124 on to the address bus. Were you to read the 16 bits at this address, you would get the word at addresses 124 (L.O. byte) and 125 (H.O. byte) – not what you'd expect. Accessing a word at an odd address requires two memory operations. First the CPU must read the byte at address 125, then it needs to read the byte at address 126. Finally, it needs to swap the positions of these bytes internally since both entered the CPU on the wrong half of the data bus.

Fortunately, the 16 bit 80x86 CPUs hide these details from you. Your programs can access words at *any* address and the CPU will properly access and swap (if necessary) the data in memory. However, to access a word at an odd address requires two memory operations (just like the 8088/80188). Therefore, accessing words at odd addresses on a 16 bit processor is slower than accessing words at even addresses. **By carefully arranging how you use memory, you can improve the speed of your program.**

Accessing 32 bit quantities always takes at least two memory operations on the 16 bit processors. If you access a 32 bit quantity at an odd address, the processor will require three memory operations to access the data.

The 32 bit 80x86 processors (the 80386, 80486, and Pentium Overdrive) use four banks of memory connected to the 32 bit data bus (see Figure 1.8).

Figure 1.8 32-Bit Processor (80386, 80486, Pentium Overdrive) Memory Organization

The address placed on the address bus is always some multiple of four. Using various “byte enable” lines, the CPU can select which of the four bytes at that address the software wants to access. As with the 16 bit processor, the CPU will automatically rearrange bytes as necessary.

With a 32 bit memory interface, the 80x86 CPU can access any byte with one memory operation. If (address MOD 4) does not equal three, then a 32 bit CPU can access a word at that address using a single memory operation. However, if the remainder is three, then it will take two memory operations to access that word (see Figure 1.9). This is the same problem encountered with the 16 bit processor, except it occurs half as often.

Figure 1.9 Accessing a Word at (Address mod 4) = 3.

A 32 bit CPU can access a double word in a single memory operation *if* the address of that value is evenly divisible by four. If not, the CPU will require two memory operations.

Once again, the CPU handles all of this automatically. In terms of loading correct data the CPU handles everything for you. However, there is a performance benefit to proper data alignment. As a general rule you should always place word values at even addresses and double word values at addresses which are evenly divisible by four. This will speed up your program.

1.2.3 The I/O Subsystem

Besides the 20, 24, or 32 address lines which access memory, the 80x86 family provides a 16 bit I/O address bus. This gives the 80x86 CPUs two separate address spaces: one for memory and one for I/O operations. Lines on the control bus differentiate between memory and I/O addresses. Other than separate control lines and a smaller bus, I/O addressing behaves exactly like memory addressing. Memory and I/O devices both share the same data bus and the L.O. 16 lines on the address bus.

There are three limitations to the I/O subsystem on the PC: first, the 80x86 CPUs require special instructions to access I/O devices; second, the designers of the PC used the “best” I/O locations for their own purposes, forcing third party developers to use less accessible locations; third, 80x86 systems can address no more than 65,536 (2^{16}) I/O addresses. When you consider that a typical video display card requires over eight megabytes of addressable locations, you can see a problem with the size of I/O bus.

Fortunately, hardware designers can map their I/O devices into the memory address space as easily as they can the I/O address space. So by using the appropriate circuitry, they can make their I/O devices look just like memory. This is how, for example, display adapters on the PC work.

1.3 HLA Support for Data Alignment

In order to write the fastest running programs, you need to ensure that your data objects are properly aligned in memory. Data becomes misaligned whenever you allocate storage for different sized objects in adjacent memory locations. Since it is nearly impossible to write a (large) program that uses objects that are all the same size, some other facility is necessary in order to realign data that would normally be unaligned in memory.

Consider the following HLA variable declarations:

```
static
dw:    dword;
b:     byte;
w:     word;
dw2:   dword;
w2:    word;
b2:    byte;
dw3:   dword;
```

The first static declaration in a program (running under Win32 and most 32-bit operating systems) places its variables at an address that is an even multiple of 4096 bytes. Since 4096 is a power of two, whatever variable first appears in the static declaration is guaranteed to be aligned on a reasonable address. Each successive variable is allocated at an address that is the sum of the sizes of all the preceding variables plus the starting address. Therefore, assuming the above variables are allocated at a starting address of 4096, then each variable will be allocated at the following addresses:

| | | // Start Adrs | Length |
|------|--------|---------------|--------|
| dw: | dword; | // 4096 | 4 |
| b: | byte; | // 4100 | 1 |
| w: | word; | // 4101 | 2 |
| dw2: | dword; | // 4103 | 4 |
| w2: | word; | // 4107 | 2 |
| b2: | byte; | // 4109 | 1 |
| dw3: | dword; | // 4110 | 4 |

With the exception of the first variable (which is aligned on a 4K boundary) and the byte variables (whose alignment doesn't matter), all of these variables are misaligned in memory. The *w*, *w2*, and *dw2* variables are aligned on odd addresses and the *dw3* variable is aligned on an even address that is not an even multiple of four.

An easy way to guarantee that your variables are aligned on an appropriate address is to put all the dword variables first, the word variables second, and the byte variables last in the declaration:

```
static
dw:    dword;
dw2:   dword;
dw3:   dword;
w:     word;
w2:    word;
b:     byte;
b2:    byte;
```

This organization produces the following addresses in memory (again, assuming the first variable is allocated at address 4096):

| | | // Start Adrs | Length |
|------|--------|---------------|--------|
| dw: | dword; | // 4096 | 4 |
| dw2: | dword; | // 4100 | 4 |
| dw3: | dword; | // 4104 | 4 |
| w: | word; | // 4108 | 2 |
| w2: | word; | // 4110 | 2 |
| b: | byte; | // 4112 | 1 |
| b2: | byte; | // 4113 | 1 |

As you can see, these variables are all aligned at reasonable addresses.

Unfortunately, it is rarely possible for you to arrange your variables in this manner. While there are lots of technical reasons that make this alignment impossible, a good practical reason for not doing this is because it doesn't let you organize your variable declarations by logical function (that is, you probably want to keep related variables next to one another regardless of their size).

To resolve this problem, HLA provides two solutions. The first is an alignment option whenever you encounter a *static* section. If you follow the static keyword by an integer constant inside parentheses, HLA will align the very next variable declaration at an address that is an even multiple of the specified constant, e.g.,

```
static( 4 )
dw:    dword;
b:     byte;
w:     word;
dw2:   dword;
w2:    word;
b2:    byte;
dw3:   dword;
```

Of course, if you have only a single *static* section in your entire program, this declaration doesn't buy you much because the first declaration in the section is already aligned on a 4096 byte boundary. However, HLA does allow you to put multiple *static* sections into your program, so you can specify an alignment constant for each *static* section:

```
static( 4 )
dw:    dword;
b:     byte;

static( 2 )
w:     word;

static( 4 )
dw2:   dword;
w2:    word;
b2:    byte;
```

```
static( 4 )
    dw3:    dword;
```

This particular sequence guarantees that all double word variables are aligned on addresses that are multiples of four and all word variables are aligned on even addresses (note that a special section was not created for `w2` since its address is going to be an even multiple of four).

While the alignment parameter to the *static* directive is useful on occasion, there are two problems with it: The first problem is that inserting so many *static* directives into the middle of your variable declarations tends to disrupt the readability of your variable declarations. Part of this problem can be overcome by simply placing a *static* directive before every variable declaration:

```
static( 4 )    dw:    dword;
static( 1 )    b:     byte;
static( 2 )    w:     word;
static( 4 )    dw2:   dword;
static( 2 )    w2:    word;
static( 1 )    b2:    byte;
static( 4 )    dw3:   dword;
```

While this approach can, arguably, make a program easier to read, it certainly involves more typing and it doesn't address the second problem: variables appearing in separate *static* sections are not guaranteed to be allocated in adjacent memory locations. Once in a while it is very important to ensure that two variables are allocated in adjacent memory cells and most programmers assume that variables declared next to one another in the source code are allocated in adjacent memory cells. The mechanism above does not guarantee this.

The second facility HLA provides to help align adjacent memory locations is the *align* directive. The *align* directive uses the following syntax:

```
align( integer_constant );
```

The integer constant must be one of the following small unsigned integer values: 1, 2, 4, 8, or 16. If HLA encounters the *align* directive in a *static* section, it will align the very next variable on an address that is an even multiple of the specified alignment constant. The previous example could be rewritten, using the *align* directive, as follows:

```
static( 4 )
    dw:    dword;
    b:     byte;
    align( 2 );
    w:     word;
    align( 4 );
    dw2:   dword;
    w2:    word;
    b2:    byte;
    align( 4 );
    dw3:   dword;
```

If you're wondering how the *align* directive works, it's really quite simple. If HLA determines that the current address is not an even multiple of the specified value, HLA will quietly emit extra bytes of padding after the previous variable declaration until the current address in the *static* section is an even multiple of the specified value. This has the effect of making your program slightly larger (by a few bytes) in exchange for faster access to your data; Given that your program will only grow by a small number of bytes when you use this feature, this is a good trade off.

1.4 System Timing

Although modern computers are quite fast and getting faster all the time, they still require a finite amount of time to accomplish even the smallest tasks. On Von Neumann machines like the 80x86, most operations are *serialized*. This means that the computer executes commands in a prescribed order. It wouldn't do, for example, to execute the statement $I := I * 5 + 2$; before $I := J$; in the following sequence:

```
I := J;
I := I * 5 + 2;
```

Clearly we need some way to control which statement executes first and which executes second.

Of course, on real computer systems, operations do not occur instantaneously. Moving a copy of J into I takes a certain amount of time. Likewise, multiplying I by five and then adding two and storing the result back into I takes time. As you might expect, the second Pascal statement above takes quite a bit longer to execute than the first. For those interested in writing fast software, a natural question to ask is, "How does the processor execute statements, and how do we measure how long they take to execute?"

The CPU is a very complex piece of circuitry. Without going into too many details, let us just say that operations inside the CPU must be very carefully coordinated or the CPU will produce erroneous results. To ensure that all operations occur at just the right moment, the 80x86 CPUs use an alternating signal called the *system clock*.

1.4.1 The System Clock

At the most basic level, the *system clock* handles all synchronization within a computer system. The system clock is an electrical signal on the control bus which alternates between zero and one at a periodic rate (see Figure 1.10). All activity within the CPU is synchronized with the edges (rising or falling) of this clock signal.

Figure 1.10 The System Clock

The frequency with which the system clock alternates between zero and one is the *system clock frequency*. The time it takes for the system clock to switch from zero to one and back to zero is the *clock period*. One full period is also called a *clock cycle*. On most modern systems, the system clock switches between zero and one at rates exceeding several hundred million times per second to several billion times per second. The clock frequency is simply the number of clock cycles which occur each second. A typical Pentium III chip, circa 2000, runs at speeds of 1 billion cycles per second or faster. "Hertz" (Hz) is the technical term meaning one cycle per second. Therefore, the aforementioned Pentium chip runs at 1000 million hertz, or 1000 megahertz (MHz), also known as one gigahertz. Typical frequencies for 80x86 parts range from 5 MHz up to several Gigahertz (GHz, or billions of cycles per second) and beyond. Note that one clock period (the amount of time for one complete clock cycle) is the reciprocal of the clock frequency. For example, a 1 MHz clock would have a clock period of one microsecond ($1/1,000,000^{\text{th}}$ of a second). Likewise, a 10 MHz clock would have a clock period of 100 nanoseconds (100 billionths of a second). A CPU running at 1 GHz would

have a clock period of one nanosecond. Note that we usually express clock periods in millionths or billionths of a second.

To ensure synchronization, most CPUs start an operation on either the *falling edge* (when the clock goes from one to zero) or the *rising edge* (when the clock goes from zero to one). The system clock spends most of its time at either zero or one and very little time switching between the two. Therefore clock edge is the perfect synchronization point.

Since all CPU operations are synchronized around the clock, the CPU cannot perform tasks any faster than the clock. However, just because a CPU is running at some clock frequency doesn't mean that it is executing that many operations each second. Many operations take multiple clock cycles to complete so the CPU often performs operations at a significantly lower rate.

1.4.2 Memory Access and the System Clock

Memory access is one of the most common CPU activities. Memory access is definitely an operation synchronized around the system clock. That is, reading a value from memory or writing a value to memory occurs no more often than once every clock cycle. Indeed, on many 80x86 processors, it takes several clock cycles to access a memory location. The *memory access time* is the number of clock cycles the system requires to access a memory location; this is an important value since longer memory access times result in lower performance.

Different 80x86 processors have different memory access times ranging from one to four clock cycles. For example, the 8088 and 8086 CPUs require *four* clock cycles to access memory; the 80486 and later CPUs require only one. Therefore, the 80486 will execute programs that access memory faster than an 8086, even when running at the same clock frequency.

Memory access time is the amount of time between a memory operation request (read or write) and the time the memory operation completes. On a 5 MHz 8088/8086 CPU the memory access time is roughly 800 ns (nanoseconds). On a 50 MHz 80486, the memory access time is slightly less than 20 ns. Note that the memory access time for the 80486 is 40 times faster than the 8088/8086. This is because the 80486's clock frequency is ten times faster and it uses one-fourth the clock cycles to access memory.

When reading from memory, the memory access time is the amount of time from the point that the CPU places an address on the address bus and the CPU takes the data off the data bus. On an 80486 CPU with a one cycle memory access time, a read looks something like shown in Figure 1.11. Writing data to memory is similar (see Figure 1.12).

Figure 1.11 The 80x86 Memory Read Cycle

Figure 1.12 The 80x86 Memory Write Cycle

Note that the CPU doesn't wait for memory. The access time is specified by the clock frequency. If the memory subsystem doesn't work fast enough, the CPU will read garbage data on a memory read operation and will not properly store the data on a memory write operation. This will surely cause the system to fail.

Memory devices have various ratings, but the two major ones are capacity and speed (access time). Typical dynamic RAM (random access memory) devices have capacities of 512 (or more) megabytes and speeds of 5-100 ns. You can buy bigger or faster devices, but they are much more expensive. A typical 500 MHz Pentium system uses 10 ns memory devices.

Wait just a second here! At 500 MHz the clock period is roughly 2 ns. How can a system designer get away with using 10 ns memory? The answer is *wait states*.

1.4.3 Wait States

A wait state is nothing more than an extra clock cycle to give some device time to complete an operation. For example, a 100 MHz 80486 system has a 10 ns clock period. This implies that you need 10 ns memory. In fact, the situation is worse than this. In most computer systems there is additional circuitry between the CPU and memory: decoding and buffering logic. This additional circuitry introduces additional delays into the system (see Figure 1.13). In this diagram, the system loses 10ns to buffering and decoding. So if the CPU needs the data back in 10 ns, the memory must respond in less than 0 ns (which is impossible).

Figure 1.13 Decoding and Buffer Delays

If cost-effective memory won't work with a fast processor, how do companies manage to sell fast PCs? One part of the answer is the wait state. For example, if you have a 20 MHz processor with a memory cycle time of 50 ns and you lose 10 ns to buffering and decoding, you'll need 40 ns memory. What if you can only afford 80 ns memory in a 20 MHz system? Adding a wait state to extend the memory cycle to 100 ns (two clock cycles) will solve this problem. Subtracting 10ns for the decoding and buffering leaves 90 ns. Therefore, 80 ns memory will respond well before the CPU requires the data.

Almost every general purpose CPU in existence provides a signal on the control bus to allow the insertion of wait states. Generally, the decoding circuitry asserts this line to delay one additional clock period, if necessary. This gives the memory sufficient access time, and the system works properly (see Figure 1.14).

Figure 1.14 Inserting a Wait State into a Memory Read Operation

Sometimes a single wait state is not sufficient. Consider an 80486 running at 50 MHz. The normal memory cycle time is less than 20 ns. Therefore, less than 10 ns are available after subtracting decoding and buffering time. If you are using 60 ns memory in the system, adding a single wait state will not do the trick. Each wait state gives you 20 ns, so with a single wait state you would need 30 ns memory. To work with 60 ns memory you would need to add *three* wait states (zero wait states = 10 ns, one wait state = 30 ns, two wait states = 50 ns, and three wait states = 70 ns).

Needless to say, from the system performance point of view, wait states are *not* a good thing. While the CPU is waiting for data from memory it cannot operate on that data. Adding a single wait state to a memory cycle on an 80486 CPU *doubles* the amount of time required to access the data. This, in turn, *halves* the speed of the memory access. Running with a wait state on every memory access is almost like cutting the processor clock frequency in half. You're going to get a lot less work done in the same amount of time.

However, we're not doomed to slow execution because of added wait states. There are several tricks hardware designers can play to achieve zero wait states *most* of the time. The most common of these is the use of *cache* (pronounced "cash") memory.

1.4.4 Cache Memory

If you look at a typical program (as many researchers have), you'll discover that it tends to access the same memory locations repeatedly. Furthermore, you also discover that a program often accesses adjacent memory locations. The technical names given to this phenomenon are *temporal locality of reference* and *spatial locality of reference*. When exhibiting spatial locality, a program accesses neighboring memory loca-

tions. When displaying temporal locality of reference a program repeatedly accesses the same memory location during a short time period. Both forms of locality occur in the following Pascal code segment:

```
for i := 0 to 10 do
  A [i] := 0;
```

There are two occurrences each of spatial and temporal locality of reference within this loop. Let's consider the obvious ones first.

In the Pascal code above, the program references the variable *i* several times. The for loop compares *i* against 10 to see if the loop is complete. It also increments *i* by one at the bottom of the loop. The assignment statement also uses *i* as an array index. This shows temporal locality of reference in action since the CPU accesses *i* at three points in a short time period.

This program also exhibits spatial locality of reference. The loop itself zeros out the elements of array *A* by writing a zero to the first location in *A*, then to the second location in *A*, and so on. Assuming that Pascal stores the elements of *A* into consecutive memory locations, each loop iteration accesses adjacent memory locations.

There is an additional example of temporal and spatial locality of reference in the Pascal example above, although it is not so obvious. Computer instructions which tell the system to do the specified task also appear in memory. These instructions appear sequentially in memory – the spatial locality part. The computer also executes these instructions repeatedly, once for each loop iteration – the temporal locality part.

If you look at the execution profile of a typical program, you'd discover that the program typically executes less than half the statements. Generally, a typical program might only use 10-20% of the memory allotted to it. At any one given time, a one megabyte program might only access four to eight kilobytes of data and code. So if you paid an outrageous sum of money for expensive zero wait state RAM, you wouldn't be using most of it at any one given time! Wouldn't it be nice if you could buy a small amount of fast RAM and dynamically reassign its address(es) as the program executes?

This is exactly what cache memory does for you. Cache memory sits between the CPU and main memory. It is a small amount of very fast (zero wait state) memory. Unlike normal memory, the bytes appearing within a cache do not have fixed addresses. Instead, cache memory can reassign the address of a data object. This allows the system to keep recently accessed values in the cache. Addresses that the CPU has never accessed or hasn't accessed in some time remain in main (slow) memory. Since most memory accesses are to recently accessed variables (or to locations near a recently accessed location), the data generally appears in cache memory.

Cache memory is not perfect. Although a program may spend considerable time executing code in one place, eventually it will call a procedure or wander off to some section of code outside cache memory. In such an event the CPU has to go to main memory to fetch the data. Since main memory is slow, this will require the insertion of wait states.

A cache *hit* occurs whenever the CPU accesses memory and finds the data in the cache. In such a case the CPU can usually access data with zero wait states. A cache *miss* occurs if the CPU accesses memory and the data is not present in cache. Then the CPU has to read the data from main memory, incurring a performance loss. To take advantage of locality of reference, the CPU copies data into the cache whenever it accesses an address not present in the cache. Since it is likely the system will access that same location shortly, the system will save wait states by having that data in the cache.

As described above, cache memory handles the temporal aspects of memory access, but not the spatial aspects. Caching memory locations *when you access them* won't speed up the program if you constantly access consecutive locations (spatial locality of reference). To solve this problem, most caching systems read several consecutive bytes from memory when a cache miss occurs⁵. The 80486, for example, reads 16 bytes at a shot upon a cache miss. If you read 16 bytes, why read them in blocks rather than as you need them? As it turns out, most memory chips available today have special modes which let you quickly access several consecutive memory locations on the chip. The cache exploits this capability to reduce the average number of wait states needed to access memory.

5. Engineers call this block of data a cache *line*.

If you write a program that randomly accesses memory, using a cache might actually slow you down. Reading 16 bytes on each cache miss is expensive if you only access a few bytes in the corresponding cache line. Nonetheless, cache memory systems work quite well in the average case.

It should come as no surprise that the ratio of cache hits to misses increases with the size (in bytes) of the cache memory subsystem. The 80486 chip, for example, has 8,192 bytes of on-chip cache. Intel claims to get an 80-95% hit rate with this cache (meaning 80-95% of the time the CPU finds the data in the cache). This sounds very impressive. However, if you play around with the numbers a little bit, you'll discover it's not all *that* impressive. Suppose we pick the 80% figure. Then one out of every five memory accesses, on the average, will not be in the cache. If you have a 50 MHz processor and a 90 ns memory access time, four out of five memory accesses require only one clock cycle (since they are in the cache) and the fifth will require about 10 wait states⁶. Altogether, the system will require 15 clock cycles to access five memory locations, or three clock cycles per access, on the average. That's equivalent to two wait states added to every memory access. Now do you believe that your machine runs at zero wait states?

There are a couple of ways to improve the situation. First, you can add more cache memory. This improves the cache hit ratio, reducing the number of wait states. For example, increasing the hit ratio from 80% to 90% lets you access 10 memory locations in 20 cycles. This reduces the average number of wait states per memory access to one wait state – a substantial improvement. Alas, you can't pull an 80486 chip apart and solder more cache onto the chip. However, the 80586/Pentium CPUs have a significantly larger cache than the 80486 and operates with fewer average wait states.

Another way to improve performance is to build a *two-level* caching system. Many 80486 systems work in this fashion. The first level is the on-chip 8,192 byte cache. The next level, between the on-chip cache and main memory, is a secondary cache built on the computer system circuit board (see Figure 1.15). Pentiums and later chips typically move the secondary cache onto the same chip carrier as the CPU (that is, Intel's designers have included the secondary cache as part of the CPU module).

Figure 1.15 A Two Level Caching System

A typical secondary cache contains anywhere from 32,768 bytes to one megabyte of memory. Common sizes on PC subsystems are 256K, 512K, and 1024 Kbytes (1 MB) of cache.

You might ask, “Why bother with a two-level cache? Why not use a 262,144 byte cache to begin with?” Well, the secondary cache generally does not operate at zero wait states. The circuitry to support 262,144 bytes of 10 ns memory (20 ns total access time) would be *very* expensive. So most system designers use

6. Ten wait states were computed as follows: five clock cycles to read the first four bytes (10+20+20+20+20=90). However, the cache always reads 16 consecutive bytes. Most memory subsystems let you read consecutive addresses in about 40 ns after accessing the first location. Therefore, the 80486 will require an additional six clock cycles to read the remaining three double words. The total is 11 clock cycles or 10 wait states.

slower memory which requires one or two wait states. This is still *much* faster than main memory. Combined with the on-chip cache, you can get better performance from the system.

Consider the previous example with an 80% hit ratio. If the secondary cache requires two cycles for each memory access and three cycles for the first access, then a cache miss on the on-chip cache will require a total of six clock cycles. All told, the average system performance will be two clocks per memory access. Quite a bit faster than the three required by the system without the secondary cache. Furthermore, the secondary cache can update its values in parallel with the CPU. So the number of cache misses (which affect CPU performance) goes way down.

You're probably thinking, "So far this all sounds interesting, but what does it have to do with programming?" Quite a bit, actually. By writing your program carefully to take advantage of the way the cache memory system works, you can improve your program's performance. By co-locating variables you commonly use together in the same cache line, you can force the cache system to load these variables as a group, saving extra wait states on each access.

If you organize your program so that it tends to execute the same sequence of instructions repeatedly, it will have a high degree of temporal locality of reference and will, therefore, execute faster.

1.5 Putting It All Together

This chapter has provided a quick overview of the components that make up a typical computer system. The remaining chapters in Topic Two will expand upon these comments to give you a complete overview of computer system organization.

Memory Access and Organization

Chapter Two

2.1 Chapter Overview

In earlier chapters you saw how to declare and access simple variables in an assembly language program. In this chapter you will learn how the 80x86 CPUs actually access memory (e.g., variables). You will also learn how to efficiently organize your variable declarations so the CPU can access them faster. In this chapter you will also learn about the 80x86 stack and how to manipulate data on the stack with some 80x86 instructions this chapter introduces. Finally, you will learn about dynamic memory allocation and the chapter concludes by discussing the HLA Standard Library Console module.

2.2 The 80x86 Addressing Modes

The 80x86 processors let you access memory in many different ways. Until now, you've only seen a single way to access a variable, the so-called *displacement-only* addressing mode that you use to access scalar variables. Now it's time to look at the many different ways that you can access memory on the 80x86.

The 80x86 memory addressing modes provide flexible access to memory, allowing you to easily access variables, arrays, records, pointers, and other complex data types. Mastery of the 80x86 addressing modes is the first step towards mastering 80x86 assembly language.

When Intel designed the original 8086 processor, they provided it with a flexible, though limited, set of memory addressing modes. Intel added several new addressing modes when it introduced the 80386 microprocessor. Note that the 80386 retained all the modes of the previous processors. However, in 32-bit environments like Win32, BeOS, and Linux, these earlier addressing modes are not very useful; indeed, HLA doesn't even support the use of these older, 16-bit only, addressing modes. Fortunately, anything you can do with the older addressing modes can be done with the new addressing modes as well (even better, as a matter of fact). Therefore, you won't need to bother learning the old 16-bit addressing modes on today's high-performance processors. Do keep in mind, however, that if you intend to work under MS-DOS or some other 16-bit operating system, you will need to study up on those old addressing modes.

2.2.1 80x86 Register Addressing Modes

Most 80x86 instructions can operate on the 80x86's general purpose register set. By specifying the name of the register as an operand to the instruction, you may access the contents of that register. Consider the 80x86 MOV (move) instruction:

```
mov( source, destination );
```

This instruction copies the data from the *source* operand to the *destination* operand. The eight-bit, 16-bit, and 32-bit registers are certainly valid operands for this instruction. The only restriction is that both operands must be the same size. Now let's look at some actual 80x86 MOV instructions:

```
mov( bx, ax );    // Copies the value from BX into AX
mov( al, dl );    // Copies the value from AL into DL
mov( edx, esi );  // Copies the value from EDX into ESI
mov( bp, sp );    // Copies the value from BP into SP
mov( cl, dh );    // Copies the value from CL into DH
mov( ax, ax );    // Yes, this is legal!
```

Remember, the registers are the best place to keep often used variables. As you'll see a little later, instructions using the registers are shorter and faster than those that access memory. Throughout this chapter you'll see the abbreviated operands *reg* and *r/m* (register/memory) used wherever you may use one of the 80x86's general purpose registers.

2.2.2 80x86 32-bit Memory Addressing Modes

The 80x86 provides hundreds of different ways to access memory. This may seem like quite a bit at first, but fortunately most of the addressing modes are simple variants of one another so they're very easy to learn. And learn them you should! The key to good assembly language programming is the proper use of memory addressing modes.

The addressing modes provided by the 80x86 family include displacement-only, base, displacement plus base, base plus indexed, and displacement plus base plus indexed. Variations on these five forms provide the many different addressing modes on the 80x86. See, from 256 down to five. It's not so bad after all!

2.2.2.1 The Displacement Only Addressing Mode

The most common addressing mode, and the one that's easiest to understand, is the *displacement-only* (or *direct*) addressing mode. The displacement-only addressing mode consists of a 32 bit constant that specifies the address of the target location. Assuming that variable *J* is an *int8* variable allocated at address \$8088, the instruction “`mov(J, al);`” loads the AL register with a copy of the byte at memory location \$8088. Likewise, if *int8* variable *K* is at address \$1234 in memory, then the instruction “`mov(dl, K);`” stores the value in the DL register to memory location \$1234 (see Figure 2.1).

Figure 2.1 Displacement Only (Direct) Addressing Mode

The displacement-only addressing mode is perfect for accessing simple scalar variables.

Intel named this the displacement-only addressing mode because a 32-bit constant (displacement) follows the MOV opcode in memory. On the 80x86 processors, this displacement is an offset from the beginning of memory (that is, address zero). The examples in this chapter will typically access bytes in memory. Don't forget, however, that you can also access words and double words on the 80x86 processors (see Figure 2.2).

Figure 2.2 Accessing a Word or DWord Using the Displacement Only Addressing Mode

2.2.2.2 The Register Indirect Addressing Modes

The 80x86 CPUs let you access memory indirectly through a register using the register indirect addressing modes. The term indirect means that the operand is not the actual address, but rather, the operand's value specifies the memory address to use. In the case of the register indirect addressing modes, the register's value is the memory location to access. For example, the instruction “`mov(eax, [ebx]);`” tells the CPU to store EAX's value at the location whose address is in EBX (the square brackets around EBX tell HLA to use the register indirect addressing mode).

There are eight forms of this addressing mode on the 80x86, best demonstrated by the following instructions:

```
mov( [eax], al );
mov( [ebx], al );
mov( [ecx], al );
mov( [edx], al );
mov( [edi], al );
mov( [esi], al );
mov( [ebp], al );
mov( [esp], al );
```

These eight addressing modes reference the memory location at the offset found in the register enclosed by brackets (EAX, EBX, ECX, EDX, EDI, ESI, EBP, or ESP, respectively).

Note that the register indirect addressing modes require a 32-bit register. You cannot specify a 16-bit or eight-bit register when using an indirect addressing mode¹. Technically, you could load a 32-bit register with an arbitrary numeric value and access that location indirectly using the register indirect addressing mode:

```
mov( $1234_5678, ebx );
mov( [ebx], al );           // Attempts to access location $1234_5678.
```

Unfortunately (or fortunately, depending on how you look at it), this will probably cause Windows to generate a protection fault since it's not always legal to access arbitrary memory locations.

1. Actually, the 80x86 does support addressing modes involving certain 16-bit registers, as mentioned earlier. However, HLA does not support these modes and they are not particularly useful under Win32.

The register indirect addressing mode has lots of uses. You can use it to access data referenced by a pointer, you can use it to step through array data, and, in general, you can use it whenever you need to modify the address of a variable while your program is running.

The register indirect addressing mode provides an example of a *anonymous* variable. When using the register indirect addressing mode you refer to the value of a variable by its numeric memory address (e.g., the value you load into a register) rather than by the name of the variable. Hence the phrase anonymous variable.

HLA provides a simple operator that you can use to take the address of a `STATIC` variable and put this address into a 32-bit register. This is the “&” (address of) operator (note that this is the same symbol that C/C++ uses for the address-of operator). The following example loads the address of variable `J` into `EBX` and then stores the value in `EAX` into `J` using the register indirect addressing mode:

```
mov( &J, ebx );           // Load address of J into EBX.
mov( eax, [ebx] );       // Store EAX into J.
```

Of course, it would have been simpler to store the value in `EAX` directly into `J` rather than using two instructions to do this indirectly. However, you can easily imagine a code sequence where the program loads one of several different addresses into `EBX` prior to the execution of the “`mov(eax, [ebx]);`” statement, thus storing `EAX` into one of several different locations depending on the execution path of the program.

Warning: the “&” (address-of) operator is not a general address-of operator like the “&” operator in C/C++. You may only apply this operator to static variables². It cannot be applied to generic address expressions or other types of variables. For more information on taking the address of such objects, see “Obtaining the Address of a Memory Object” on page 183.

2.2.2.3 Indexed Addressing Modes

The indexed addressing modes use the following syntax:

```
mov( VarName[ eax ], al );
mov( VarName[ ebx ], al );
mov( VarName[ ecx ], al );
mov( VarName[ edx ], al );
mov( VarName[ edi ], al );
mov( VarName[ esi ], al );
mov( VarName[ ebp ], al );
mov( VarName[ esp ], al );
```

VarName is the name of some variable in your program.

The indexed addressing mode computes an *effective address*³ by adding the address of the specified variable to the value of the 32-bit register appearing inside the square brackets. This sum is the actual address in memory that the instruction will access. So if *VarName* is at address \$1100 in memory and `EBX` contains eight, then “`mov(VarName[ebx], al);`” loads the byte at address \$1108 into the `AL` register (see Figure 2.3).

2. Note: the term “static” here indicates a `STATIC`, `READONLY`, `STORAGE`, or `DATA` object.

3. The effective address is the ultimate address in memory that an instruction will access, once all the address calculations are complete.

Figure 2.3 Indexed Addressing Mode

The indexed addressing mode is really handy for accessing elements of arrays. You will see how to use this addressing mode for that purpose a little later in this text. A little later in this chapter you will see how to use the indexed addressing mode to step through data values in a table.

2.2.2.4 Variations on the Indexed Addressing Mode

There are two important syntactical variations of the indexed addressing mode. Both forms generate the same basic machine instructions, but their syntax suggests other uses for these variants.

The first variant uses the following syntax:

```
mov( [ ebx + constant ], al );
mov( [ ebx - constant ], al );
```

These examples use only the EBX register. However, you can use any of the other 32-bit general purpose registers in place of EBX. This addressing mode computes its effective address by adding the value in EBX to the specified constant, or subtracting the specified constant from EBX (See Figure 2.4 and Figure 2.5).

Figure 2.4 Indexed Addressing Mode Using a Register Plus a Constant

Figure 2.5 Indexed Addressing Mode Using a Register Minus a Constant

This particular variant of the addressing mode is useful if a 32-bit register contains the *base address* of a multi-byte object and you wish to access a memory location some number of bytes before or after that location. One important use of this addressing mode is accessing fields of a record (or structure) when you have a pointer to the record data. You'll see a little later in this text that this addressing mode is also invaluable for accessing automatic (local) variables in procedures.

The second variant of the indexed addressing mode is actually a combination of the previous two forms. The syntax for this version is the following:

```
mov( VarName[ ebx + constant ], al );
mov( VarName[ ebx - constant ], al );
```

Once again, this example uses only the EBX register. You may, however, substitute any of the 32-bit general purpose registers in place of EBX in these two examples. This particular form is quite useful when accessing elements of an array of records (structures) in an assembly language program (more on that in a few chapters).

These instructions compute their effective address by adding or subtracting the *constant* value from *VarName* and then adding the value in EBX to this result. Note that HLA, not the CPU, computes the sum or difference of *VarName* and *constant*. The actual machine instructions above contain a single constant value that the instructions add to the value in EBX at run-time. Since HLA substitutes a constant for *VarName*, it can reduce an instruction of the form

```
mov( VarName[ ebx + constant], al );
```

to an instruction of the form:

```
mov( constant1[ ebx + constant2], al );
```

Because of the way these addressing modes work, this is semantically equivalent to

```
mov( [ebx + (constant1 + constant2)], al );
```

HLA will add the two constants together at compile time, effectively producing the following instruction:

```
mov( [ebx + constant_sum], al );
```

So, HLA converts the first addressing mode of this sequence to the last in this sequence.

Of course, there is nothing special about subtraction. You can easily convert the addressing mode involving subtraction to addition by simply taking the two's complement of the 32-bit constant and then adding this complemented value (rather than subtracting the uncomplemented value). Other transformations are equally possible and legal. The end result is that these three variations on the indexed addressing mode are indeed equivalent.

2.2.2.5 Scaled Indexed Addressing Modes

The scaled indexed addressing modes are similar to the indexed addressing modes with two differences: (1) the scaled indexed addressing modes allow you to combine two registers plus a displacement, and (2) the scaled indexed addressing modes let you multiply the index register by a (scaling) factor of one, two, four, or eight. The allowable forms for these addressing modes are

```

VarName [ IndexReg32*scale ]
VarName [ IndexReg32*scale + displacement ]
VarName [ IndexReg32*scale - displacement ]

[ BaseReg32 + IndexReg32*scale ]
[ BaseReg32 + IndexReg32*scale + displacement ]
[ BaseReg32 + IndexReg32*scale - displacement ]

VarName [ BaseReg32 + IndexReg32*scale ]
VarName [ BaseReg32 + IndexReg32*scale + displacement ]
VarName [ BaseReg32 + IndexReg32*scale - displacement ]

```

In these examples, *BaseReg₃₂* represents any general purpose 32-bit register, *IndexReg₃₂* represents any general purpose 32-bit register except ESP, and *scale* must be one of the constants: 1, 2, 4, or 8.

The primary difference between the scaled indexed addressing mode and the indexed addressing mode is the inclusion of the *IndexReg₃₂*scale* component. The effective address computation is extended by adding in the value of this new register after it has been multiplied by the specified scaling factor (see Figure 2.6 for an example involving EBX as the base register and ESI as the index register).

```
mov( VarName[ ebx + esi*scale ], al );
```

Figure 2.6 The Scaled Indexed Addressing Mode

In Figure 2.6, suppose that EBX contains \$100, ESI contains \$20, and *VarName* is at base address \$2000 in memory, then the following instruction:

```
mov( VarName[ ebx + esi*4 + 4 ], al );
```

will move the byte at address \$2184 ($\$1000 + \$100 + \$20*4 + 4$) into the AL register.

The scaled indexed addressing mode is typically used to access elements of arrays whose elements are two, four, or eight bytes each. This addressing mode is also useful for access elements of an array when you have a pointer to the beginning of the array.

Warning: although this addressing mode contains to variable components (the base and index registers), don't get the impression that you use this addressing mode to access elements of a two-dimensional array by loading the two array indices into the two registers. Two-dimensional array access is quite a bit

more complicated than this. A later chapter in this text will consider multi-dimensional array access and discuss how to do this.

2.2.2.6 Addressing Mode Wrap-up

Well, believe it or not, you've just learned several hundred addressing modes! That wasn't hard now, was it? If you're wondering where all these modes came from, just consider the fact that the register indirect addressing mode isn't a single addressing mode, but eight different addressing modes (involving the eight different registers). Combinations of registers, constant sizes, and other factors multiply the number of possible addressing modes on the system. In fact, you only need to memorize less than two dozen forms and you've got it made. In practice, you'll use less than half the available addressing modes in any given program (and many addressing modes you may never use at all). So learning all these addressing modes is actually much easier than it sounds.

2.3 Run-Time Memory Organization

An operating system like Windows tends to put different types of data into different sections (or segments) of main memory. Although it is possible to reconfigure memory to your choice by running the Linker and specify various parameters, by default an HLA program loads into memory using the following basic organization:

Figure 2.7 Win32 Typical Run-Time Memory Organization

The lowest memory addresses are reserved by the operating system. Generally, your application is not allowed to access data (or execute instructions) at the lowest addresses in memory. One reason the O/S reserves this space is to help trap NULL pointer references. If you attempt to access memory location zero, the operating system will generate a "general protection fault" meaning you've accessed a memory location that doesn't contain valid data. Since programmers often initialize pointers to NULL (zero) to indicate that the pointer is not pointing anywhere, an access of location zero typically means that the programmer has made a mistake and has not properly initialized a pointer to a legal (non-NULL) value. Also note that if you attempt to use one of the 80x86 sixteen-bit addressing modes (HLA doesn't allow this, but were you to

encode the instruction yourself and execute it...) the address will always be in the range 0..\$1FFFE⁴. This will also access a location in the reserved area, generating a fault.

The remaining six areas in the memory map hold different types of data associated with your program. These sections of memory include the stack section, the heap section, the code section, the READONLY section, the STATIC section, and the STORAGE section. Each of these memory sections correspond to some type of data you can create in your HLA programs. The following sections discuss each of these sections in detail.

2.3.1 The Code Section

The code section contains the machine instructions that appear in an HLA program. HLA translates each machine instruction you write into a sequence of one or more byte values. The CPU interprets these byte values as machine instructions during program execution.

By default, when HLA links your program it tells the system that your program can execute instructions out of the code segment and you can read data from the code segment. Note, specifically, that you cannot write data to the code segment. The Windows operating system will generate a general protection fault if you attempt to store any data into the code segment.

Remember, machine instructions are nothing more than data bytes. In theory, you could write a program that stores data values into memory and then transfers control to the data it just wrote, thereby producing a program that writes itself as it executes. This possibility produces romantic visions of Artificially Intelligent programs that modify themselves to produce some desired result. In real life, the effect is somewhat less glamorous.

Prior to the popularity of *protected mode operating systems*, like Windows, a program could overwrite the machine instructions during execution. Most of the time this was caused by defects in a program, not by some super-smart artificial intelligence program. A program would begin writing data to some array and fail to stop once it reached the end of the array, eventually overwriting the executing instructions that make up the program. Far from improving the quality of the code, such a defect usually causes the program to fail spectacularly.

Of course, if a feature is available, someone is bound to take advantage of it. Some programmers have discovered that in some special cases, using *self-modifying code*, that is, a program that modifies its machine instructions during execution, can produce slightly faster or slightly smaller programs. Unfortunately, self-modifying code is very difficult to test and debug. Given the speed of modern processors combined with their instruction set and wide variety of addressing modes, there is almost no reason to use self-modifying code in a modern program. Indeed, protected mode operating systems like Windows make it difficult for you to write self modifying code.

HLA automatically stores the data associated with your machine code into the code section. In addition to machine instructions, you can also store data into the code section by using the following pseudo-opcodes:

- byte
- word
- dword
- uns8
- uns16
- uns32
- int8
- int16
- in32
- boolean
- char

4. It's \$1FFFE, not \$FFFF because you could use the indexed addressing mode with a displacement of \$FFFF along with the value \$FFFF in a 16-bit register.

The syntax for each of these *pseudo-opcodes*⁵ is exemplified by the following BYTE statement:

```
byte comma_separated_list_of_byte_constants ;
```

Here are some examples:

```
boolean    true;
char       'A';
byte       0,1,2;
byte       "Hello", 0
word       0,2;
int8       -5;
uns32      356789, 0;
```

If more than one value appears in the list of values after the pseudo-opcode, HLA emits each successive value to the code stream. So the first *byte* statement above emits three bytes to the code stream, the values zero, one, and two. If a string appears within a byte statement, HLA emits one byte of data for each character in the string. Therefore, the second byte statement above emits six bytes: the characters 'H', 'e', 'l', 'l', and 'o', followed by a zero byte.

Keep in mind that the CPU will attempt to treat data you emit to the code stream as machine instructions unless you take special care not to allow the execution of the data. For example, if you write something like the following:

```
mov( 0, ax );
byte 0,1,2,3;
add( bx, cx );
```

Your program will attempt to execute the 0, 1, 2, and 3 byte values as a machine instruction after executing the MOV. Unless you know the machine code for a particular instruction sequence, sticking such data values into the middle of your code will almost always produce unexpected results. More often than not, this will crash your program. Therefore, you should never insert arbitrary data bytes into the middle of an instruction stream unless you know exactly what executing those data values will do in your program⁶.

In the chapter on intermediate procedures, we will take another look at embedding data into the code stream. This is a convenient way to pass certain types of parameters to various procedures. In the chapter on advanced control structures, you will see other reasons for embedding data into the code stream. For now, just keep in mind that it is possible to do this but that you should avoid embedding data into the code stream.

2.3.2 The Read-Only Data Section

The READONLY data section holds constants, tables, and other data that your program must not change during program execution. You can place read only objects in your program by declaring them in the READONLY declaration section. The READONLY data declaration section is very similar to the STATIC section with three primary differences:

- The READONLY section begins with the reserved word READONLY rather than STATIC,
- All declarations in the READONLY section must have an initializer, and
- You are not allowed to store data into a READONLY object while the program is running.

Example:

```
readonly
pi:      real32 := 3.14159;
```

5. A pseudo-opcode is a data declaration statement that emits data to the code section, but isn't a true machine instruction (e.g., BYTE is a pseudo-opcode, MOV is a machine instruction).

6. The main reason for encoding machine code using a data directive like *byte* is to implement machine instructions that HLA does not support (for example, to implement machine instructions added after HLA was written but before HLA could be updated for the new instruction(s)).

```
e:          real32 := 2.71;
MaxU16:    uns16  := 65_535;
MaxI16:    int16  := 32_767;
```

All READONLY object declarations must have an initializer because you cannot initialize the value under program control (since you are not allowed to write data into a READONLY object). The operating system will generate an exception and abort your program if you attempt to write a value to a READONLY object. For all intents and purposes, READONLY objects can be thought of as constants. However, these constants to consume memory and other than the fact that you cannot write data to READONLY objects, they behave like, and can be used like, STATIC variables.

The READONLY reserved word allows an alignment parameter, just like the STATIC keyword. You may also place the ALIGN directive in the READONLY section in order to align individual objects on a specific boundary. The following example demonstrates both of these features in the READONLY section:

```
readonly( 8 )
  pi:    real64 := 3.14159265359;
  aChar: char   := 'a';
  align(4);
  d:      dword := 4;
```

2.3.3 The Storage Section

The READONLY section requires that you initialize all objects you declare. The STATIC section lets you optionally initialize objects (or leave them uninitialized, in which case they have the default initial value of zero). The STORAGE section completes the initialization coverage: you use it to declare variables that are always uninitialized when the program begins running. The STORAGE section begins with the “storage” reserved word and then contains variable declarations that are identical to those appearing in the STATIC section except that you are not allowed to initialize the object. Here is an example:

```
storage
  UninitUns32:    uns32;
  i:              int32;
  character:     char;
  b:              byte;
```

Variables you declare in the STORAGE section may consume less disk space in the executable file for the program. This is because HLA writes out initial values for READONLY and STATIC objects to the executable file, but uses a compact representation for uninitialized variables you declare in the STORAGE section.

Like the STATIC and READONLY sections, you can supply an alignment parameter after the STORAGE keyword and the ALIGN directive may appear within the STORAGE section. Of course, aligning your data can produce faster access to that data at the expense of a slightly larger STORAGE section. The following example demonstrates the use of these two features in the STORAGE section:

```
storage( 4 )
  d:    dword;
  b:    byte;
  align(2);
  w:    word;
```

2.3.4 The Static Sections

In addition to declaring static variables, you can also embed lists of data into the STATIC memory segment. You use the same technique to embed data into your STATIC section that you use to embed data into

the code section: you use the *byte*, *word*, *dword*, *uns32*, etc., pseudo-opcodes. Consider the following example:

```
static
  b: byte := 0;
     byte 1,2,3;

  u: uns32 := 1;
     uns32 5,2,10;

  c: char;
     char 'a', 'b', 'c', 'd', 'e', 'f';

  bn: boolean;
     boolean true;
```

Data that HLA writes to the `STATIC` memory segment using these pseudo-opcodes is written to the segment after the preceding variables. For example, the byte values one, two, and three are emitted to the `STATIC` section after *b*'s zero byte in the example above. Since there aren't any labels associated with these values, you do not have direct access to these values in your program. The section on address expressions, later in this chapter, will discuss how to access these extra values.

In the examples above, note that the *c* and *bn* variables do not have an (explicit) initial value. However, HLA always initializes variables in the `STATIC` section to all zero bits, so HLA assigns the `NULL` character (ASCII code zero) to *c* as its initial value. Likewise, HLA assigns `false` as the initial value for *bn*. In particular, you should note that your variable declarations in the `STATIC` section always consume memory, even if you haven't assigned them an initial value. Any data you declare in a pseudo-opcode like `BYTE` will always follow the actual data associated with the variable declaration.

2.3.5 The `NOSTORAGE` Attribute

The `NOSTORAGE` attribute lets you declare variables in the static data declaration sections (i.e., `STATIC`, `READONLY`, and `STORAGE`) without actually allocating memory for the variable. The `NOSTORAGE` option tells HLA to assign the current address in a data declaration section to a variable but not allocate any storage for the object. Therefore, that variable will share the same memory address as the next object appearing in the variable declaration section. Here is the syntax for the `NOSTORAGE` option:

```
variableName: varType; NOSTORAGE;
```

Note that you follow the type name with “`nostorage;`” rather than some initial value or just a semicolon. The following code sequence provides an example of using the `NOSTORAGE` option in the `READONLY` section:

```
readonly
  abcd: dword; nostorage;
       byte 'a', 'b', 'c', 'd';
```

In this example, *abcd* is a double word whose L.O. byte contains 97 ('a'), byte #1 contains 98 ('b'), byte #2 contains 99 ('c'), and the H.O. byte contains 100 ('d'). HLA does not reserve storage for the *abcd* variable, so HLA associates the following four bytes in memory (allocated by the `BYTE` directive) with *abcd*.

Note that the `NOSTORAGE` attribute is only legal in the `STATIC`, `STORAGE`, and `READONLY` sections. HLA does not allow its use in the `VAR` section.

2.3.6 The `Var` Section

HLA provides another variable declaration section, the `VAR` section, that you can use to create *automatic* variables. Your program will allocate storage for automatic variables whenever a program unit (i.e.,

main program or procedure) begins execution, and it will deallocate storage for automatic variables when that program unit returns to its caller. Of course, any automatic variables you declare in your main program have the same *lifetime*⁷ as all the STATIC, READONLY, and STORAGE objects, so the automatic allocation feature of the VAR section is wasted on the main program. In general, you should only use automatic objects in procedures (see the chapter on procedures for details). HLA allows them in your main program's declaration section as a generalization.

Since variables you declare in the VAR section are created at run-time, HLA does not allow initializers on variables you declare in this section. So the syntax for the VAR section is nearly identical to that for the STORAGE section; the only real difference in the syntax between the two is the use of the VAR reserved word rather than the STORAGE reserved word. The following example illustrates this:

```
var
  vInt:  int32;
  vChar: char;
```

HLA allocates variables you declare in the VAR section in the stack segment. HLA does not allocate VAR objects at fixed locations within the stack segment; instead, it allocates these variables in an *activation record* associated with the current program unit. The chapter on intermediate procedures will discuss activation records in greater detail, for now it is important only to realize that HLA programs use the EBP register as a pointer to the current activation record. Therefore, anytime you access a var object, HLA automatically replaces the variable name with “[EBP+displacement]”. Displacement is the offset of the object in the activation record. This means that you cannot use the full scaled indexed addressing mode (a base register plus a scaled index register) with VAR objects because VAR objects already use the EBP register as their base register. Although you will not directly use the two register addressing modes often, the fact that the VAR section has this limitation is a good reason to avoid using the VAR section in your main program.

The VAR section supports the align parameter and the ALIGN directive, like the other declaration sections, however, these align directives only guarantee that the alignment within the activation record is on the boundary you specify. If the activation record is not aligned on a reasonable boundary (unlikely, but possible) then the actual variable alignment won't be correct.

2.3.7 Organization of Declaration Sections Within Your Programs

The STATIC, READONLY, STORAGE, and VAR sections may appear zero or more times between the PROGRAM header and the associated BEGIN for the main program. Between these two points in your program, the declaration sections may appear in any order as the following example demonstrates:

```
program demoDeclarations;

static
  i_static:  int32;

var
  i_auto:    int32;

storage
  i_uninit:  int32;

readonly
  i_readonly: int32 := 5;

static
  j:        uns32;
```

7. The lifetime of a variable is the point from which memory is first allocated to the point the memory is deallocated for that variable.

```

var
    k:char;

readonly
    i2:uns8 := 9;

storage
    c:char;

storage
    d:dword;

begin demoDeclarations;

    << code goes here >>

end demoDeclarations;

```

In addition to demonstrating that the sections may appear in an arbitrary order, this section also demonstrates that a given declaration section may appear more than once in your program. When multiple declaration sections of the same type (e.g., the three STORAGE sections above) appear in a declaration section of your program, HLA combines them into a single section⁸.

2.4 Address Expressions

In the section on addressing modes (see “The 80x86 Addressing Modes” on page 151) this chapter pointed out that addressing modes take a couple generic forms, including:

```

    VarName[ Reg32 ]
    VarName[ Reg32 + offset ]
    VarName[ RegNotESP32*Scale ]
    VarName[ Reg32 + RegNotESP32*Scale ]
    VarName[ RegNotESP32*Scale + offset ]
        and
    VarName[ Reg32 + RegNotESP32*Scale + offset ]

```

Another legal form, which isn’t actually a new addressing mode but simply an extension of the displacement-only addressing mode is

```

    VarName[ offset ]

```

This latter example computes its effective address by adding the (constant) offset within the brackets to the specified variable address. For example, the instruction “MOV(Address[3], AL);” loads the AL register with the byte in memory that is three bytes beyond the *Address* object.

8. Remember, though, that HLA combines *static* and *data* declarations into the same memory segment.

Figure 2.8 Using an Address Expression to Access Data Beyond a Variable

It is extremely important to remember that the *offset* value in these examples must be a constant. If *Index* is an *int32* variable, then “Variable[Index]” is not a legal specification. If you wish to specify an index that varies at run-time, then you must use one of the indexed or scaled indexed addressing modes; that is, any index that changes at run-time must be held in a general purpose 32-bit register.

Another important thing to remember is that the offset in “Address[offset]” is a byte offset. Despite the fact that this syntax is reminiscent of array indexing in a high level language like C/C++ or Pascal, this does not properly index into an array of objects unless *Address* is an array of bytes.

This text will consider an *address expression* to be any legal 80x86 addressing mode that includes a displacement (i.e., variable name) or an offset. In addition to the above forms, the following are also address expressions:

$$[\text{Reg}_{32} + \text{offset}]$$

$$[\text{Reg}_{32} + \text{RegNotESP}_{32} * \text{Scale} + \text{offset}]$$

This text will *not* consider the following to be address expressions since they do not involve a displacement or offset component:

$$[\text{Reg}_{32}]$$

$$[\text{Reg}_{32} + \text{RegNotESP}_{32} * \text{Scale}]$$

Address expressions are special because those instructions containing an address expression always encode a displacement constant as part of the machine instruction. That is, the machine instruction contains some number of bits (usually eight or thirty-two) that hold a numeric constant. That constant is the sum of the displacement (i.e., the address or offset of the variable) plus the offset supplied in the addressing mode. Note that HLA automatically adds these two values together for you (or subtracts the offset if you use the “-” rather than “+” operator in the addressing mode).

Until this point, the offset in all the addressing mode examples has always been a single numeric constant. However, HLA also allows a *constant expression* anywhere an offset is legal. A constant expression consists of one or more constant terms manipulated by operators such as addition, subtraction, multiplication, division, modulo, and a wide variety of other operators. Most address expressions, however, will only involve addition, subtraction, multiplication, and sometimes, division. Consider the following example:

```
mov( X[ 2*4+1 ], al );
```

This instruction will move the byte at address $X+9$ into the AL register.

The value of an address expression is always computed at compile-time, never while the program is running. When HLA encounters the instruction above, it calculates $2*4+1$ on the spot and adds this result to

the base address of *X* in memory. HLA encodes this single sum (base address of *X* plus nine) as part of the instruction; HLA does not emit extra instructions to compute this sum for you at run-time (which is good, doing so would be less efficient). Since HLA computes the value of address expressions at compile-time, all components of the expression must be constants since HLA cannot know what the value of a variable will be at run-time while it is compiling the program.

Address expressions are very useful for accessing addition bytes in memory beyond a variable, particularly when you've used the *byte*, *word*, *dword*, etc., statements in a *STATIC*, or *READONLY* section to tack on additional bytes after a data declaration. For example, consider the following program:

```

program adrsExpressions;
#include( "stdlib.hhf" );
static
    i: int8; nostorage;
    byte 0, 1, 2, 3;

begin adrsExpressions;

    stdout.put
    (
        "i[0]=", i[0], nl,
        "i[1]=", i[1], nl,
        "i[2]=", i[2], nl,
        "i[3]=", i[3], nl
    );

end adrsExpressions;

```

Program 3.1 Demonstration of Address Expressions

Throughout this chapter and those that follow you will see several additional uses of address expressions.

2.5 Type Coercion

Although HLA is fairly loose when it comes to type checking, HLA does ensure that you specify appropriate operand sizes to an instruction. For example, consider the following (incorrect) program:

```

program hasErrors;
static
    i8: int8;
    i16: int16;
    i32: int32;
begin hasErrors;

    mov( i8, eax );
    mov( i16, al );
    mov( i32, ax );

end hasErrors;

```

HLA will generate errors for the three MOV instructions appearing in this program. This is because the operand sizes do not agree. The first instruction attempts to move a byte into EAX, the second instruction attempts to move a word into AL and the third instruction attempts to move a dword into AX. The MOV instruction, of course, requires that its two operands both be the same size.

While this is a good feature in HLA⁹, there are times when it gets in the way of the task at hand. For example, consider the following data declaration:

```
static
    byte_values: byte; nostorage;
                byte    0, 1;
    ...

    mov( byte_values, ax );
```

In this example let's assume that the programmer really wants to load the word starting at address *byte_values* in memory into the AX register because they want to load AL with zero and AH with one using a single instruction. HLA will refuse, claiming there is a type mismatch error (since *byte_values* is a *byte* object and AX is a *word* object). The programmer could break this into two instructions, one to load AL with the byte at address *byte_values* and the other to load AH with the byte at address *byte_values[1]*. Unfortunately, this decomposition makes the program slightly less efficient (which was probably the reason for using the single MOV instruction in the first place). Somehow, it would be nice if we could tell HLA that we know what we're doing and we want to treat the *byte_values* variable as a *word* object. HLA's *type coercion* facilities provide this capability.

Type coercion¹⁰ is the process of telling HLA that you want to treat an object as an explicitly specified type, regardless of its declared type. To coerce the type of a variable, you use the following syntax:

```
(type newTypeName addressingMode)
```

The *newTypeName* component is the new type you wish HLA to apply to the memory location specified by *addressingMode*. You may use this coercion operator anywhere a memory address is legal. To correct the previous example, so HLA doesn't complain about type mismatches, you would use the following statement:

```
mov( (type word byte_values), ax );
```

This instruction tells HLA to load the AX register with the word starting at address *byte_values* in memory. Assuming *byte_values* still contains its initial values, this instruction will load zero into AL and one into AH.

Type coercion is necessary when you specify an anonymous variable as the operand to an instruction that modifies memory directly (e.g., NEG, SHL, NOT, etc.). Consider the following statement:

```
not( [ebx] );
```

HLA will generate an error on this instruction because it cannot determine the size of the memory operand. That is, the instruction does not supply sufficient information to determine whether the program should invert the bits in the byte pointed at by EBX, the word pointed at by EBX, or the double word pointed at by EBX. You must use type coercion to explicitly tell HLA the size of the memory operand when using anonymous variables with these types of instructions:

```
not( (type byte [ebx]) );
not( (type word [ebx]) );
not( (type dword [ebx]) );
```

Warning: do not use the type coercion operator unless you know exactly what you are doing and the effect that it has on your program. Beginning assembly language programmers often use type coercion as a tool to quiet the compiler when it complains about type mismatches without solving the underlying problem. For example, consider the following statement:

```
mov( eax, (type dword byteVar) );
```

9. After all, if the two operand sizes are different this usually indicates an error in the program.

10. Also called type casting in some languages.

Without the type coercion operator, HLA probably complains about this instruction because it attempts to store a 32-bit register into an eight-bit memory location (assuming *byteVar* is a byte variable). A beginning programmer, wanting their program to compile, may take a short cut and use the type coercion operator as shown in this instruction; this certainly quiets the compiler - it will no longer complain about a type mismatch. So the beginning programmer is happy. But the program is still incorrect, the only difference is that HLA no longer warns you about your error. The type coercion operator does not fix the problem of attempting to store a 32-bit value into an eight-bit memory location - it simply allows the instruction to store a 32-bit value *starting at the address* specified by the eight-bit variable. The program still stores away four bytes, overwriting the three bytes following *byteVar* in memory. This often produces unexpected results including the phantom modification of variables in your program¹¹. Another, rarer, possibility is for the program to abort with a general protection fault. This can occur if the three bytes following *byteVar* are not allocated actual memory or if those bytes just happen to fall in a read-only segment in memory. The important thing to remember about the type coercion operator is this: "If you can't exactly state the affect this operator has, don't use it."

Also keep in mind that the type coercion operator does not perform any translation of the data in memory. It simply tells the compiler to treat the bits in memory as a different type. It will not automatically sign extend an eight-bit value to 32 bits nor will it convert an integer to a floating point value. It simply tells the compiler to treat the bit pattern that exists in memory as a different type.

2.6 Register Type Coercion

You can also cast a register as a specific type using the type coercion operator. By default, the eight-bit registers are of type *byte*, the 16-bit registers are of type *word*, and the 32-bit registers are of type *dword*. With type coercion, you can cast a register as a different type *as long as the size of the new type agrees with the size of the register*. This is an important restriction that does not apply when applying type coercion to a memory variable.

Most of the time you do not need to coerce a register to a different type. After all, as *byte*, *word*, and *dword* objects, they are already compatible with all one, two, and four byte objects. However, there are a few instances where register type coercion is handy, if not downright necessary. Two examples include boolean expressions in HLA high level language statements (e.g., IF and WHILE) and register I/O in the *stdout.put* and *stdin.get* (and related) statements.

In boolean expressions, *byte*, *word*, and *dword* objects are always treated as unsigned values. Therefore, without type coercion register objects are always treated as unsigned values so the boolean expression in the following IF statement is always false (since there is no unsigned value less than zero):

```
if( eax < 0 ) then

    stdout.put( "EAX is negative!", nl );

endif;
```

You can overcome this limitation by casting EAX as an *int32* value:

```
if( (type int32 eax) < 0 ) then

    stdout.put( "EAX is negative!", nl );

endif;
```

In a similar vein, the HLA Standard Library *stdout.put* routine always outputs *byte*, *word*, and *dword* values as hexadecimal numbers. Therefore, if you attempt to print a register, the *stdout.put* routine will print it as a hex value. If you would like to print the value as some other type, you can use register type coercion to achieve this:

11. If you have a variable immediately following *byteVar* in this example, the MOV instruction will surely overwrite the value of that variable, whether or not you intend this to happen.

```
stdout.put( "AL printed as a char = '", (type char al), "'", nl );
```

The same is true for the *stdin.get* routine. It will always read a hexadecimal value for a register unless you coerce its type to something other than *byte*, *word*, or *dword*.

You will see some additional uses for register type coercion in the next chapter.

2.7 The Stack Segment and the Push and Pop Instructions

This chapter mentioned that all variables you declare in the VAR section wind up in the stack memory segment (see “The Var Section” on page 162). However, VAR objects are not the only things that wind up in the stack segment in memory; your programs manipulate data in the stack segment in many different ways. This section introduces a set of instructions, the PUSH and POP instructions, that also manipulate data in the stack segment.

The stack segment in memory is where the 80x86 maintains the *stack*. The stack is a dynamic data structure that grows and shrinks according to certain memory needs of the program. The stack also stores important information about program including local variables, subroutine information, and temporary data.

The 80x86 stack is controlled by the ESP (stack pointer) register. When your program begins execution, the operating system initializes ESP with the address of the last memory location in the stack memory segment. Data is written to the stack segment by “pushing” data onto the stack and “popping” or “pulling” data off of the stack. Whenever you push data onto the stack, the 80x86 decrements the stack pointer by the size of the data you are pushing and then it copies the data to memory where ESP is then pointing. As a concrete example, consider the 80x86 PUSH instruction:

```
push( reg16 );
push( reg32 );
push( memory16 );
push( memory32 );
pushw( constant );
pushd( constant );
```

These six forms allow you to push *word* or *dword* registers, memory locations, and constants. You should specifically note that you cannot push *byte* typed objects onto the stack.

2.7.1 The Basic PUSH Instruction

The PUSH instruction does the following:

```
ESP := ESP - Size_of_Register_or_Memory_Operand (2 or 4)
[ESP] := Operand's_Value
```

The PUSHW and PUSHHD operand sizes are always two or four bytes, respectively.

Assuming that ESP contains \$00FF_FFE8, then the instruction “PUSH(EAX);” will set ESP to \$00FF_FFE4 and store the current value of EAX into memory location \$00FF_FFE4 as shown in Figure 2.9 and Figure 2.10:

Figure 2.9 Stack Segment Before “PUSH(EAX);” Operation

Figure 2.10 Stack Segment After “PUSH(EAX);” Operation

Note that the “PUSH(EAX);” instruction does not affect the value in the EAX register.

Although the 80x86 supports 16-bit push operations, these are intended primarily for use in 16-bit environments such as DOS. For maximum performance, the stack pointer should always be an even multiple of four; indeed, your program may malfunction under Win32 if ESP contains a value that is not a multiple of four and you make an HLA Standard Library or Win32 API call. The only reason for pushing less than four bytes at a time on the stack is because you’re building up a double word via two successive word pushes.

2.7.2 The Basic POP Instruction

To retrieve data you’ve pushed onto the stack, you use the POP instruction. The basic POP instruction allows the following different forms:

```
pop( reg16 );
pop( reg32 );
pop( memory16 );
```

```
pop( memory32 );
```

Like the PUSH instruction, the POP instruction only supports 16-bit and 32-bit operands; you cannot pop an eight-bit value from the stack. Also like the PUSH instruction, you should avoid popping 16-bit values (unless you do two 16-bit pops in a row) because 16-bit pops may leave the ESP register containing a value that is not an even multiple of four. One major difference between PUSH and POP is that you cannot POP a constant value (which makes sense, because the operand for PUSH is a source operand while the operand for POP is a destination operand).

Formally, here's what the POP instruction does:

```
Operand := [ESP]
ESP := ESP + Size_of_Operand (2 or 4)
```

As you can see, the POP operation is the converse of the PUSH operation. Note that the POP instruction copies the data from memory location [ESP] before adjusting the value in ESP. See Figure 2.11 and Figure 2.12 for details on this operation:

Figure 2.11 Memory Before a “POP(EAX);” Operation

Figure 2.12 Memory After the “POP(EAX);” Instruction

Note that the value popped from the stack is still present in memory. Popping a value does not erase the value in memory, it just adjusts the stack pointer so that it points at the next value above the popped value. However, you should never attempt to access a value you've popped off the stack. The next time something is pushed onto the stack, the popped value will be obliterated. Since your code isn't the only thing that uses the stack (i.e., the operating system uses the stack as do other subroutines), you cannot rely on data remaining in stack memory once you've popped it off the stack.

2.7.3 Preserving Registers With the PUSH and POP Instructions

Perhaps the most common use of the PUSH and POP instructions is to save register values during intermediate calculations. A problem with the 80x86 architecture is that it provides very few general purpose registers. Since registers are the best place to hold temporary values, and registers are also needed for the various addressing modes, it is very easy to run out of registers when writing code that performs complex calculations. The PUSH and POP instructions can come to your rescue when this happens.

Consider the following program outline:

```
<< Some sequence of instructions that use the EAX register >>

<< Some sequence of instructions that need to use EAX, for a
    different purpose than the above instructions >>

<< Some sequence of instructions that need the original value in EAX >>
```

The PUSH and POP instructions are perfect for this situation. By inserting a PUSH instruction before the middle sequence and a POP instruction after the middle sequence above, you can preserve the value in EAX across those calculations:

```
<< Some sequence of instructions that use the EAX register >>
push( eax );
<< Some sequence of instructions that need to use EAX, for a
    different purpose than the above instructions >>
pop( eax );
<< Some sequence of instructions that need the original value in EAX >>
```

The PUSH instruction above copies the data computed in the first sequence of instructions onto the stack. Now the middle sequence of instructions can use EAX for any purpose it chooses. After the middle sequence of instructions finishes, the POP instruction restores the value in EAX so the last sequence of instructions can use the original value in EAX.

2.7.4 The Stack is a LIFO Data Structure

Of course, you can push more than one value onto the stack without first popping previous values off the stack. However, the stack is a last-in, first-out (LIFO) data structure, so you must be careful how you push and pop multiple values. For example, suppose you want to preserve EAX and EBX across some block of instructions, the following code demonstrates the obvious way to handle this:

```
push( eax );
push( ebx );
<< Code that uses EAX and EBX goes here >>
pop( eax );
pop( ebx );
```

Unfortunately, this code will not work properly! Figures 2.13, 2.14, 2.15, and 2.16 show the problem. Since this code pushes EAX first and EBX second, the stack pointer is left pointing at the value in EBX pushed

onto the stack. When the POP(EAX) instruction comes along, it removes the value that was originally in EBX from the stack and places it in EAX! Likewise, the POP(EBX) instruction pops the value that was originally in EAX into the EBX register. The end result is that this code has managed to swap the values in the registers by popping them in the same order that it pushed them.

Figure 2.13 Stack After Pushing EAX

Figure 2.14 Stack After Pushing EBX

Figure 2.15 Stack After Popping EAX

Figure 2.16 Stack After Popping EBX

To rectify this problem, you need to note that the stack is a last-in, first-out data structure, so the first thing you must pop is the last thing you've pushed onto the stack. To do this, you must always observe the following maxim:

- ❑ **Always pop values in the reverse order that you push them.**

The correction to the previous code is

```
push( eax );
push( ebx );
<< Code that uses EAX and EBX goes here >>
pop( ebx );
pop( eax );
```

Another important maxim to remember is

- ❑ **Always pop exactly the same number of bytes that you push.**

This generally means that the number of pushes and pops must exactly agree. If you have too few pops, you will leave data on the stack which may confuse the running program¹²; If you have too many pops, you will accidentally remove previously pushed data, often with disastrous results.

A corollary to the maxim above is “Be careful when pushing and popping data within a loop.” Often it is quite easy to put the pushes in a loop and leave the pops outside the loop (or vice versa), creating an inconsistent stack. Remember, it is the execution of the PUSH and POP instructions that matters, not the number of PUSH and POP instructions that appear in your program. At run-time, the number (and order) of the PUSH instructions the program executes must match the number (and reverse order) of the POP instructions.

2.7.5 Other PUSH and POP Instructions

The 80x86 provides several additional PUSH and POP instructions in addition to the basic instructions described in the previous sections. These instructions include the following:

- PUSHA
- PUSHAD
- PUSHF
- PUSHFD
- POPA
- POPAD
- POPF
- POPFD

The PUSHA instruction pushes all the general-purpose 16-bit registers onto the stack. This instruction is primarily intended for older 16-bit operating systems like DOS. In general, you will have very little need for this instruction. The PUSHAD instruction pushes the registers onto the stack in the following order:

```
ax
cx
dx
bx
sp
bp
si
di
```

The PUSHAD instruction pushes all the 32-bit (dword) registers onto the stack. It pushes the registers onto the stack in the following order:

```
eax
ecx
edx
ebx
esp
ebp
esi
edi
```

Since the SP/ESP register is inherently modified by the PUSHAD and PUSHAD instructions, you may wonder why Intel bothered to push it at all. It was probably easier in the hardware to go ahead and push SP/ESP rather than make a special case out of it. In any case, these instructions do push SP or ESP so don't worry about it too much - there is nothing you can do about it.

12. You'll see why when we cover procedures.

The POPA and POPAD instructions provide the corresponding “pop all” operation to the PUSHA and PUSHAD instructions. This will pop the registers pushed by PUSHA or PUSHAD in the appropriate order (that is, POPA and POPAD will properly restore the register values by popping them in the reverse order that PUSHA or PUSHAD pushed them).

Although the PUSHA/POPA and PUSHAD/POPAD sequences are short and convenient, they are actually slower than the corresponding sequence of PUSH/POP instructions, this is especially true when you consider that you rarely need to push a majority, much less all the registers¹³. So if you’re looking for the maximum amount of speed, you should carefully consider whether to use the PUSHA(D)/POPA(D) instructions. This text generally opts for convenience and readability; so it will use the PUSHAD and POPAD instructions without worrying about lost efficiency.

The PUSHF, PUSHFD, POPF, and POPFD instructions push and pop the (E)FLAGS register. These instructions allow you to preserve condition code and other flag settings across the execution of some sequence of instructions. Unfortunately, unless you go to a lot of trouble, it is difficult to preserve individual flags. When using the PUSHF(D) and POPF(D) instructions it’s an all or nothing proposition - you preserve all the flags when you push them, you restore all the flags when you pop them.

Like the PUSHA and POPA instructions, you should really use the PUSHFD and POPFD instructions to push the full 32-bit version of the EFLAGS register. Although the extra 16-bits you push and pop are essentially ignored when writing applications, you still want to keep the stack aligned by pushing and popping only double words.

2.7.6 Removing Data From the Stack Without Popping It

Once in a while you may discover that you’ve pushed data onto the stack that you no longer need. Although you could pop the data into an unused register or memory location, there is an easier way to remove unwanted data from the stack - simply adjust the value in the ESP register to skip over the unwanted data on the stack.

Consider the following dilemma:

```

push( eax );
push( ebx );

<< Some code that winds up computing some values we want to keep
    into EAX and EBX >>

if( Calculation_was_performed ) then

    // Whoops, we don't want to pop EAX and EBX!
    // What to do here?

else

    // No calculation, so restore EAX, EBX.

    pop( ebx );
    pop( eax );

endif;
```

Within the THEN section of the IF statement, this code wants to remove the old values of EAX and EBX without otherwise affecting any registers or memory locations. How to do this?

Since the ESP register simply contains the memory address of the item on the top of the stack, we can remove the item from the top of stack by adding the size of that item to the ESP register. In the example

13. For example, it is extremely rare for you to need to push and pop the ESP register with the PUSHAD/POPAD instruction sequence.

Figure 2.18 Removing Data from the Stack, After `ADD(8, ESP);`

Effectively, this code pops the data off the stack without moving it anywhere. Also note that this code is more efficient than two dummy POP instructions because it can remove any number of bytes from the stack with a single ADD instruction.

Warning: remember to keep the stack aligned on a double word boundary. Therefore, you should always add a constant that is an even multiple of four to ESP when removing data from the stack.

2.7.7 Accessing Data You've Pushed on the Stack Without Popping It

Once in a while you will push data onto the stack and you will want to get a copy of that data's value, or perhaps you will want to change that data's value, without actually popping the data off the stack (that is, you wish to pop the data off the stack at a later time). The 80x86 "[reg₃₂ + offset]" addressing mode provides the mechanism for this.

Consider the stack after the execution of the following two instructions (see Figure 2.19):

```
push( eax );
push( ebx );
```

Figure 2.19 Stack After Pushing EAX and EBX

If you wanted to access the original EBX value without removing it from the stack, you could cheat and pop the value and then immediately push it again. Suppose, however, that you wish to access EAX's old value; or some other value even farther up on the stack. Popping all the intermediate values and then pushing them back onto the stack is problematic at best, impossible at worst. However, as you will notice from Figure 2.19, each of the values pushed on the stack is at some offset from the ESP register in memory. Therefore, we can use the "[ESP + offset]" addressing mode to gain direct access to the value we are interested in. In the example above, you can reload EAX with its original value by using the single instruction:

```
mov( [esp+4], eax );
```

This code copies the four bytes starting at memory address ESP+4 into the EAX register. This value just happens to be the value of EAX that was earlier pushed onto the stack. This same technique can be used to access other data values you've pushed onto the stack.

Warning: Don't forget that the offsets of values from ESP into the stack change every time you push or pop data. Abusing this feature can create code that is hard to modify; if you use this feature throughout your code, it will make it difficult to push and pop other data items between the point you first push data onto the stack and the point you decide to access that data again using the "[ESP + offset]" memory addressing mode.

The previous section pointed out how to remove data from the stack by adding a constant to the ESP register. That code example could probably be written more safely as:

```
push( eax );
push( ebx );

<< Some code that winds up computing some values we want to keep
    into EAX and EBX >>

if( Calculation_was_performed ) then

    // Overwrite saved values on stack with new EAX/EBX values.
    // (so the pops that follow won't change the values in EAX/EBX.)
    mov( eax, [esp+4] );
    mov( ebx, [esp] );

endif;
pop( ebx );
pop( eax );
```

In this code sequence, the calculated result was stored over the top of the values saved on the stack. Later on, when the values are popped off the stack, the program loads these calculated values into EAX and EBX.

2.8 Dynamic Memory Allocation and the Heap Segment

Although static and automatic variables are all a simple program may need, more sophisticated programs need the ability to allocate and deallocate storage dynamically (at run-time) under program control. In the C language, you would use the *malloc* and *free* functions for this purpose. C++ provides the *new* and *delete* operators. Pascal uses *new* and *dispose*. Other languages provide comparable routines. These memory allocation routines share a couple of things in common: they let the programmer request how many bytes of storage to allocate, they return a *pointer* to the newly allocated storage, and they provide a facility for returning the storage to the system so the system can reuse it in a future allocation call. As you've probably guessed, HLA also provides a set of routines in the HLA Standard Library that handles memory allocation and deallocation.

The HLA Standard Library *malloc* and *free* routines handle the memory allocation and deallocation chores (respectively)¹⁴. The *malloc* routine uses the following calling sequence:

```
malloc( Number_of_Bytes_Requested );
```

The single parameter is a *dword* value (an unsigned constant) specifying the number of bytes of storage you are requesting. This procedure calls the Windows API to allocate storage in the *heap* segment in memory. Windows locates an unused block of memory of the specified size in the heap segment and marks the block as “in use” so that future calls to *malloc* will not reallocate this same storage. After marking the block as “in use” the *malloc* routine returns a pointer to the first byte of this storage in the EAX register.

For many objects, you will know the number of bytes you need to represent that object in memory. For example, if you wish to allocate storage for an *uns32* variable, you could use the following call to the *malloc* routine:

```
malloc( 4 );
```

Although you can specify a literal constant as this example suggests, it's generally a poor idea to do so when allocating storage for a specific data type. Instead, use the HLA built-in compile-time function *@size* to compute the size of some data type. The *@size* function uses the following syntax:

```
@size( variable_or_type_name )
```

The *@size* function returns an unsigned integer constant that specifies the size of its parameter in bytes. So you should rewrite the previous call to *malloc* as follows:

```
malloc( @size( uns32 ) );
```

This call will properly allocate a sufficient amount of storage for the specified object, regardless of its type. While it is unlikely that the number of bytes required by an *uns32* object will ever change, this is not necessarily true for other data types; so you should always use *@size* rather than a literal constant in these calls.

Upon return from the *malloc* routine, the EAX register contains the address of the storage you have requested (see Figure 2.20):

14. HLA provides some other memory allocation and deallocation routines as well. See the HLA Standard Library documentation for more details.

Figure 2.20 Call to Malloc Returns a Pointer in the EAX Register

To access the storage *malloc* allocates you must use a register indirect addressing mode. The following code sequence demonstrates how to assign the value 1234 to the *uns32* variable *malloc* creates:

```
malloc( @size( uns32 ) );
mov( 1234, (type uns32 [eax]));
```

Note the use of the type coercion operation. This is necessary in this example because anonymous variables don't have a type associated with them and the constant 1234 could be a *word* or *dword* value. The type coercion operator eliminates the ambiguity.

A call to the *malloc* routine is not guaranteed to succeed. By default, Windows only reserves about a megabyte for the heap; HLA modifies this default to about 16 megabytes. If there isn't a single contiguous block of free memory in the heap segment that is large enough to satisfy the request, then the *malloc* routine will raise an *ex.MemoryAllocationFailure* exception. If you do not provide a TRY..EXCEPTION..ENDTRY handler to deal with this situation, a memory allocation failure will cause your program to abort execution. Since most programs do not allocate massive amounts of dynamic storage using *malloc*, this exception rarely occurs. However, you should never assume that the memory allocation will always occur without error.

When you are done using a value that *malloc* allocates on the heap, you can release the storage (that is, mark it as "no longer in use") by calling the *free* procedure. The *free* routine requires a single parameter that must be an address previously returned by the *malloc* routine that you have not already freed. The following code fragment demonstrates the nature of the *malloc/free* pairing:

```
malloc( @size( uns32));

<< use the storage pointed at by EAX >>
<< Note: this code must not modify EAX >>

free( eax );
```

This code demonstrates a very important point - in order to properly free the storage that *malloc* allocates, you must preserve the value that *malloc* returns. There are several ways to do this if you need to use EAX for some other purpose; you could save the pointer value on the stack using PUSH and POP instructions or you could save EAX's value in a variable until you need to free it.

Storage you release is available for reuse by future calls to the *malloc* routine. Like automatic variables you declare in the VAR section, the ability to allocate storage while you need it and then free the storage for other use when you are done with it improves the memory efficiency of your program. By deallocating storage once you are finished with it, your program can reuse that storage for other purposes allowing your program to operate with less memory than it would if you statically allocated storage for the individual objects.

There are several problems that can occur when you use pointers. You should be aware of a few common errors that beginning programmers make when using dynamic storage allocation routines like *malloc* and *free*:

- Mistake #1: Continuing to refer to storage after you free it. Once you return storage to the system via the call to *free*, you should no longer access the data allocated by the call to *malloc*. Doing so may cause a protection fault or, worse yet, corrupt other data in your program without indicating an error.
- Mistake #2: Calling *free* twice to release a single block of storage. Doing so may accidentally free some other storage that you did not intend to release or, worse yet, it may corrupt the system memory management tables.

A later chapter will discuss some additional problems you will typically encounter when dealing with dynamically allocated storage.

The examples thus far in this section have all allocated storage for a single unsigned 32-bit object. Obviously you can allocate storage for any data type using a call to *malloc* by simply specifying the size of that object as *malloc*'s parameter. It is also possible to allocate storage for a sequence of contiguous objects in memory when calling *malloc*. For example, the following code will allocate storage for a sequence of 8 characters:

```
malloc( @size( char ) * 8 );
```

Note the use of the constant expression to compute the number of bytes required by an eight-character sequence. Since “@size(char)” always returns a constant value (one in this case), the compiler can compute the value of the expression “@size(char) * 8” without generating any extra machine instructions.

Calls to *malloc* always allocate multiple bytes of storage in contiguous memory locations. Hence the former call to *malloc* produces the sequence appearing in Figure 2.21:

Figure 2.21 Allocating a Sequence of Eight Character Objects Using Malloc

To access these extra character values you use an offset from the base address (contained in EAX upon return from *malloc*). For example, “MOV(CH, [EAX + 2]);” stores the character found in CH into the third

byte that *malloc* allocates. You can also use an addressing mode like “[EAX + EBX]” to step through each of the allocated objects under program control. For example, the following code will set all the characters in a block of 128 bytes to the NULL character (#0):

```

malloc( 128 );
mov( 0, ebx );
while( ebx < 128 ) do

    mov( 0, (type byte [eax+ebx]) );
    add( 1, ebx );

endwhile;

```

The chapter on arrays, later in this text, discusses additional ways to deal with blocks of memory.

2.9 The INC and DEC Instructions

As the example in the last section indicates, indeed, as several examples up to this point have indicated, adding or subtracting one from a register or memory location is a very common operation. In fact, this operation is so common that Intel’s engineer’s included a pair of instructions to perform these specific operations: the INC (increment) and DEC (decrement) instructions.

The INC and DEC instructions use the following syntax:

```

inc( mem/reg );
dec( mem/reg );

```

The single operand can be any legal eight-bit, 16-bit, or 32-bit register or memory operand. The INC instruction will add one to the specified operand, the DEC instruction will subtract one from the specified operand.

These two instructions are slightly more efficient (they are smaller) than the corresponding ADD or SUB instructions. There is also one slight difference between these two instructions and the corresponding ADD or SUB instructions: they do not affect the carry flag.

As an example of the INC instruction, consider the example from the previous section, recoded to use INC rather than ADD:

```

malloc( 128 );
mov( 0, ebx );
while( ebx < 128 ) do

    mov( 0, (type byte [eax+ebx]) );
    inc( ebx );

endwhile;

```

2.10 Obtaining the Address of a Memory Object

In the section “The Register Indirect Addressing Modes” on page 153 this chapter discusses how to use the address-of operator, “&”, to take the address of a static variable¹⁵. Unfortunately, you cannot use the address-of operator to take the address of an automatic variable (one you declare in the VAR section), you cannot use it to compute the address of an anonymous variable, nor can you use this operator to take the address of a memory reference that uses an indexed or scaled indexed addressing mode (even if a static variable is part of the address expression). You may only use the address-of operator to take the address of a static variable that uses the displacement-only memory addressing mode. Often, you will need to take the

15. A static variable is one that you declare in the *static*, *readonly*, *storage*, or *data* sections of your program.

address of other memory objects as well; fortunately, the 80x86 provides the load effective address instruction, LEA, to give you this capability.

The LEA instruction uses the following syntax:

```
lea( reg32, Memory_operand );
```

The first operand must be a 32-bit register, the second operand can be any legal memory reference using any valid memory addressing mode. This instruction will load the address of the specified memory location into the register. This instruction does not modify the value of the memory operand in any way, nor does it reference that value in memory.

Once you load the effective address of a memory location into a 32-bit general purpose register, you can use the register indirect, indexed, or scaled indexed addressing modes to access the data at the specified memory address. For example, consider the following code:

```
data
  b:byte;
    byte 7, 0, 6, 1, 5, 2, 4, 3;
    .
    .
    .
  lea( ebx, b );
  mov( 0, ecx );
  while( ecx < 8 ) do

    stdout.put( "[ebx+ecx]=", (type byte [ebx+ecx]), nl );
    inc( ecx );

  endwhile;
```

This code steps through each of the eight bytes following the *b* label in the DATA section and prints their values. Note the use of the “[ebx+ecx]” addressing mode. The EBX register holds the base address of the list (that is, the address of the first item in the list) and ECX contains the byte index into the list.

2.11 Bonus Section: The HLA Standard Library CONSOLE Module

The HLA Standard Library contains a module that lets you control output to the *console* device. The console device is the virtual text/video display of the command window. The procedures in the console module let you clear the screen, position the cursor, output text to a specific cursor position in the window, adjust the window size, control the color of the output characters, handle mouse events, and do other console-related operations. The judicious use of the console module lets you transform a drab, boring text-based application into a visually appealing text-based application. The sample programs in this section demonstrate some of the capabilities of the HLA Standard Library console module.

Note: to use the console module routines in your program you must include one (or both) of the following statements in your HLA program:

```
#include( "stdlib.hhf" );
#include( "console.hhf" );
```

2.11.1 Clearing the Screen

Perhaps the most important routine in the console module, based on HLA user requests, is the *console.cls()* procedure. This routine clears the screen and positions the cursor to coordinate (0,0)¹⁶. The following sample application demonstrates the use of this routine.

16. In console coordinates, location (0,0) is the upper left hand corner of the screen. The X coordinates increase as you progress from left to right and the Y coordinates increase as you progress from top to bottom on the screen.

```

program testCls;
#include( "stdlib.hhf" );
begin testCls;

    // Throw up some text to prove that
    // this program really clears the screen:

    stdout.put
    (
        nl,
        "HLA console.cls() Test Routine", nl
        "-----", nl
        nl
        "This routine will clear the screen and move the cursor to (0,0),", nl
        "then it will print a short message and quit", nl
        nl
        "Press the Enter key to continue:"
    );

    // Make the user hit Enter to continue. This is so that they
    // can see that the screen is not blank.

    stdin.readLine();

    // Okay, clear the screen and print a simple message:

    console.cls();
    stdout.put( "The screen was cleared.", nl );

end testCls;

```

Program 3.2 The console.cls() Routine

2.11.2 Positioning the Cursor

After clearing the screen, the most often requested console capability is cursor positioning. The HLA Standard Library *console.gotoxy* procedure handles this task. The *console.gotoxy* call uses the following syntax:

```
console.gotoxy( RowPosition, ColumnPosition );
```

Note that *RowPosition* and *ColumnPosition* must be 16-bit values (constants, variables, or registers).

The astute reader will notice that the first parameter, the *RowPosition*, is actually the Y coordinate and the second parameter, *ColumnPosition*, is the X coordinate. This coordinate ordering may seem counter-intuitive given the name of the procedure (*gotoxy*, with X appearing in the name before Y). However, in actual practice most people find it more intuitive to specify the Y coordinate first and the X coordinate second. The name “gotoxy” sounds better than “gotoyx” so HLA uses “gotoxy” despite the minor inconsistency between the name and the parameter ordering.

The following program demonstrates the *console.gotoxy* procedure:

```

program testGotoxy;
#include( "stdlib.hhf" );

```

```

var
  x:int16;
  y:int16;

begin testGotoxy;

  // Throw up some text to prove that
  // this program really clears the screen:

  stdout.put
  (
    nl,
    "HLA console.gotoxy() Test Routine", nl,
    "-----", nl,
    nl,
    "This routine will clear the screen then demonstrate the use", nl,
    "of the gotoxy routine to position the cursor at various", nl,
    "points on the screen.",nl,
    nl,
    "Press the Enter key to continue:"
  );

  // Make the user hit Enter to continue. This is so that they
  // can control when they see the effect of console.gotoxy.

  stdin.readLn();

  // Okay, clear the screen:

  console.cls();

  // Now demonstrate the gotoxy routine:

  console.gotoxy( 5,10 );
  stdout.put( "(5,10)" );

  console.gotoxy( 10, 5 );
  stdout.put( "(10,5)" );

  mov( 20, x );
  for( mov( 0,y ); y<20; inc(y)) do

    console.gotoxy( y, x );
    stdout.put( "(" , x, "," , y, ")" );
    inc( x );

  endfor;

end testGotoxy;

```

Program 3.3 The console.gotoxy(row,column) Routine

2.11.3 Locating the Cursor

In addition to letting you specify a new cursor position, the HLA console module provides routines that let you determine the current cursor position. The *console.getX()* and *console.getY()* routines return the X

and Y coordinates (respectively) of the current cursor position in the EAX register. The following program demonstrates the use of these two functions.

```

program testGetxy;
#include( "stdlib.hhf" );

var
    x:uns32;
    y:uns32;

begin testGetxy;

    // Begin by getting the current cursor position

    console.getX();
    mov( eax, x );

    console.getY();
    mov( eax, y );

    // Clear the screen and print a banner message:

    console.cls();

    stdout.put
    (
        nl,
        "HLA console.GetX() and console.GetY() Test Routine", nl,
        "-----", nl,
        nl,
        "This routine will clear the screen then demonstrate the use", nl,
        "of the GetX and GetY routines to reposition the cursor", nl,
        "to its original location on the screen.",nl,
        nl,
        "Press the Enter key to continue:"
    );

    // Make the user hit Enter to continue. This is so that they
    // can control when they see the effect of console.gotoxy.

    stdin.readLn();

    // Now demonstrate the GetX and GetY routines by calling
    // the gotoxy routine to move the cursor back to its original
    // position.

    console.gotoxy( (type uns16 y), (type uns16 x) );
    stdout.put( "*<- Cursor was originally here.", nl );

end testGetxy;

```

Program 3.4 The console.GetX() and console.GetY() Routines

2.11.4 Text Attributes

The HLA console module lets you specify the color of the text you print to the console window. You may specify one of sixteen different foreground or background colors for each character you print. The foreground color is the color of the dots that make up the actual character on the display; the background color is the color of the other pixels (dots) in the character cell. The console module supports any of the following available foreground and background colors:

```
win.bgnd_Black
win.bgnd_Blue
win.bgnd_Green
win.bgnd_Cyan
win.bgnd_Red
win.bgnd_Magenta
win.bgnd_Brown
win.bgnd_LightGray
win.bgnd_DarkGray
win.bgnd_LightBlue
win.bgnd_LightGreen
win.bgnd_LightCyan
win.bgnd_LightRed
win.bgnd_LightMagenta
win.bgnd_Yellow
win.bgnd_White
```

```
win.fgnd_Black
win.fgnd_Blue
win.fgnd_Green
win.fgnd_Cyan
win.fgnd_Red
win.fgnd_Magenta
win.fgnd_Brown
win.fgnd_LightGray
win.fgnd_DarkGray
win.fgnd_LightBlue
win.fgnd_LightGreen
win.fgnd_LightCyan
win.fgnd_LightRed
win.fgnd_LightMagenta
win.fgnd_Yellow
win.fgnd_White
```

The “win32.hhf” header file defines the symbolic constants for these colors. Therefore, you must include one of the following statements in your program to have access to these colors:

```
#include( "stdlib.hhf" );
#include( "win32.hhf" );
```

The first routine to take advantage of these color attributes is the *console.setOutputAttr* routine. A call to this procedure uses the following syntax:

```
console.setOutputAttr( ColorValues );
```

The single parameter to this routine is a single foreground or background color, or a pair of colors (one background and one foreground) combined with the “|” operator¹⁷. E.g.,

```
console.setOutputAttr( win.fgnd_Yellow );
console.setOutputAttr( win.bgnd_White );
```

17. This is the bitwise OR operator.

```
console.setOutputAttr( win.fgnd_Yellow | win.bgnd_Blue );
```

If you do not specify both colors, the default for the missing color is black. Therefore, the first call above sets the foreground color to yellow and the background color to black. Likewise, the second call above sets the foreground color to black and the background color to white.

The `console.setOutputAttr` routine does not automatically change the color of all characters on the screen. Instead, it only affects the color of the characters output after the call. Therefore, you can switch between various colors on a character-by-character basis, as necessary. The following sample program demonstrates the use of `console.setOutputAttr` routine.

```
program testSetOutputAttr;
#include( "stdlib.hhf" );

var
  x:uns32;
  y:uns32;

begin testSetOutputAttr;

  // Clear the screen and print a banner message:

  console.cls();

  console.setOutputAttr( win.fgnd_LightRed | win.bgnd_Black );
  stdout.put
  (
    nl,
    "HLA console.setOutputAttr Test Routine", nl,
    "-----", nl,
    nl,
    "Press the Enter key to continue:"
  );

  // Make the user hit Enter to continue. This is so that they
  // can control when they see the effect of console.gotoxy.

  stdin.readLine();

  console.setOutputAttr( win.fgnd_Yellow | win.bgnd_Blue );
  stdout.put
  (
    "                                ", nl
    " In blue and yellow           ", nl,
    "                                ", nl,
    " Press Enter to continue ", nl
    "                                ", nl
    nl
  );
  stdin.readLine();

  // Note: set the attributes back to black and white when
  // the program exits so the console window doesn't continue
  // displaying text in Blue and Yellow.

  console.setOutputAttr( win.fgnd_White | win.bgnd_Black );
```

```
end testSetOutputAttr;
```

Program 3.5 The console.setOutputAttr Routine

2.11.5 Filling a Rectangular Section of the Screen

The *console.fillRect* procedure gives you the ability to fill a rectangular portion of the screen with a single character and a set of text attributes. The call to this routine uses the following syntax:

```
console.fillRect( ULrow, ULcol, LRrow, LRcol, character, attr );
```

The *ULrow* and *ULcol* parameters must be 16-bit values that specify the row and column number of the upper left hand corner of the rectangle to draw. Likewise, the *LRrow* and *LRcol* parameters are 16-bit values that specify the lower right hand corner of the rectangle to draw. The *character* parameter is the character you wish to draw throughout the rectangular block. This is normally a space if you want to produce a simple rectangle. The *attr* parameter is a text attribute parameter, identical to the parameter for the *console.setOutputAttr* routine that the previous section describes. The following sample program demonstrates the use of the *console.fillRect* procedure.

```
program testFillRect;
#include( "stdlib.hhf" );

var
  x:uns32;
  y:uns32;

begin testFillRect;

  console.setOutputAttr( win.fgnd_LightRed | win.bgnd_Black );
  stdout.put
  (
    nl,
    "HLA console.fillRect Test Routine", nl,
    "-----", nl,
    nl,
    "Press the Enter key to continue:"
  );

  // Make the user hit Enter to continue.

  stdin.readLine();
  console.cls();

  // Test outputting rectangular blocks of color.
  // Note that the blocks are always filled with spaces,
  // so there is no need to specify a foreground color.

  console.fillRect( 2, 50, 5, 55, ' ', win.bgnd_Black );
  console.fillRect( 6, 50, 9, 55, ' ', win.bgnd_Green );
  console.fillRect( 10, 50, 13, 55, ' ', win.bgnd_Cyan );
  console.fillRect( 14, 50, 17, 55, ' ', win.bgnd_Red );
  console.fillRect( 18, 50, 21, 55, ' ', win.bgnd_Magenta );

  console.fillRect( 2, 60, 5, 65, ' ', win.bgnd_Brown );
  console.fillRect( 6, 60, 9, 65, ' ', win.bgnd_LightGray );
  console.fillRect( 10, 60, 13, 65, ' ', win.bgnd_DarkGray );
```

```

console.fillRect( 14, 60, 17, 65, ' ', win.bgnd_LightBlue );
console.fillRect( 18, 60, 21, 65, ' ', win.bgnd_LightGreen );

console.fillRect( 2, 70, 5, 75, ' ', win.bgnd_LightCyan );
console.fillRect( 6, 70, 9, 75, ' ', win.bgnd_LightRed );
console.fillRect( 10, 70, 13, 75, ' ', win.bgnd_LightMagenta );
console.fillRect( 14, 70, 17, 75, ' ', win.bgnd_Yellow );
console.fillRect( 18, 70, 21, 75, ' ', win.bgnd_White );

// Note: set the attributes back to black and white when
// the program exits so the console window doesn't continue
// displaying text in Blue and Yellow.

console.setOutputAttr( win.fgnd_White | win.bgnd_Black );

end testFillRect;

```

2.11.6 Console Direct String Output

Although you can use the standard output routines (e.g., *stdout.put*) to write text to the console window, the console module provides a couple of convenient routines that output strings to the display. These routines combine the standard library *stdout.puts* routine with *console.gotoxy* and *console.setOutputAttr*. Two common console output routines are

```

console.puts( Row, Col, StringToPrint );
console.putsx( Row, Col, Color, MaxChars, StringToPrint );

```

The *Row* and *Col* parameters specify the coordinate of the first output character. *StringToPrint* is the string to display at the specified coordinate. The *console.putsx* routine supports two additional parameters; *Color*, that specifies the output foreground and background colors for the text, and *MaxChars* that specifies the maximum number of characters to print from *StringToPrint*¹⁸. The following sample program demonstrates these two routines

```

program testPutsx;
#include( "stdlib.hhf" );

var
  x:uns32;
  y:uns32;

begin testPutsx;

  // Clear the screen and print a banner message:

  console.cls();

  // Note that console.puts always defaults to black and white text.
  // The following setOutputAttr call proves this.

```

18. If *StringToPrint* is a constant, then *MaxChars* should specify the exact length of the string. When you learn about string variables in the next chapter you will see the purpose of the *MaxChars* parameter; it lets you ensure that the text you output fits within a certain range of cells on the screen.

```

console.setOutputAttr( win.fgnd_LightRed | win.bgnd_Black );

// Display the text in black and white:

console.puts
(
    10,
    10,
    "HLA console.setOutputAttr Test Routine"
);
console.puts
(
    11,
    10,
    "-----"
);
console.puts
(
    13,
    10,
    "Press the Enter key to continue:"
);

// Make the user hit Enter to continue.

stdin.readLine();

// Demonstrate the console.putsx routine.
// Note that the colors set by putsx are
// "local" to this call. Hence, the current
// output attribute colors will not be affected
// by this call.

console.putsx
(
    15,
    15,
    win.bgnd_White | win.fgnd_Blue,
    35,
    "Putsx at (15, 15) of length 35....."
);

console.putsx
(
    16,
    15,
    win.bgnd_White | win.fgnd_Red,
    40,
    "1234567890123456789012345678901234567890"
);

// Since the following is a stdout call, the text
// will use the current output attribute, which
// is the red/black attributes set at the beginning
// of this program.

console.gotoxy( 23, 0 );
stdout.put( "Press enter to continue:" );
stdin.readLine();

```

```

// Note: set the attributes back to black and white when
// the program exits.

console.setOutputAttr( win.fgnd_White | win.bgnd_Black );
console.cls();

end testPutsx;

```

2.11.7 Other Console Module Routines

The sample programs in this chapter have really only touched on the capabilities of the HLA Standard Library Console Module. In addition to the routines this section demonstrates, the HLA Standard Library provides procedures to scroll the window, to resize the window, to read characters off the screen, to clear selected portions of the screen, to grab and restore data on the screen, and so forth. Space limitations preclude the further demonstration of the console module in this text. However, if you are interested you should read the HLA Standard Library documentation to learn more about the console module.

2.12 Putting It All Together

This chapter discussed the 80x86 address modes and other related topics. It began by discussing the 80x86's register, displacement-only (direct), register indirect, and indexed addressing modes. A good knowledge of these addressing modes and their uses is essential if you want to write good assembly language programs. Although this chapter does not delve deeply into the use of each of these addressing modes, it does present their syntax and a few simple examples of each (later chapters will expand on how you use each of these addressing modes).

After discussing addressing modes, this chapter described how HLA and Windows organize your code and data in memory. At this point this chapter also discussed the HLA `STATIC`, `DATA`, `READONLY`, `STORAGE`, and `VAR` data declaration sections. The alignment of data in memory can affect the performance of your programs; therefore, when discussing this topic, this chapter also described how to properly align objects in memory to obtain the fastest executing code.

One special section of memory is the 80x86 stack. In addition to briefly discussing the stack, this chapter also described how to use the stack to save temporary values using the `PUSH` and `POP` instructions (and several variations on these instructions).

To a running program, a variable is really nothing more than a simple address in memory. In an HLA source file, however, you may specify the address and type of an object in memory using powerful address expressions and type coercion operators. These chapter discusses the syntax for these expressions and operators and gives several examples of why you would want to use them.

This chapter concludes by discussing two modules in the HLA Standard Library: the dynamic memory allocation routines (*malloc* and *free*) and the console module. The console module is interesting because it lets you write more interesting programs by varying the text display.

Logic circuits are the basis for modern digital computer systems. To appreciate how computer systems operate you will need to understand digital logic and boolean algebra.

This Chapter provides only a basic introduction to boolean algebra. That subject alone is often the subject of an entire textbook. This Chapter will concentrate on those subjects that support other chapters in this text.

3.1 Chapter Overview

Boolean logic forms the basis for computation in modern binary computer systems. You can represent any algorithm, or any electronic computer circuit, using a system of boolean equations. This chapter provides a brief introduction to boolean algebra, truth tables, canonical representation, of boolean functions, boolean function simplification, logic design, and combinatorial and sequential circuits.

This material is especially important to those who want to design electronic circuits or write software that controls electronic circuits. Even if you never plan to design hardware or write software than controls hardware, the introduction to boolean algebra this chapter provides is still important since you can use such knowledge to optimize certain complex conditional expressions within IF, WHILE, and other conditional statements.

The section on minimizing (optimizing) logic functions uses *Veitch Diagrams* or *Karnaugh Maps*. The optimizing techniques this chapter uses reduce the number of *terms* in a boolean function. You should realize that many people consider this optimization technique obsolete because reducing the number of terms in an equation is not as important as it once was. This chapter uses the mapping method as an example of boolean function optimization, not as a technique one would regularly employ. If you are interested in circuit design and optimization, you will need to consult a text on logic design for better techniques.

3.2 Boolean Algebra

Boolean algebra is a deductive mathematical system closed over the values zero and one (false and true). A *binary operator* “ \circ ” defined over this set of values accepts a pair of boolean inputs and produces a single boolean value. For example, the boolean AND operator accepts two boolean inputs and produces a single boolean output (the logical AND of the two inputs).

For any given algebra system, there are some initial assumptions, or *postulates*, that the system follows. You can deduce additional rules, theorems, and other properties of the system from this basic set of postulates. Boolean algebra systems often employ the following postulates:

- *Closure*. The boolean system is *closed* with respect to a binary operator if for every pair of boolean values, it produces a boolean result. For example, logical AND is closed in the boolean system because it accepts only boolean operands and produces only boolean results.
- *Commutativity*. A binary operator “ \circ ” is said to be commutative if $A \circ B = B \circ A$ for all possible boolean values A and B .
- *Associativity*. A binary operator “ \circ ” is said to be associative if

$$(A \circ B) \circ C = A \circ (B \circ C)$$
 for all boolean values A , B , and C .
- *Distribution*. Two binary operators “ \circ ” and “ $\%$ ” are distributive if

$$A \circ (B \% C) = (A \circ B) \% (A \circ C)$$

for all boolean values A , B , and C .

- *Identity.* A boolean value I is said to be the *identity element* with respect to some binary operator “ \circ ” if $A \circ I = A$.
- *Inverse.* A boolean value I is said to be the *inverse element* with respect to some binary operator “ \circ ” if $A \circ I = B$ and $B \neq A$ (i.e., B is the opposite value of A in a boolean system).

For our purposes, we will base boolean algebra on the following set of operators and values:

The two possible values in the boolean system are zero and one. Often we will call these values false and true (respectively).

The symbol “ \bullet ” represents the logical AND operation; e.g., $A \bullet B$ is the result of logically ANDing the boolean values A and B . When using single letter variable names, this text will drop the “ \bullet ” symbol; Therefore, AB also represents the logical AND of the variables A and B (we will also call this the product of A and B).

The symbol “ $+$ ” represents the logical OR operation; e.g., $A + B$ is the result of logically ORing the boolean values A and B . (We will also call this the sum of A and B .)

Logical complement, negation, or not, is a unary operator. This text will use the (‘) symbol to denote logical negation. For example, A' denotes the logical NOT of A .

If several different operators appear in a single boolean expression, the result of the expression depends on the *precedence* of the operators. We’ll use the following precedences (from highest to lowest) for the boolean operators: parenthesis, logical NOT, logical AND, then logical OR. The logical AND and OR operators are *left associative*. If two operators with the same precedence are adjacent, you must evaluate them from left to right. The logical NOT operation is right associative, although it would produce the same result using left or right associativity since it is a unary operator.

We will also use the following set of postulates:

- P1 Boolean algebra is closed under the AND, OR, and NOT operations.
- P2 The identity element with respect to \bullet is one and $+$ is zero. There is no identity element with respect to logical NOT.
- P3 The \bullet and $+$ operators are commutative.
- P4 \bullet and $+$ are distributive with respect to one another. That is, $A \bullet (B + C) = (A \bullet B) + (A \bullet C)$ and $A + (B \bullet C) = (A + B) \bullet (A + C)$.
- P5 For every value A there exists a value A' such that $A \bullet A' = 0$ and $A + A' = 1$. This value is the logical complement (or NOT) of A .
- P6 \bullet and $+$ are both associative. That is, $(A \bullet B) \bullet C = A \bullet (B \bullet C)$ and $(A + B) + C = A + (B + C)$.

You can prove all other theorems in boolean algebra using these postulates. This text will not go into the formal proofs of these theorems, however, it is a good idea to familiarize yourself with some important theorems in boolean algebra. A sampling includes:

Th1: $A + A = A$

Th2: $A \bullet A = A$

Th3: $A + 0 = A$

Th4: $A \bullet 1 = A$

Th5: $A \bullet 0 = 0$

Th6: $A + 1 = 1$

Th7: $(A + B)' = A' \bullet B'$

Th8: $(A \bullet B)' = A' + B'$

Th9: $A + A \bullet B = A$

Th10: $A \bullet (A + B) = A$

Th11: $A + A'B = A + B$

$$\text{Th12: } A' \cdot (A + B') = A'B'$$

$$\text{Th13: } AB + AB' = A$$

$$\text{Th14: } (A'+B') \cdot (A' + B) = A'$$

$$\text{Th15: } A + A' = 1$$

$$\text{Th16: } A \cdot A' = 0$$

Theorems seven and eight above are known as *DeMorgan's Theorems* after the mathematician who discovered them.

The theorems above appear in pairs. Each pair (e.g., Th1 & Th2, Th3 & Th4, etc.) form a *dual*. An important principle in the boolean algebra system is that of *duality*. Any valid expression you can create using the postulates and theorems of boolean algebra remains valid if you interchange the operators and constants appearing in the expression. Specifically, if you exchange the \cdot and $+$ operators and swap the 0 and 1 values in an expression, you will wind up with an expression that obeys all the rules of boolean algebra. *This does not mean the dual expression computes the same values*, it only means that both expressions are legal in the boolean algebra system. Therefore, this is an easy way to generate a second theorem for any fact you prove in the boolean algebra system.

Although we will not be proving any theorems for the sake of boolean algebra in this text, we will use these theorems to show that two boolean equations are identical. This is an important operation when attempting to produce *canonical representations* of a boolean expression or when simplifying a boolean expression.

3.3 Boolean Functions and Truth Tables

A boolean *expression* is a sequence of zeros, ones, and *literals* separated by boolean operators. A literal is a primed (negated) or unprimed variable name. For our purposes, all variable names will be a single alphabetic character. A boolean function is a specific boolean expression; we will generally give boolean functions the name F with a possible subscript. For example, consider the following boolean:

$$F_0 = AB+C$$

This function computes the logical AND of A and B and then logically ORs this result with C . If $A=1$, $B=0$, and $C=1$, then F_0 returns the value one ($1 \cdot 0 + 1 = 1$).

Another way to represent a boolean function is via a *truth table*. A previous chapter (see “Logical Operations on Bits” on page 55) used truth tables to represent the AND and OR functions. Those truth tables took the forms:

Table 14: AND Truth Table

| AND | 0 | 1 |
|-----|---|---|
| 0 | 0 | 0 |
| 1 | 0 | 1 |

Table 15: OR Truth Table

| OR | 0 | 1 |
|----|---|---|
| 0 | 0 | 1 |
| 1 | 1 | 1 |

For binary operators and two input variables, this form of a truth table is very natural and convenient. However, reconsider the boolean function F_0 above. That function has *three* input variables, not two. Therefore, one cannot use the truth table format given above. Fortunately, it is still very easy to construct truth tables for three or more variables. The following example shows one way to do this for functions of three or four variables:

Table 16: Truth Table for a Function with Three Variables

| F = AB + C | | BA | | | |
|------------|---|----|----|----|----|
| | | 00 | 01 | 10 | 11 |
| C | 0 | 0 | 0 | 0 | 1 |
| | 1 | 1 | 1 | 1 | 1 |

Table 17: Truth Table for a Function with Four Variables

| F = AB + CD | | BA | | | |
|-------------|----|----|----|----|----|
| | | 00 | 01 | 10 | 11 |
| DC | 00 | 0 | 0 | 0 | 1 |
| | 01 | 0 | 0 | 0 | 1 |
| | 10 | 0 | 0 | 0 | 1 |
| | 11 | 1 | 1 | 1 | 1 |

In the truth tables above, the four columns represent the four possible combinations of zeros and ones for A & B (B is the H.O. or leftmost bit, A is the L.O. or rightmost bit). Likewise the four rows in the second truth table above represent the four possible combinations of zeros and ones for the C and D variables. As before, D is the H.O. bit and C is the L.O. bit.

Table 18 shows another way to represent truth tables. This form has two advantages over the forms above – it is easier to fill in the table and it provides a compact representation for two or more functions.

Table 18: Another Format for Truth Tables

| C | B | A | F = ABC | F = AB + C | F = A+BC |
|---|---|---|---------|------------|----------|
| 0 | 0 | 0 | 0 | 0 | 0 |
| 0 | 0 | 1 | 0 | 0 | 1 |
| 0 | 1 | 0 | 0 | 0 | 0 |
| 0 | 1 | 1 | 0 | 1 | 1 |
| 1 | 0 | 0 | 0 | 1 | 0 |
| 1 | 0 | 1 | 0 | 1 | 1 |
| 1 | 1 | 0 | 0 | 1 | 1 |
| 1 | 1 | 1 | 1 | 1 | 1 |

Note that the truth table above provides the values for three separate functions of three variables.

Although you can create an infinite variety of boolean functions, they are not all unique. For example, $F=A$ and $F=AA$ are two different functions. By theorem two, however, it is easy to show that these two functions are equivalent, that is, they produce exactly the same outputs for all input combinations. If you fix the number of input variables, there are a finite number of unique boolean functions possible. For example, there are only 16 unique boolean functions with two inputs and there are only 256 possible boolean functions of three input variables. Given n input variables, there are 2^{2^n} (two raised to the two raised to the n^{th} power)¹ unique boolean functions of those n input values. For two input variables, $2^{2^2} = 2^4$ or 16 different functions. With three input variables there are $2^{2^3} = 2^8$ or 256 possible functions. Four input variables create 2^{2^4} or 2^{16} , or 65,536 different unique boolean functions.

When dealing with only 16 boolean functions, it's easy enough to name each function. The following table lists the 16 possible boolean functions of two input variables along with some common names for those functions:

Table 19: The 16 Possible Boolean Functions of Two Variables

| Function # | Description |
|------------|--|
| 0 | Zero or Clear. Always returns zero regardless of A and B input values. |
| 1 | Logical NOR ($\text{NOT}(A \text{ OR } B)) = (A+B)'$ |
| 2 | Inhibition = AB' (A, not B). Also equivalent to $A > B$ or $B < A$. |
| 3 | NOT B. Ignores A and returns B'. |
| 4 | Inhibition = BA' (B, not A). Also equivalent to $B > A$ or $A < B$. |
| 5 | NOT A. Returns A' and ignores B |
| 6 | Exclusive-or (XOR) = $A \oplus B$. Also equivalent to $A \neq B$. |
| 7 | Logical NAND ($\text{NOT}(A \text{ AND } B)) = (A \cdot B)'$ |
| 8 | Logical AND = $A \cdot B$. Returns A AND B. |

1. In this context, the operator “**” means exponentiation.

Table 19: The 16 Possible Boolean Functions of Two Variables

| Function # | Description |
|------------|--|
| 9 | Equivalence = $(A = B)$. Also known as exclusive-NOR (not exclusive-or). |
| 10 | Copy A. Returns the value of A and ignores B's value. |
| 11 | Implication, B implies A, or $A + B'$. (if B then A). Also equivalent to $B \geq A$. |
| 12 | Copy B. Returns the value of B and ignores A's value. |
| 13 | Implication, A implies B, or $B + A'$ (if A then B). Also equivalent to $A \geq B$. |
| 14 | Logical OR = $A+B$. Returns A OR B. |
| 15 | One or Set. Always returns one regardless of A and B input values. |

Beyond two input variables there are too many functions to provide specific names. Therefore, we will refer to the function's number rather than the function's name. For example, F_8 denotes the logical AND of A and B for a two-input function and F_{14} is the logical OR operation. Of course, the only problem is to determine a function's number. For example, given the function of three variables $F=AB+C$, what is the corresponding function number? This number is easy to compute by looking at the truth table for the function (see Table 22 on page 203). If we treat the values for A, B, and C as bits in a binary number with C being the H.O. bit and A being the L.O. bit, they produce the binary numbers in the range zero through seven. Associated with each of these binary strings is a zero or one function result. If we construct a binary value by placing the function result in the bit position specified by A, B, and C, the resulting binary number is that function's number. Consider the truth table for $F=AB+C$:

| | | | | | | | | | |
|----------|--|---|---|---|---|---|---|---|---|
| CBA: | | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| F=AB+C : | | 1 | 1 | 1 | 1 | 1 | 0 | 0 | 0 |

If we treat the function values for F as a binary number, this produces the value $F8_{16}$ or 248_{10} . We will usually denote function numbers in decimal.

This also provides the insight into why there are 2^{2^n} different functions of n variables: if you have n input variables, there are 2^n bits in function's number. If you have m bits, there are 2^m different values. Therefore, for n input variables there are $m=2^n$ possible bits and 2^m or 2^{2^n} possible functions.

3.4 Algebraic Manipulation of Boolean Expressions

You can transform one boolean expression into an equivalent expression by applying the postulates the theorems of boolean algebra. This is important if you want to convert a given expression to a *canonical form* (a standardized form) or if you want to minimize the number of literals (primed or unprimed variables) or terms in an expression. Minimizing terms and expressions can be important because electrical circuits often consist of individual components that implement each term or literal for a given expression. Minimizing the expression allows the designer to use fewer electrical components and, therefore, can reduce the cost of the system.

Unfortunately, there are no fixed rules you can apply to optimize a given expression. Much like constructing mathematical proofs, an individual's ability to easily do these transformations is usually a function of experience. Nevertheless, a few examples can show the possibilities:

$$\begin{aligned}
 ab + ab' + a'b &= a(b+b') + a'b && \text{By P4} \\
 &= a \bullet 1 + a'b && \text{By P5} \\
 &= a + a'b && \text{By Th4} \\
 &= a + b && \text{By Th11}
 \end{aligned}$$

$$\begin{aligned}
 (a'b + a'b' + b')' &= (a'(b+b') + b')' && \text{By P4} \\
 &= (a' \bullet 1 + b')' && \text{By P5} \\
 &= (a' + b') && \text{By Th4} \\
 &= ((ab)')' && \text{By Th8} \\
 &= ab && \text{By definition of not}
 \end{aligned}$$

$$\begin{aligned}
 b(a+c) + ab' + bc' + c &= ba + bc + ab' + bc' + c && \text{By P4} \\
 &= a(b+b') + b(c + c') + c && \text{By P4} \\
 &= a \bullet 1 + b \bullet 1 + c && \text{By P5} \\
 &= a + b + c && \text{By Th4}
 \end{aligned}$$

Although these examples all use algebraic transformations to simplify a boolean expression, we can also use algebraic operations for other purposes. For example, the next section describes a canonical form for boolean expressions. We can use algebraic manipulation to produce canonical forms even though the canonical forms are rarely optimal.

3.5 Canonical Forms

Since there are a finite number of boolean functions of n input variables, yet an infinite number of possible logic expressions you can construct with those n input values, clearly there are an infinite number of logic expressions that are equivalent (i.e., they produce the same result given the same inputs). To help eliminate possible confusion, logic designers generally specify a boolean function using a *canonical*, or standardized, form. For any given boolean function there exists a unique canonical form. This eliminates some confusion when dealing with boolean functions.

Actually, there are several different canonical forms. We will discuss only two here and employ only the first of the two. The first is the so-called *sum of minterms* and the second is the *product of maxterms*. Using the duality principle, it is very easy to convert between these two.

A *term* is a variable or a product (logical AND) of several different literals. For example, if you have two variables, A and B , there are eight possible terms: A , B , A' , B' , $A'B'$, $A'B$, AB' , and AB . For three variables we have 26 different terms: A , B , C , A' , B' , C' , $A'B'$, $A'B$, AB' , AB , $A'C'$, $A'C$, AC' , AC , $B'C'$, $B'C$, BC' , BC , $A'B'C'$, $AB'C'$, $A'BC'$, ABC' , $A'B'BC$, $AB'BC$, $A'BC$, and ABC . As you can see, as the number of variables increases, the number of terms increases dramatically. A *minterm* is a product containing exactly n literals. For example, the minterms for two variables are $A'B'$, AB' , $A'B$, and AB . Likewise, the minterms for three variables A , B , and C are $A'B'C'$, $AB'C'$, $A'BC'$, ABC' , $A'B'BC$, $AB'BC$, $A'BC$, and ABC . In general, there are 2^n minterms for n variables. The set of possible minterms is very easy to generate since they correspond to the sequence of binary numbers:

Table 20: Minterms for Three Input Variables

| Binary Equivalent (CBA) | Minterm |
|-------------------------|----------|
| 000 | $A'B'C'$ |
| 001 | $AB'C'$ |
| 010 | $A'BC'$ |
| 011 | ABC' |
| 100 | $A'B'C$ |
| 101 | $AB'C$ |
| 110 | $A'BC$ |
| 111 | ABC |

We can specify *any* boolean function using a sum (logical OR) of minterms. Given $F_{248}=AB+C$ the equivalent canonical form is $ABC+A'BC+AB'C+A'B'C+ABC'$. Algebraically, we can show that these two are equivalent as follows:

$$\begin{aligned}
 ABC+A'BC+AB'C+A'B'C+ABC' &= BC(A+A') + B'C(A+A') + ABC' && \text{By P4} \\
 &= BC \bullet 1 + B'C \bullet 1 + ABC' && \text{By Th15} \\
 &= C(B+B') + ABC' && \text{By P4} \\
 &= C + ABC' && \text{By Th15 \& Th4} \\
 &= C + AB && \text{By Th11}
 \end{aligned}$$

Obviously, the canonical form is not the optimal form. On the other hand, there is a big advantage to the sum of minterms canonical form: it is very easy to generate the truth table for a function from this canonical form. Furthermore, it is also very easy to generate the logic equation from the truth table.

To build the truth table from the canonical form, simply convert each minterm into a binary value by substituting a "1" for unprimed variables and a "0" for primed variables. Then place a "1" in the corresponding position (specified by the binary minterm value) in the truth table:

1) Convert minterms to binary equivalents:

$$\begin{aligned}
 F_{248} &= CBA + CBA' + CB'A + CB'A' + C'BA \\
 &= 111 + 110 + 101 + 100 + 011
 \end{aligned}$$

2) Substitute a one in the truth table for each entry above:

Table 21: Creating a Truth Table from Minterms, Step One

| C | B | A | F = AB+C |
|---|---|---|----------|
| 0 | 0 | 0 | |
| 0 | 0 | 1 | |
| 0 | 1 | 0 | |
| 0 | 1 | 1 | 1 |
| 1 | 0 | 0 | 1 |
| 1 | 0 | 1 | 1 |
| 1 | 1 | 0 | 1 |
| 1 | 1 | 1 | 1 |

Finally, put zeros in all the entries that you did not fill with ones in the first step above:

Table 22: Creating a Truth Table from Minterms, Step Two

| C | B | A | F = AB+C |
|---|---|---|----------|
| 0 | 0 | 0 | 0 |
| 0 | 0 | 1 | 0 |
| 0 | 1 | 0 | 0 |
| 0 | 1 | 1 | 1 |
| 1 | 0 | 0 | 1 |
| 1 | 0 | 1 | 1 |
| 1 | 1 | 0 | 1 |
| 1 | 1 | 1 | 1 |

Going in the other direction, generating a logic function from a truth table, is almost as easy. First, locate all the entries in the truth table with a one. In the table above, these are the last five entries. The number of table entries containing ones determines the number of minterms in the canonical equation. To generate the individual minterms, substitute A , B , or C for ones and A' , B' , or C' for zeros in the truth table above. Then compute the sum of these items. In the example above, F_{248} contains one for $CBA = 111, 110, 101, 100$, and 011 . Therefore, $F_{248} = CBA + CBA' + CB'A + CB'A' + C'AB$. The first term, CBA , comes from the last entry in the table above. C , B , and A all contain ones so we generate the minterm CBA (or ABC , if you prefer). The second to last entry contains 110 for CBA , so we generate the minterm CBA' . Likewise, 101 produces $CB'A$; 100 produces $CB'A'$, and 011 produces $C'BA$. Of course, the logical OR and logical AND operations are both commutative, so we can rearrange the terms within the minterms as we please and we can rearrange the minterms within the sum as we see fit. This process works equally well for any number of variables. Consider the function $F_{53504} = ABCD + A'BCD + A'B'CD + A'B'C'D$. Placing ones in the appropriate positions in the truth table generates the following:

Table 23: Creating a Truth Table with Four Variables from Minterms

| D | C | B | A | $F = ABCD + A'BCD + A'B'CD + A'B'C'D$ |
|---|---|---|---|---------------------------------------|
| 0 | 0 | 0 | 0 | |
| 0 | 0 | 0 | 1 | |
| 0 | 0 | 1 | 0 | |
| 0 | 0 | 1 | 1 | |
| 0 | 1 | 0 | 0 | |
| 0 | 1 | 0 | 1 | |
| 0 | 1 | 1 | 0 | |
| 0 | 1 | 1 | 1 | |
| 1 | 0 | 0 | 0 | 1 |
| 1 | 0 | 0 | 1 | |
| 1 | 0 | 1 | 0 | |
| 1 | 0 | 1 | 1 | |
| 1 | 1 | 0 | 0 | 1 |
| 1 | 1 | 0 | 1 | |
| 1 | 1 | 1 | 0 | 1 |
| 1 | 1 | 1 | 1 | 1 |

The remaining elements in this truth table all contain zero.

Perhaps the easiest way to generate the canonical form of a boolean function is to first generate the truth table for that function and then build the canonical form from the truth table. We'll use this technique, for example, when converting between the two canonical forms this chapter presents. However, it is also a simple matter to generate the sum of minterms form algebraically. By using the distributive law and theorem 15 ($A + A' = 1$) makes this task easy. Consider $F_{248} = AB + C$. This function contains two terms, AB and C , but they are not minterms. Minterms contain each of the possible variables in a primed or unprimed form. We can convert the first term to a sum of minterms as follows:

$$\begin{aligned}
 AB &= AB \bullet 1 && \text{By Th4} \\
 &= AB \bullet (C + C') && \text{By Th 15} \\
 &= ABC + ABC' && \text{By distributive law} \\
 &= CBA + C'BA && \text{By associative law}
 \end{aligned}$$

Similarly, we can convert the second term in F_{248} to a sum of minterms as follows:

$$\begin{aligned}
 C &= C \bullet 1 && \text{By Th4} \\
 &= C \bullet (A + A') && \text{By Th15} \\
 &= CA + CA' && \text{By distributive law} \\
 &= CA \bullet 1 + CA' \bullet 1 && \text{By Th4} \\
 &= CA \bullet (B + B') + CA' \bullet (B + B') && \text{By Th15} \\
 &= CAB + CAB' + CA'B + CA'B' && \text{By distributive law} \\
 &= CBA + CBA' + CB'A + CB'A' && \text{By associative law}
 \end{aligned}$$

The last step (rearranging the terms) in these two conversions is optional. To obtain the final canonical form for F_{248} we need only sum the results from these two conversions:

$$\begin{aligned} F_{248} &= (CBA + C'BA) + (CBA + CBA' + CB'A + CB'A') \\ &= CBA + CBA' + CB'A + CB'A' + C'BA \end{aligned}$$

Another way to generate a canonical form is to use *products of maxterms*. A maxterm is the sum (logical OR) of all input variables, primed or unprimed. For example, consider the following logic function G of three variables:

$$G = (A+B+C) \cdot (A'+B+C) \cdot (A+B'+C) .$$

Like the sum of minterms form, there is exactly one product of maxterms for each possible logic function. Of course, for every product of maxterms there is an equivalent sum of minterms form. In fact, the function G , above, is equivalent to

$$F_{248} = CBA + CBA' + CB'A + CB'A' + C'BA = AB + C.$$

Generating a truth table from the product of maxterms is no more difficult than building it from the sum of minterms. You use the duality principle to accomplish this. Remember, the duality principle says to swap AND for OR and zeros for ones (and vice versa). Therefore, to build the truth table, you would first swap primed and non-primed literals. In G above, this would yield:

$$G = (A' + B' + C') \cdot (A + B' + C') \cdot (A' + B + C')$$

The next step is to swap the logical OR and logical AND operators. This produces

$$G = A'B'C' + AB'C' + A'BC'$$

Finally, you need to swap all zeros and ones. This means that you store *zeros* into the truth table for each of the above entries and then fill in the rest of the truth table with ones. This will place a zero in entries zero, one, and two in the truth table. Filling the remaining entries with ones produces F_{248} .

You can easily convert between these two canonical forms by generating the truth table for one form and working backwards from the truth table to produce the other form. For example, consider the function of two variables, $F_7 = A + B$. The sum of minterms form is $F_7 = A'B + AB' + AB$. The truth table takes the form:

Table 24: F_7 (OR) Truth Table for Two Variables

| F_7 | A | B |
|-------|---|---|
| 0 | 0 | 0 |
| 0 | 1 | 0 |
| 1 | 0 | 1 |
| 1 | 1 | 1 |

Working backwards to get the product of maxterms, we locate all entries that have a zero result. This is the entry with A and B equal to zero. This gives us the first step of $G=A'B'$. However, we still need to invert all the variables to obtain $G=AB$. By the duality principle we need to swap the logical OR and logical AND operators obtaining $G=A+B$. This is the canonical *product of maxterms* form.

Since working with the product of maxterms is a little messier than working with sums of minterms, this text will generally use the sum of minterms form. Furthermore, the sum of minterms form is more common in boolean logic work. However, you will encounter both forms when studying logic design.

3.6 Simplification of Boolean Functions

Since there are an infinite variety of boolean functions of n variables, but only a finite number of unique boolean functions of those n variables, you might wonder if there is some method that will simplify a given boolean function to produce the optimal form. Of course, you can always use algebraic transformations to produce the optimal form, but using heuristics does not guarantee an optimal transformation. There are, however, two methods that *will* reduce a given boolean function to its optimal form: the map method and the prime implicants method. In this text we will only cover the mapping method, see any text on logic design for other methods.

Since for any logic function some optimal form must exist, you may wonder why we don't use the optimal form for the canonical form. There are two reasons. First, there may be several optimal forms. They are not guaranteed to be unique. Second, it is easy to convert between the canonical and truth table forms.

Using the map method to optimize boolean functions is practical only for functions of two, three, or four variables. With care, you can use it for functions of five or six variables, but the map method is cumbersome to use at that point. For more than six variables, attempting map simplifications by hand would not be wise².

The first step in using the map method is to build a two-dimensional truth table for the function (see Figure 3.1)

Four Variable Truth Table

Figure 3.1 Two, Three, and Four Dimensional Truth Tables

2. However, it's probably quite reasonable to write a *program* that uses the map method for seven or more variables.

Warning: Take a careful look at these truth tables. They do not use the same forms appearing earlier in this chapter. In particular, the progression of the values is 00, 01, 11, 10, not 00, 01, 10, 11. This is very important! If you organize the truth tables in a binary sequence, the mapping optimization method will not work properly. We will call this a *truth map* to distinguish it from the standard truth table.

Assuming your boolean function is in canonical form (sum of minterms), insert ones for each of the truth map entries corresponding to a minterm in the function. Place zeros everywhere else. For example, consider the function of three variables $F=C'B'A + C'BA' + C'BA + CB'A' + CB'A + CBA' + CBA$. Figure 3.2 shows the truth map for this function.

| | | | | | |

$$F=C'B'A + C'BA' + C'BA + CB'A' + CB'A + CBA' + CBA.$$

Figure 3.2 A Simple Truth Map

The next step is to draw rectangles around rectangular groups of ones. The rectangles you enclose must have sides whose lengths are powers of two. For functions of three variables, the rectangles can have sides whose lengths are one, two, and four. The set of rectangles you draw must surround all cells containing ones in the truth map. The trick is to draw all possible rectangles unless a rectangle would be completely enclosed within another. Note that the rectangles may overlap if one does not enclose the other. In the truth map in Figure 3.3 there are three such rectangles (see Figure 3.3)

| | | | | | |
|---|---|----|----|----|----|

Three possible rectangles whose lengths and widths are powers of two.

Figure 3.3 Surrounding Rectangular Groups of Ones in a Truth Map

Each rectangle represents a term in the simplified boolean function. Therefore, the simplified boolean function will contain only three terms. You build each term using the process of elimination. You eliminate any variables whose primed and unprimed form both appear within the rectangle. Consider the long skinny rectangle above that is sitting in the row where $C=1$. This rectangle contains both A and B in primed and unprimed form. Therefore, we can eliminate A and B from the term. Since the rectangle sits in the $C=1$ region, this rectangle represents the single literal C .

Now consider the blue square above. This rectangle includes C , C' , B , B' and A . Therefore, it represents the single term A . Likewise, the red square above contains C , C' , A , A' and B . Therefore, it represents the single term B .

The final, optimal, function is the sum (logical OR) of the terms represented by the three squares. Therefore, $F = A + B + C$. You do not have to consider the remaining squares containing zeros.

When enclosing groups of ones in the truth map, you must consider the fact that a truth map forms a *torus* (i.e., a doughnut shape). The right edge of the map *wraps around* to the left edge (and vice-versa). Likewise, the top edge *wraps around* to the bottom edge. This introduces additional possibilities when surrounding groups of ones in a map. Consider the boolean function $F = C'B'A' + C'BA' + CB'A' + CBA'$. Figure 3.4 shows the truth map for this function.

Figure 3.4 Truth Map for $F = C'B'A' + C'BA' + CB'A' + CBA'$

At first glance, you would think that there are two possible rectangles here as Figure 3.5 shows.

Figure 3.5 First Attempt at Surrounding Rectangles Formed by Ones

However, because the truth map is a continuous object with the right side and left sides connected, we can form a single, square rectangle, as Figure 3.6 shows.

Figure 3.6 Correct Rectangle for the Function

So what? Why do we care if we have one rectangle or two in the truth map? The answer is because the larger the rectangles are, the more terms they will eliminate. The fewer rectangles that we have, the fewer terms will appear in the final boolean function. For example, the former example with two rectangles generates a function with two terms. The first rectangle (on the left) eliminates the C variable, leaving $A'B'$ as its term. The second rectangle, on the right, also eliminates the C variable, leaving the term BA' . Therefore, this truth map would produce the equation $F=A'B' + A'B$. We know this is not optimal, see Th 13. Now consider the second truth map above. Here we have a single rectangle so our boolean function will only have a single term. Obviously this is more optimal than an equation with two terms. Since this rectangle includes both C and C' and also B and B' , the only term left is A' . This boolean function, therefore, reduces to $F=A'$.

There are only two cases that the truth map method cannot handle properly: a truth map that contains all zeros or a truth map that contains all ones. These two cases correspond to the boolean functions $F=0$ and $F=1$ (that is, the function number is 2^{n-1}), respectively. These functions are easy to generate by inspection of the truth map.

An important thing you must keep in mind when optimizing boolean functions using the mapping method is that you always want to pick the largest rectangles whose sides' lengths are a power of two. You must do this even for overlapping rectangles (unless one rectangle encloses another). Consider the boolean function $F = C'B'A' + C'BA' + CB'A' + C'AB + CBA' + CBA$. This produces the truth map appearing in Figure 3.7.

| | | | | | |
|---|---|----|----|----|----|
| | | BA | | | |
| | | 00 | 01 | 11 | 10 |
| C | 0 | 1 | 0 | 1 | 1 |
| | 1 | 1 | 0 | 1 | 1 |

Figure 3.7 Truth Map for $F = C'B'A' + C'BA' + CB'A' + C'AB + CBA' + CBA$

The initial temptation is to create one of the sets of rectangles found in Figure 3.8. However, the correct mapping appears in Figure 3.9

Figure 3.8 Obvious Choices for Rectangles

Figure 3.9 Correct Set of Rectangles for $F = C'B'A' + C'BA' + CB'A' + C'AB + CBA' + CBA$

All three mappings will produce a boolean function with two terms. However, the first two will produce the expressions $F = B + A'B'$ and $F = AB + A'$. The third form produces $F = B + A'$. Obviously, this last form is more optimal than the other two forms (see theorems 11 and 12).

For functions of three variables, the size of the rectangle determines the number of terms it represents:

- A rectangle enclosing a single square represents a minterm. The associated term will have three literals (assuming we're working with functions of three variables).
- A rectangle surrounding two squares containing ones represents a term containing two literals.
- A rectangle surrounding four squares containing ones represents a term containing a single literal.
- A rectangle surrounding eight squares represents the function $F = 1$.

Truth maps you create for functions of four variables are even trickier. This is because there are lots of places rectangles can hide from you along the edges. Figure 3.10 shows some possible places rectangles can hide.

Figure 3.10 Partial Pattern List for 4x4 Truth Map

This list of patterns doesn't even begin to cover all of them! For example, these diagrams show none of the 1x2 rectangles. You must exercise care when working with four variable maps to ensure you select the largest possible rectangles, especially when overlap occurs. This is particularly important with you have a rectangle next to an edge of the truth map.

As with functions of three variables, the size of the rectangle in a four variable truth map controls the number of terms it represents:

- A rectangle enclosing a single square represents a minterm. The associated term will have four literals.
- A rectangle surrounding two squares containing ones represents a term containing three literals.
- A rectangle surrounding four squares containing ones represents a term containing two literals.
- A rectangle surrounding eight squares containing ones represents a term containing a single literal.
- A rectangle surrounding sixteen squares represents the function $F=1$.

This last example demonstrates an optimization of a function containing four variables. The function is $F = D'C'B'A' + D'C'B'A + D'C'BA + D'C'BA' + D'CB'A + D'CB'A + DCB'A + DCBA + DC'B'A' + DC'BA'$, the truth map appears in Figure 3.11.

Figure 3.11 Truth Map for $F = D'C'B'A' + D'C'B'A + D'C'BA + D'C'BA' + D'CB'A + D'CB'A + DCB'A + DCBA + DC'B'A' + DC'BA'$

Here are two possible sets of maximal rectangles for this function, each producing three terms (see Figure 3.12). Both functions are equivalent; both are as optimal as you can get³. Either will suffice for our purposes.

Figure 3.12 Two Combinations of Surrounded Values Yielding Three Terms

First, let's consider the term represented by the rectangle formed by the four corners. This rectangle contains $B, B', D,$ and D' ; so we can eliminate those terms. The remaining terms contained within these rectangles are C' and A' , so this rectangle represents the term $C'A'$.

The second rectangle, common to both maps in Figure 3.12, is the rectangle formed by the middle four squares. This rectangle includes the terms $A, B, B', C, D,$ and D' . Eliminating $B, B', D,$ and D' (since both primed and unprimed terms exist), we obtain CA as the term for this rectangle.

3. Remember, there is no guarantee that there is a unique optimal solution.

The map on the left in Figure 3.12 has a third term represented by the top row. This term includes the variables A, A', B, B', C' and D' . Since it contains $A, A', B,$ and B' , we can eliminate these terms. This leaves the term $C'D'$. Therefore, the function represented by the map on the left is $F=C'A' + CA + C'D'$.

The map on the right in Figure 3.12 has a third term represented by the top/middle four squares. This rectangle subsumes the variables $A, B, B', C, C',$ and D' . We can eliminate $B, B', C,$ and C' since both primed and unprimed versions appear, this leaves the term AD . Therefore, the function represented by the function on the right is $F=C'A' + CA + AD'$.

Since both expressions are equivalent, contain the same number of terms, and the same number of operators, either form is equivalent. Unless there is another reason for choosing one over the other, you can use either form.

3.7 What Does This Have To Do With Computers, Anyway?

Although there is a tenuous relationship between boolean functions and boolean expressions in programming languages like C or Pascal, it is fair to wonder why we're spending so much time on this material. However, the relationship between boolean logic and computer systems is much stronger than it first appears. There is a one-to-one relationship between boolean functions and electronic circuits. Electrical engineers who design CPUs and other computer related circuits need to be intimately familiar with this stuff. Even if you never intend to design your own electronic circuits, understanding this relationship is important if you want to make the most of any computer system.

3.7.1 Correspondence Between Electronic Circuits and Boolean Functions

There is a one-to-one correspondence between an electrical circuits and boolean functions. For any boolean function you can design an electronic circuit and vice versa. Since boolean functions only require the AND, OR, and NOT boolean operators⁴, we can construct any electronic circuit using these operations exclusively. The boolean AND, OR, and NOT functions correspond to the following electronic circuits, the AND, OR, and inverter (NOT) gates (see Figure 3.13).

Figure 3.13 AND, OR, and Inverter (NOT) Gates

One interesting fact is that you only need a single gate type to implement *any* electronic circuit. This gate is the NAND gate, shown in Figure 3.14.

Figure 3.14 The NAND Gate

To prove that we can construct any boolean function using only NAND gates, we need only show how to build an inverter (NOT), an AND gate, and an OR gate from a NAND (since we can create any boolean func-

4. We know this is true because these are the only operators that appear within canonical forms.

tion using only AND, NOT, and OR). Building an inverter is easy, just connect the two inputs together (see Figure 3.15).

Figure 3.15 Inverter Built from a NAND Gate

Once we can build an inverter, building an AND gate is easy – just invert the output of a NAND gate. After all, NOT (NOT (A AND B)) is equivalent to A AND B (see Figure 3.16). Of course, this takes two NAND gates to construct a single AND gate, but no one said that circuits constructed only with NAND gates would be optimal, only that it is possible.

Figure 3.16 Constructing an AND Gate From Two NAND Gates

The remaining gate we need to synthesize is the logical-OR gate. We can easily construct an OR gate from NAND gates by applying DeMorgan's theorems.

| | | |
|----------------------|---------------------------|------------------------------------|
| $(A \text{ or } B)'$ | $= A' \text{ and } B'$ | DeMorgan's Theorem. |
| $A \text{ or } B$ | $= (A' \text{ and } B')'$ | Invert both sides of the equation. |
| $A \text{ or } B$ | $= A' \text{ nand } B'$ | Definition of NAND operation. |

By applying these transformations, you get the circuit in Figure 3.17.

Figure 3.17 Constructing an OR Gate from NAND Gates

Now you might be wondering why we would even bother with this. After all, why not just use logical AND, OR, and inverter gates directly? There are two reasons for this. First, NAND gates are generally less expensive to build than other gates. Second, it is also much easier to build up complex integrated circuits from the same basic building blocks than it is to construct an integrated circuit using different basic gates.

Note, by the way, that it is possible to construct any logic circuit using only NOR gates⁵. The correspondence between NAND and NOR logic is orthogonal to the correspondence between the two canonical forms appearing in this chapter (sum of minterms vs. product of maxterms). While NOR logic is useful for many circuits, most electronic designs use NAND logic. See the exercises for more examples.

5. NOR is NOT (A OR B).

3.7.2 Combinatorial Circuits

A combinatorial circuit is a system containing basic boolean operations (AND, OR, NOT), some inputs, and a set of outputs. Since each output corresponds to an individual logic function, a combinatorial circuit often implements several different boolean functions. It is very important that you remember this fact – each output represents a different boolean function.

A computer's CPU is built up from various combinatorial circuits. For example, you can implement an addition circuit using boolean functions. Suppose you have two one-bit numbers, A and B . You can produce the one-bit sum and the one-bit carry of this addition using the two boolean functions:

$$\begin{aligned} S &= AB' + A'B && \text{Sum of } A \text{ and } B. \\ C &= AB && \text{Carry from addition of } A \text{ and } B. \end{aligned}$$

These two boolean functions implement a *half-adder*. Electrical engineers call it a half adder because it adds two bits together but cannot add in a carry from a previous operation. A *full adder* adds three one-bit inputs (two bits plus a carry from a previous addition) and produces two outputs: the sum and the carry. The two logic equations for a full adder are

$$\begin{aligned} S &= A'B'C_{in} + A'BC_{in}' + AB'C_{in}' + ABC_{in} \\ C_{out} &= AB + AC_{in} + BC_{in} \end{aligned}$$

Although these logic equations only produce a single bit result (ignoring the carry), it is easy to construct an n -bit sum by combining adder circuits (see Figure 3.18). So, as this example clearly illustrates, we can use logic functions to implement arithmetic and boolean operations.

Figure 3.18 Building an N-Bit Adder Using Half and Full Adders

Another common combinatorial circuit is the *seven-segment decoder*. This is a combinatorial circuit that accepts four inputs and determines which of the segments on a seven-segment LED display should be on (logic one) or off (logic zero). Since a seven segment display contains seven output values (one for each segment), there will be seven logic functions associated with the display (segment zero through segment six). See Figure 3.19 for the segment assignments. Figure 3.20 shows the segment assignments for each of the ten decimal values.

Figure 3.19 Seven Segment Display

Figure 3.20 Seven Segment Values for “0” Through “9”

The four inputs to each of these seven boolean functions are the four bits from a binary number in the range 0..9. Let D be the H.O. bit of this number and A be the L.O. bit of this number. Each logic function should produce a one (segment on) for a given input if that particular segment should be illuminated. For example S_4 (segment four) should be on for binary values 0000, 0010, 0110, and 1000. For each value that illuminates a segment, you will have one minterm in the logic equation:

$$S_4 = D' C' B' A' + D' C' B A' + D' C B A' + D C' B' A' .$$

S_0 , as a second example, is on for values zero, two, three, five, six, seven, eight, and nine. Therefore, the logic function for S_0 is

$$S_0 = D' C' B' A' + D' C' B A' + D' C' B A + D' C B' A + D' C B A' + D' C B A + D C' B' A' + D C' B' A$$

You can generate the other five logic functions in a similar fashion (see the exercises).

Decoder circuits are among the more important circuits in computer system design. They provide the ability to recognize (or ‘decode’) a string of bits. One very common use for a decoder is memory expansion. For example, suppose a system designer wishes to install four (identical) 256 MByte memory modules in a system to bring the total to one gigabyte of RAM. These 256 MByte memory modules have 28 address lines assuming each memory modules is eight bits wide ($2^{28} \times 8$ bits is 256 MBytes)⁶. Unfortunately, if the system designer hooked up those four memory modules to the CPU’s address bus they would all respond to the same addresses on the bus. Pandemonium would result. To correct this problem, we need to select each memory module when a different set of addresses appear on the address bus. By adding a chip enable line to each of the memory modules and using a two-input, four-output decoder circuit, we can easily do this. See Figure 3.21 for the details.

6. Actually, most memory modules are wider than eight bits, so a real 256 MByte memory module will have fewer than 28 address lines, but we will ignore this technicality in this example.

Figure 3.21 Adding Four 256 MByte Memory Modules to a System

The two-line to four-line decoder circuit in Figure 3.21 actually incorporates four different logic functions, one function for each of the outputs. Assume the inputs are A and B ($A=A_{28}$ and $B=A_{29}$) then the four output functions have the following (simple) equations:

$$\begin{aligned} Q_0 &= A' B' \\ Q_1 &= A B' \\ Q_2 &= A' B \\ Q_3 &= A B \end{aligned}$$

Following standard electronic circuit notation, these equations use “Q” to denote an output (electronic designers use “Q” for output rather than “O” because “Q” looks somewhat like an “O” and is more easily differentiated from zero). Also note that most circuit designers use *active low logic* for decoders and chip enables. This means that they enable a circuit with a low input value (zero) and disable the circuit with a high input value (one). Likewise, the output lines of a decoder chip are normally high and go low when the inputs select a given output line. This means that the equations above really need to be inverted for real-world examples. We’ll ignore this issue here and use positive (or active high) logic⁷.

Another big use for decoding circuits is to decode a byte in memory that represents a machine instruction in order to activate the corresponding circuitry to perform whatever tasks the instruction requires. We’ll cover this subject in much greater depth in a later chapter, but a simple example at this point will provide another solid example for using decoders.

Most modern (Von Neumann) computer systems represent machine instructions via values in memory. To execute an instruction the CPU fetches a value from memory, decodes that value, and then does the appropriate activity the instruction specifies. Obviously, the CPU uses decoding circuitry to decode the instruction. To see how this is done, let’s create a very simple CPU with a very simple instruction set. Figure 3.22 provides the instruction format (that is, it specifies all the numeric codes) for our simple CPU.

7. Electronic circuits often use active low logic because the circuits that employ them typically require fewer transistors to implement.

Instruction (opcode) Format:

| | |
|---|--|
| <p>iii</p> <p>000 = MOV</p> <p>001 = ADD</p> <p>010 = SUB</p> <p>011 = MUL</p> <p>100 = DIV</p> <p>101 = AND</p> <p>110 = OR</p> <p>111 = XOR</p> | <p>ss & dd</p> <p>00 = EAX</p> <p>01 = EBX</p> <p>10 = ECX</p> <p>11 = EDX</p> |
|---|--|

Figure 3.22 Instruction (opcode) Format for a Very Simple CPU

To determine the eight-bit operation code (opcode) for a given instruction, the first thing you do is choose the instruction you want to encode. Let’s pick “MOV(EAX, EBX);” as our simple example. To convert this instruction to its numeric equivalent we must first look up the value for MOV in the *iii* table above; the corresponding value is 000. Therefore, we must substitute 000 for *iii* in the opcode byte.

Second, we consider our source operand. The source operand is EAX, whose encoding in the source operand table (*ss & dd*) is 00. Therefore, we substitute 00 for *ss* in the instruction opcode.

Next, we need to convert the destination operand to its numeric equivalent. Once again, we look up the value for this operand in the *ss & dd* table. The destination operand is EBX and it’s value is 01. So we substitute 01 for *dd* in our opcode byte. Assembling these three fields into the opcode byte (a packed data type), we obtain the following bit value: %00000001. Therefore, the numeric value \$1 is the value for the “MOV(EAX, EBX);” instruction (see Figure 3.23).

Figure 3.23 Encoding the MOV(EAX, EBX); Instruction

As another example, consider the “AND(EDX, ECX);” instruction. For this instruction the *iii* field is %101, the *ss* field is %11, and the *dd* field is %10. This yields the opcode %01011110 or \$5E. You may easily create other opcodes for our simple instruction set using this same technique.

Warning: please do not come to the conclusion that these encodings apply to the 80x86 instruction set. The encodings in this examples are highly simplified in order to demonstrate instruction decoding. They do not correspond to any real-life CPU, and they especially don’t apply to the x86 family.

In these past few examples we were actually *encoding* the instructions. Of course, the real purpose of this exercise is to discover how the CPU can use a decoder circuit to decode these instructions and execute them at run time. A typical set of decoder circuits for this might look like that in Figure 3.24:

Note: the circuitry attached to the destination register bits is identical to the circuitry for the source register bits.

Figure 3.24 Decoding Simple Machine Instructions

Notice how this circuit uses three separate decoders to decode the individual fields of the opcode. This is much less complex than creating a seven-line to 128-line decoder to decode each individual opcode. Of course, all that the circuit above will do is tell you which instruction and what operands a given opcode spec-

ifies. To actually execute this instruction you must supply additional circuitry to select the source and destination operands from an array of registers and act accordingly upon those operands. Such circuitry is beyond the scope of this chapter, so we'll save the juicy details for later.

Combinatorial circuits are the basis for many components of a basic computer system. You can construct circuits for addition, subtraction, comparison, multiplication, division, and many other operations using combinatorial logic.

3.7.3 Sequential and Clocked Logic

One major problem with combinatorial logic is that it is *memoryless*. In theory, all logic function outputs depend only on the current inputs. Any change in the input values is immediately reflected in the outputs⁸. Unfortunately, computers need the ability to *remember* the results of past computations. This is the domain of sequential or clocked logic.

A *memory cell* is an electronic circuit that remembers an input value after the removal of that input value. The most basic memory unit is the *set/reset flip-flop*. You can construct an *SR flip-flop* using two NAND gates, as shown in Figure 3.25.

Figure 3.25 Set/Reset Flip Flop Constructed from NAND Gates

The *S* and *R* inputs are normally high. If you *temporarily* set the *S* input to zero and then bring it back to one (*toggle* the *S* input), this forces the *Q* output to one. Likewise, if you toggle the *R* input from one to zero back to one, this sets the *Q* output to zero. The *Q'* input is generally the inverse of the *Q* output.

Note that if both *S* and *R* are one, then the *Q* output depends upon *Q*. That is, whatever *Q* happens to be, the top NAND gate continues to output that value. If *Q* was originally one, then there are two ones as inputs to the bottom flip-flop (*Q* nand *R*). This produces an output of zero (*Q'*). Therefore, the two inputs to the top NAND gate are zero and one. This produces the value one as an output (matching the original value for *Q*).

If the original value for *Q* was zero, then the inputs to the bottom NAND gate are *Q*=0 and *R*=1. Therefore, the output of this NAND gate is one. The inputs to the top NAND gate, therefore, are *S*=1 and *Q'*=1. This produces a zero output, the original value of *Q*.

Suppose *Q* is zero, *S* is zero and *R* is one. This sets the two inputs to the top flip-flop to one and zero, forcing the output (*Q*) to one. Returning *S* to the high state does not change the output at all. You can obtain this same result if *Q* is one, *S* is zero, and *R* is one. Again, this produces an output value of one. This value remains one even when *S* switches from zero to one. Therefore, toggling the *S* input from one to zero and then back to one produces a one on the output (i.e., *sets* the flip-flop). The same idea applies to the *R* input, except it forces the *Q* output to zero rather than to one.

There is one catch to this circuit. It does not operate properly if you set both the *S* and *R* inputs to zero simultaneously. This forces both the *Q* and *Q'* outputs to one (which is logically inconsistent). Whichever

8. In practice, there is a short *propagation delay* between a change in the inputs and the corresponding outputs in any electronic implementation of a boolean function.

input remains zero the longest determines the final state of the flip-flop. A flip-flop operating in this mode is said to be *unstable*.

The only problem with the S/R flip-flop is that you must use separate inputs to remember a zero or a one value. A memory cell would be more valuable to us if we could specify the data value to remember on one input and provide a *clock input* to *latch* the input value. This type of flip-flop, the D flip-flop (for *data*) uses the circuit in Figure 3.26.

Assuming you fix the Q and Q' outputs to either 0/1 or 1/0, sending a *clock pulse* that goes from zero to one back to zero will copy the D input to the Q output. It will also copy D' to Q' . The exercises at the end of this topic section will expect you to describe this operation in detail, so study this diagram carefully.

Although remembering a single bit is often important, in most computer systems you will want to remember a group of bits. You can remember a sequence of bits by combining several D flip-flops in parallel. Concatenating flip-flops to store an n -bit value forms a *register*. The electronic schematic in Figure 3.27 shows how to build an eight-bit register from a set of D flip-flops.

Figure 3.27 An Eight-bit Register Implemented with Eight D Flip-flops

Note that the eight D flip-flops use a common clock line. This diagram does not show the Q' outputs on the flip-flops since they are rarely required in a register.

D flip-flops are useful for building many sequential circuits above and beyond simple registers. For example, you can build a *shift register* that shifts the bits one position to the left on each clock pulse. A four-bit shift register appears in Figure 3.28.

Figure 3.28 A Four-bit Shift Register Built from D Flip-flops

You can even build a *counter*, that counts the number of times the clock toggles from one to zero and back to one using flip-flops. The circuit in Figure 3.29 implements a four bit counter using D flip-flops.

Figure 3.29 Four-bit Counter Built from D Flip-flops

Surprisingly, you can build an entire CPU with combinatorial circuits and only a few additional sequential circuits beyond these. For example, you can build a simple state machine known as a sequencer by combining a counter and a decoder as shown in Figure 3.30. For each cycle of the clock this sequencer activates one of its output lines. Those lines, in turn, may control other circuitry. By “firing” these circuits on each of the 16 output lines of the decoder, we can control the order in which these 16 different circuits accomplish their tasks. This is a fundamental need in a CPU since we often need to control the sequence of various operations (for example, it wouldn’t be a good thing if the “ADD(EAX, EBX);” instruction stored the result into EBX before fetching the source operand from EAX (or EBX). A simple sequencer such as this one can tell the CPU when to fetch the first operand, when to fetch the second operand, when to add them together, and when to store the result away. But we’re getting a little ahead of ourselves, we’ll discuss this in greater detail in the next chapter.

Figure 3.30 A Simple 16-State Sequencer

3.8 Okay, What Does It Have To Do With Programming, Then?

Once you have registers, counters, and shift registers, you can build *state machines*. The implementation of an algorithm in hardware using state machines is well beyond the scope of this text. However, one important point must be made with respect to such circuitry – *any algorithm you can implement in software you can also implement directly in hardware*. This suggests that boolean logic is the basis for computation on all modern computer systems. Any program you can write, you can specify as a sequence of boolean equations.

Of course, it is much easier to specify a solution to a programming problem using languages like Pascal, C, or even assembly language than it is to specify the solution using boolean equations. Therefore, it is unlikely that you would ever implement an entire program using a set of state machines and other logic circuitry. Nevertheless, there are times when a hardware implementation is better. A hardware solution can be one, two, three, or more *orders of magnitude* faster than an equivalent software solution. Therefore, some time critical operations may require a hardware solution.

A more interesting fact is that the converse of the above statement is also true. Not only can you implement all software functions in hardware, but it is also possible to *implement all hardware functions in software*. This is an important revelation because many operations you would normally implement in hardware are *much cheaper* to implement using software on a microprocessor. Indeed, this is a primary use of *assembly language* in modern systems – to inexpensively replace a complex electronic circuit. It is often possible to replace many tens or hundreds of dollars of electronic components with a single \$5 microcomputer chip. The whole field of *embedded systems* deals with this very problem. Embedded systems are computer systems embedded in other products. For example, most microwave ovens, TV sets, video games, CD players, and other consumer devices contain one or more complete computer systems whose sole purpose is to replace a complex hardware design. Engineers use computers for this purpose because they are *less expensive* and *easier to design with* than traditional electronic circuitry.

You can easily design software that reads switches (input variables) and turns on motors, LEDs or lights, locks or unlocks a door, etc. (output functions). To write such software, you will need an understanding of boolean functions and how to implement such functions in software.

Of course, there is one other reason for studying boolean functions, even if you never intend to write software intended for an embedded system or write software that manipulates real-world devices. Many high level languages process boolean expressions (e.g., those expressions that control an IF statement or WHILE loop). By applying transformations like DeMorgan's theorems or a mapping optimization it is often possible

to improve the performance of high level language code. Therefore, studying boolean functions *is* important even if you never intend to design an electronic circuit. It can help you write better code in a traditional programming language.

For example, suppose you have the following statement in Pascal:

```
if ((x=y) and (a <> b)) or ((x=y) and (c <= d)) then SomeStmt;
```

You can use the distributive law to simplify this to:

```
if ((x=y) and ((a <> b) or (c <= d))) then SomeStmt;
```

Likewise, we can use DeMorgan's theorem to reduce

```
while (not((a=b) and (c=d))) do Something;
```

to

```
while (a <> b) or (c <> d) do Something;
```

So as you can see, understanding a little boolean algebra can actually help you write better software.

3.9 Putting It All Together

A good understanding of boolean algebra and digital design is absolutely necessary for anyone who wants to understand the internal operation of a CPU. As an added bonus, programmers who understand digital design can write better assembly language (and high level language) programs. This chapter provides a basic introduction to boolean algebra and digital circuit design. Although a detailed knowledge of this material isn't necessary if you simply want to write assembly language programs, this knowledge will help explain why Intel chose to implement instructions in certain ways; questions that will undoubtedly arise as we begin to look at the low-level implementation of the CPU.

This chapter is not, by any means, a complete treatment of this subject. If you're interested in learning more about boolean algebra and digital circuit design, there are dozens and dozens of texts on this subject available. Since this is a text on assembly language programming, we cannot afford to spend additional time on this subject; please see one of these other texts for more information.

4.1 Chapter Overview

This chapter discusses history of the 80x86 CPU family and the major improvements occurring along the line. The historical background will help you better understand the design compromises they made as well as understand the legacy issues surrounding the CPU's design. This chapter also discusses the major advances in computer architecture that Intel employed while improving the x86¹.

4.2 The History of the 80x86 CPU Family

Intel developed and delivered the first commercially viable microprocessor way back in the early 1970's: the 4004 and 4040 devices. These four-bit microprocessors, intended for use in calculators, had very little power. Nevertheless, they demonstrated the future potential of the microprocessor – an entire CPU on a single piece of silicon². Intel rapidly followed their four-bit offerings with their 8008 and 8080 eight-bit CPUs. A small outfit in Santa Fe, New Mexico, incorporated the 8080 CPU into a box they called the Altair 8800. Although this was not the world's first "personal computer" (there were some limited distribution machines built around the 8008 prior to this), the Altair was the device that sparked the imaginations of hobbyists the world over and the personal computer revolution was born.

Intel soon had competition from Motorola, MOS Technology, and an upstart company formed by disgruntled Intel employees, Zilog. To compete, Intel produced the 8085 microprocessor. To the software engineer, the 8085 was essentially the same as the 8080. However, the 8085 had lots of hardware improvements that made it easier to design into a circuit. Unfortunately, from a software perspective the other manufacturer's offerings were better. Motorola's 6800 series was easier to program, MOS Technologies' 65xx family was easier to program and very inexpensive, and Zilog's Z80 chip was upwards compatible with the 8080 with lots of additional instructions and other features. By 1978 most personal computers were using the 6502 or Z80 chips, not the Intel offerings.

Sometime between 1976 and 1978 Intel decided that they needed to leap-frog the competition and produce a 16-bit microprocessor that offered substantially more power than their competitor's eight-bit offerings. This initiative led to the design of the 8086 microprocessor. The 8086 microprocessor was not the world's first (there were some oddball 16-bit microprocessors prior to this point) but it was certainly the highest performance single-chip 16-bit microprocessor when it was first introduced.

During the design timeframe of the 8086 memory was very expensive. Sixteen Kilobytes of RAM was selling above \$200 at the time. One problem with a 16-bit CPU is that programs tend to consume more memory than their counterparts on an eight-bit CPU. Intel, ever cogniscent of the fact that designers would reject their CPU if the total system cost was too high, made a special effort to design an instruction set that had a high memory density (that is, packed as many instructions into as little RAM as possible). Intel achieved their design goal and programs written for the 8086 were comparable in size to code running on eight-bit microprocessors. However, those design decisions still haunt us today as you'll soon see.

At the time Intel designed the 8086 CPU the average lifetime of a CPU was only a couple of years. Their experiences with the 4004, 4040, 8008, 8080, and 8085 taught them that designers would quickly ditch the old technology in favor of the new technology as long as the new stuff was radically better. So Intel designed the 8086 assuming that whatever compromises they made in order to achieve a high instruction density would be fixed in newer chips. Based on their experience, this was a reasonable assumption.

Intel's competitors were not standing still. Zilog created their own 16-bit processor that they called the Z8000, Motorola created the 68000, their own 16-bit processor, and National Semiconductor introduced the

1. Note that Intel wasn't the inventor of most of these new technological advances. They simply duplicated research long since commercially employed by mainframe designers.

2. Prior to this point, commercial computer systems used multiple semiconductor devices to implement the CPU.

16032 device (later to be renamed the 32016). The designers of these chips had different design goals than Intel. Primarily, they were more interested in providing a reasonable instruction set for programmers even if their code density wasn't anywhere near as high as the 8086. The Motorola and National offers even provided 32-bit integer registers, making programming the chips even easier. All in all, these chips were much better (from a software development standpoint) than the Intel chip.

Intel wasn't resting on its laurels with the 8086. Immediately after the release of the 8086 they created an eight-bit version, the 8088. The purpose of this chip was to reduce system cost (since a minimal system could get by with half the memory chips and cheaper peripherals since the 8088 had an eight-bit data bus). In the very early 1980's, Intel also began work on their intended successor to the 8086 – the iAPX432 CPU. Intel fully expected the 8086 and 8088 to die away and that system designers who were creating general purpose computer systems would choose the '432 chip instead.

Then a major event occurred that would forever change history: in 1980 a small group at IBM got the go-ahead to create a "personal computer" along the likes of the Apple II and TRS-80 computers (the most popular PCs at the time). IBM's engineers probably evaluated lots of different CPUs and system designs. Ultimately, they settled on the 8088 chip. Most likely they chose this chip because they could create a minimal system with only 16 Kilobytes of RAM and a set of cheap eight-bit peripheral devices. So Intel's design goals of creating CPUs that worked well in low-cost systems landed them a very big "design win" from IBM.

Intel was still hard at work on the (ill-fated) iAPX432 project, but a funny thing happened – IBM PCs started selling far better than anyone had ever dreamed. As the popularity of the IBM PCs increased (and as people began "cloning" the PC), lots of software developers began writing software for the 8088 (and 8086) CPU, mostly in assembly language. In the meantime, Intel was pushing their iAPX432 with the Ada programming language (which was supposed to be the next big thing after Pascal, a popular language at the time). Unfortunately for Intel, no one was interested in the '432. Their PC software, written mostly in assembly language wouldn't run on the '432 and the '432 was notoriously slow. It took a while, but the iAPX432 project eventually died off completely and remains a black spot on Intel's record to this day.

Intel wasn't sitting pretty on the 8086 and 8088 CPUs, however. In the late 1970's and early 1980's they developed the 80186 and 80188 CPUs. These CPUs, unlike their previous CPU offerings, were fully upwards compatible with the 8086 and 8088 CPUs. In the past, whenever Intel produced a new CPU it did not necessarily run the programs written for the previous processors. For example, the 8086 did not run 8080 software and the 8080 did not run 4040 software. Intel, recognizing that there was a tremendous investment in 8086 software, decided to create an upgrade to the 8086 that was superior (both in terms of hardware capability and with respect to the software it would execute). Although the 80186 did not find its way into many PCs, it was a very popular chip in embedded applications (i.e., non-computer devices that use a CPU to control their functions). Indeed, variants of the 80186 are in common use even today.

The unexpected popularity of the IBM PC created a problem for Intel. This popularity obliterated the assumption that designers would be willing to switch to a better chip when such a chip arrived, even if it meant rewriting their software. Unfortunately, IBM and tens of thousands of software developers weren't willing to do this to make life easy for Intel. They wanted to stick with the 8086 software they'd written but they also wanted something a little better than the 8086. If they were going to be forced into jumping ship to a new CPU, the Motorola, Zilog, and National offerings were starting to look pretty good. So Intel did something that saved their bacon and has infuriated computer architects ever since: they started creating upwards compatible CPUs that continued to execute programs written for previous members of their growing CPU family while adding new features.

As noted earlier, memory was very expensive when Intel first designed the 8086 CPU. At that time, computer systems with a megabyte of memory usually cost megabucks. Intel was expecting a typical computer system employing the 8086 to have somewhere between 4 Kilobytes and 64 Kilobytes of memory. So when they designed in a one megabyte limitation, they figured no one would ever install that much memory in a system. Of course, by 1983 people were still using 8086 and 8088 CPUs in their systems and memory prices had dropped to the point where it was very common to install 640 Kilobytes of memory on a PC (the IBM PC design effectively limited the amount of RAM to 640 Kilobytes even though the 8086 was capable of addressing one megabyte). By this time software developers were starting to write more sophisticated programs and users were starting to use these programs in more sophisticated ways. The bottom line was that everyone was bumping up against the one megabyte limit of the 8086. Despite the investment in exist-

ing software, Intel was about to lose their cash cow if they didn't do something about the memory addressing limitations of their 8086 family (the 68000 and 32016 CPUs could address up to 16 Megabytes at the time and many system designers [e.g., Apple] were defecting to these other chips). So Intel introduced the 80286 which was a big improvement over the previous CPUs. The 80286 added lots of new instructions to make programming a whole lot easier and they added a new "protected" mode of operation that allowed access to as much as 16 megabytes of memory. They also improved the internal operation of the CPU and bumped up the clock frequency so that the 80286 ran about 10 times faster than the 8088 in IBM PC systems.

IBM introduced the 80286 in their IBM PC/AT (AT = "advanced technology"). This change proved enormously popular. PC/AT clones based on the 80286 started appearing everywhere and Intel's financial future was assured.

Realizing that the 80x86 (x = "", "1", or "2") family was a big money maker, Intel immediately began the process of designing new chips that continued to execute the old code while improving performance and adding new features. Intel was still playing catch-up with their competitors in the CPU arena with respect to features, but they were definitely the king of the hill with respect to CPUs installed in PCs. One significant difference between Intel's chips and many of their competitors was that their competitors (notably Motorola and National) had a 32-bit internal architecture while the 80x86 family was stuck at 16-bits. Again, concerned that people would eventually switch to the 32-bit devices their competitors offered, Intel upgraded the 80x86 family to 32 bits by adding the 80386 to the product line.

The 80386 was truly a remarkable chip. It maintained almost complete compatibility with the previous 16-bit CPUs while fixing most of the real complaints people had with those older chips. In addition to supporting 32-bit computing, the 80386 also bumped up the maximum addressability to four gigabytes as well as solving some problems with the "segmented" organization of the previous chips (a big complaint by software developers at the time). The 80386 also represented the most radical change to ever occur in the 80x86 family. Intel more than doubled the total number of instructions, added new memory management facilities, added hardware debugging support for software, and introduced many other features. Continuing the trend they set with the 80286, the 80386 executed instructions faster than previous generation chips, even when running at the same clock speed plus the new chip ran at a higher clock speed than the previous generation chips. Therefore, it ran existing 8088 and 80286 programs faster than on these older chips. Unfortunately, while people adopted the new chip for its higher performance, they didn't write new software to take advantage of the chip's new features. But more on that in a moment.

Although the 80386 represented the most radical change in the 80x86 architecture from the programmer's view, Intel wasn't done wringing all the performance out of the x86 family. By the time the 80386 appeared, computer architects were making a big noise about the so-called RISC (Reduced Instruction Set Computer) CPUs. While there were several advantages to these new RISC chips, a important advantage of these chips is that they purported to execute one instruction every clock cycle. The 80386 instructions required a wildly varying number of cycles to execute ranging from a few cycles per instruction to well over a hundred. Although comparing RISC processors directly with the 80386 was dangerous (because many 80386 instructions actually did the work of two or more RISC instructions), there was a general perception that, at the same clock speed, the 80386 was slower since it executed fewer instructions in a given amount of time.

The 80486 CPU introduced two major advances in the x86 design. First, the 80486 integrated the floating point unit (or FPU) directly onto the CPU die. Prior to this point Intel supplied a separate, external, chip to provide floating point calculations (these were the 8087, 80287, and 80387 devices). By incorporating the FPU with the CPU, Intel was able to speed up floating point operations and provide this capability at a lower cost (at least on systems that required floating point arithmetic). The second major architectural advance was the use of *pipelined instruction execution*. This feature (which we will discuss in detail a little later in this chapter) allowed Intel to overlap the execution of two or more instructions. The end result of pipelining is that they effectively reduced the number of cycles each instruction required for execution. With pipelining, many of the simpler instructions had an aggregate throughput of one instruction per clock cycle (under ideal conditions) so the 80486 was able to compete with RISC chips in terms of clocks per instruction cycle.

While Intel was busy adding pipelining to their x86 family, the companies building RISC CPUs weren't standing still. To create ever faster and faster CPU offerings, RISC designers began creating *superscalar* CPUs that could actually execute more than one instruction per clock cycle. Once again, Intel's CPUs were perceived as following the leaders in terms of CPU performance. Another problem with Intel's CPU is that

the integrated FPU, though faster than the earlier models, was significantly slower than the FPUs on the RISC chips. As a result, those designing high-end engineering workstations (that typically require good floating point hardware support) began using the RISC chips because they were faster than Intel's offerings.

From the programmer's perspective, there was very little difference between an 80386 with an 80387 FPU and an 80486 CPU. There were only a handful of new instructions (most of which had very little utility in standard applications) and not much in the way of other architectural features that software could use. The 80486, from the software engineer's point of view, was just a really fast 80386/80387 combination.

So Intel went back to their CAD³ tools and began work on their next CPU. This new CPU featured a superscalar design with vastly improved floating point performance. Finally, Intel was closing in on the performance of the RISC chips. Like the 80486 before it, this new CPU added only a small number of new instructions and most of those were intended for use by operating systems, not application software.

Intel did not designate this new chip the 80586. Instead, they called it the *Pentium™ Processor*⁴. The reason they discontinued referring to processors by number and started naming them was because of confusion in the marketplace. Intel was not the only company producing x86 compatible CPUs. AMD, Cyrix, and a host of others were also building and selling these chips in direct competition with Intel. Until the 80486 came along, the internal design of the CPUs were relatively simple and even small companies could faithfully reproduce the functionality of Intel's CPUs. The 80486 was a different story altogether. This chip was quite complex and taxed the design capabilities of the smaller companies. Some companies, like AMD, actually licensed Intel's design and they were able to produce chips that were compatible with Intel's (since they were, effectively, Intel's chips). Other companies attempted to create their own version of the 80486 and fell short of the goal. Perhaps they didn't integrate an FPU or the new instructions on the 80486. Many didn't support pipelining. Some chips lacked other features found on the 80486. In fact, most of the (non-Intel) chips were really 80386 devices with some very slight improvements. Nevertheless, they called these chips 80486 CPUs.

This created massive confusion in the marketplace. Prior to this, if you'd purchased a computer with an 80386 chip you knew the capabilities of the CPU. All 80386 chips were equivalent. However, when the 80486 came along and you purchased a computer system with an 80486, you didn't know if you were getting an actual 80486 or a remarked 80386 CPU. To counter this, Intel began their enormously successful "Intel Inside" campaign to let people know that there was a difference between Intel CPUs and CPUs from other vendors. This marketing campaign was so successful that people began specifying Intel CPUs even though some other vendor's chips (i.e., AMD) were completely compatible.

Not wanting to repeat this problem with the 80586 generation, Intel ditched the numeric designation of their chips. They created the term "Pentium Processor" to describe their new CPU so they could trademark the name and prevent other manufacturers from using the same designation for their chip. Initially, of course, savvy computer users griped about Intel's strong-arm tactics but the average user benefited quite a bit from Intel's marketing strategy. Other manufacturers release their own 80586 chips (some even used the "586" designation), but they couldn't use the Pentium Processor name on their parts so when someone purchased a system with a Pentium in it, they knew it was going to have all the capabilities of Intel's chip since it had to be Intel's chip. This was a good thing because most of the other '586 class chips that people produced at that time were not as powerful as the Pentium.

The Pentium cemented Intel's position as champ of the personal computer. It had near RISC performance and ran tons of existing software. Only the Apple Macintosh and high-end UNIX workstations and servers went the RISC route. Together, these other machines comprised less than 10% of the total desktop computer market.

Intel still was not satisfied. They wanted to control the server market as well. So they developed the Pentium Pro CPU. The Pentium Pro had a couple of features that made it ideal for servers. Intel improved the 32-bit performance of the CPU (at the expense of its 16-bit performance), they added better support for multiprocessing to allow multiple CPUs in a system (high-end servers usually have two or more processors), and they added a handful of new instructions to improve the performance of certain instruction sequences on the pipelined architecture. Unfortunately, most application software written at the time of the Pentium Pro's

release was 16-bit software which actually ran slower on the Pentium Pro than it did on a Pentium at equivalent clock frequencies. So although the Pentium Pro did wind up in a few server machines, it was never as popular as the other chips in the Intel line.

The Pentium Pro had another big strike against it: shortly after the introduction of the Pentium Pro, Intel's engineers introduced an upgrade to the standard Pentium chip, the MMX (multimedia extension) instruction set. These new instructions (nearly 60 in all) gave the Pentium additional power to handle computer video and audio applications. These extensions became popular overnight, putting the last nail in the Pentium Pro's coffin. The Pentium Pro was slower than the standard Pentium chip and slower than high-end RISC chips, so it didn't see much use.

Intel corrected the 16-bit performance in the Pentium Pro, added the MMX extensions and called the result the Pentium II⁵. The Pentium II demonstrated an interesting point. Computers had reached a point where they were powerful enough for most people's everyday activities. Prior to the introduction of the Pentium II, Intel (and most industry pundits) had assumed that people would always want more power out of their computer systems. Even if they didn't need the machines to run faster, surely the software developers would write larger (and slower) systems requiring more and more CPU power. The Pentium II proved this idea wrong. The average user needed email, word processing, Internet access, multimedia support, simple graphics editing capabilities, and a spreadsheet now and then. Most of these applications, at least as home users employed them, were fast enough on existing CPUs. The applications that were slow (e.g., Internet access) were generally beyond the control of the CPU (i.e., the modem was the bottleneck not the CPU). As a result, when Intel introduced their pricey Pentium II CPUs, they discovered that system manufacturers started buying other people's x86 chips because they were far less expensive and quite suitable for their customer's applications. This nearly stunned Intel since it contradicted their experience up to that point.

Realizing that the competition was capturing the low-end market and stealing sales away, Intel devised a low-cost (lower performance) version of the Pentium II that they named *Celeron*⁶. The initial Celerons consisted of a Pentium II CPU without the on-board level two cache. Without the cache, the chip ran only a little bit better than half the speed of the Pentium II part. Nevertheless, the performance was comparable to other low-cost parts so Intel's fortunes improved once more.

While designing the low-end Celeron, Intel had not lost sight of the fact that they wanted to capture a chunk of the high-end workstation and server market as well. So they created a third version of the Pentium II, the Xeon Processor with improved cache and the capability of multiprocessor more than two CPUs. The Pentium II supports a two CPU multiprocessor system but it isn't easy to expand it beyond this number; the Xeon processor corrected this limitation. With the introduction of the Xeon processor (plus special versions of Unix and Windows NT), Intel finally started to make some serious inroads into the server and high-end workstation markets.

You can probably imagine what followed the Pentium II. Yep, the Pentium III. The Pentium III introduced the SIMD (pronounced SIM-DEE) extensions to the instruction set. These new instructions provided high performance floating point operations for certain types of computations that allow the Pentium III to compete with high-end RISC CPUs. The Pentium III also introduced another handful of integer instructions to aid certain applications.

With the introduction of the Pentium III, nearly all serious claims about RISC chips offering better performance were fading away. In fact, for most applications, the Intel chips were actually faster than the RISC chips available at the time. As this is being written, Intel was just introducing the Pentium IV chip and was slating it to run at 1.4 GHz, a much higher clock frequency than its RISC contemporaries. One would think that Intel would soon own it all. Surely by the time of the Pentium V, the RISC competition wouldn't be a factor anymore.

There is one problem with this theory: even Intel is admitting that they've pushed the x86 architecture about as far as they can. For nearly 20 years, computer architects have blasted Intel's architecture as being gross and bloated having to support code written for the 8086 processor way back in 1978. Indeed, Intel's design decisions (like high instruction density) that seemed so important in 1978 are holding back the CPU today. So-called "clean" designs, that don't have to support legacy applications, allow CPU designers to cre-

5. Interestingly enough, by the time the Pentium II appeared, the 16-bit efficiency was no longer a factor since most software was written as 32-bit code.

6. The term "Celeron Processor" is also an Intel trademark.

ate high-performance CPUs with far less effort than Intel's. Worse, those decisions Intel made in the 1976-1978 time frame are beginning to catch up with them and will eventually stall further development of the CPU. Computer architects have been warning everyone about this problem for twenty years; it is a testament to Intel's design effort (and willingness to put money into R&D) that they've taken the CPU as far as they have.

The biggest problem on the horizon is that most RISC manufacturers are now extending their architectures to 64-bits. This has two important impacts on computer systems. First, arithmetic calculations will be somewhat faster as will many internal operations and second, the CPUs will be able to directly address more than four gigabytes of main memory. This last factor is probably the most important for server and workstation systems. Already, high-end servers have more than four gigabytes installed. In the future, the ability to address more than four gigabytes of physical RAM will become essential for servers and high-end workstations. As the price of a gigabyte or more of memory drops below \$100, you'll see low-end personal computers with more than four gigabytes installed. To effectively handle this kind of memory, Intel will need a 64-bit processor to compete with the RISC chips.

Perhaps Intel has seen the light and decided it's time to give up on the x86 architecture. Towards the middle to end of the 1990's Intel announced that they were going to create a partnership with Hewlett-Packard to create a new 64-bit processor based around HP's PA-RISC architecture. This new 64-bit chip would execute x86 code in a special "emulation" mode and run native 64-bit code using a new instruction set. It's too early to tell if Intel will be successful with this strategy, but there are some major risks (pardon the pun) with this approach. The first such CPUs (just becoming available as this is being written) run 32-bit code far slower than the Pentium III and IV chips. Not only does the emulation of the x86 instruction set slow things down, but the clock speeds of the early CPUs are half the speed of the Pentium IVs. This is roughly the same situation Intel had with the Pentium Pro running 16-bit code slower than the Pentium. Second, the 64-bit CPUs (the IA64 family) rely heavily on compiler technology and are using a commercially untested architecture. This is similar to the situation with the iAPX432 project that failed quite miserably. Hopefully Intel knows what they're doing and ten years from now we'll all be using IA64 processors and wondering why anyone ever stuck with the IA32. On the other hand, hopefully Intel has a back-up plan in case the IA64 initiative fails.

Intel is betting that people will move to the IA64 when they need 64-bit computing capabilities. AMD, on the other hand, is betting that people would rather have a 64-bit x86 processor. Although the details are sketchy, AMD has announced that they will extend the x86 architecture to 64 bits in much the same way that Intel extend the 8086 and 80286 to 32-bits with the introduction of the the 80386 microprocessor. Only time will tell if Intel or AMD (or both) are successful with their visions.

b. Maximum clock frequency at introduction was very limited sampling. Usually, the chips were available at the next lower clock frequency in Intel's scale. Also note that by the introduction of the next generation this value was usually much higher.

c. Shortly after the introduction of the 25MHz 80486, Intel began using "Clock doubling" techniques to run the CPU twice as fast internally as the external clock. Hence, a 50 MHz 80486 DX2 chip was really running at 25 MHz externally and 50 MHz internally. Most chips after the 80486 employ a different internal clock frequency compared to the external (or "bus") frequency.

4.3 A History of Software Development for the x86

A section on the history of software development may seem unusual in a chapter on CPU Architecture. However, the 80x86's architecture is inexorably tied to the development of the software for this platform. Many architectural design decisions were a direct result of ensuring compatibility with existing software. So to fully understand the architecture, you must know a little bit about the history of the software that runs on the chip.

From the date of the very first working sample of the 8086 microprocessor to the latest and greatest IA-64 CPU, Intel has had an important goal: as much as possible, ensure compatibility with software written for previous generations of the processor. This mantra existed even on the first 8086, before there was a previous generation of the family. For the very first member of the family, Intel chose to include a modicum of compatibility with their previous eight-bit microprocessor, the 8085. The 8086 was not capable of running 8085 software, but Intel designed the 8086 instruction set to provide almost a one for one mapping of 8085 instructions to 8086 instructions. This allowed 8085 software developers to easily translate their existing assembly language programs to the 8086 with very little effort (in fact, software translators were available that did about 85% of the work for these developers).

Intel did not provide *object code compatibility*⁷ with the 8085 instruction set because the design of the 8085 instruction set did not allow the expansion Intel needed for the 8086. Since there was very little software running on the 8085 that needed to run on the 8086, Intel felt that making the software developers responsible for this translation was a reasonable thing to do.

When Intel introduced the 8086 in 1978, the majority of the world's 8085 (and Z80) software was written in Microsoft's BASIC running under Digital Research's CP/M operating system. Therefore, to "port" the majority of business software (such that it existed at the time) to the 8086 really only required two things: porting the CP/M operating system (which was less than eight kilobytes long) and Microsoft's BASIC (most versions were around 16 kilobytes at the time). Porting such small programs may have seemed like a bit of work to developers of that era, but such porting is trivial compared with the situation that exists today. Anyway, as Intel expected, both Microsoft and Digital Research ported their products to the 8086 in short

7. That is, the ability to run 8085 machine code directly.

order so it was possible for a large percentage of the 8085 software to run on 8086 within about a year of the 8086's introduction.

Unfortunately, there was no great rush by computer hobbyists (the computer users of that era) to switch to the 8086. About this time the Radio Shack TRS-80 and the Apple II microcomputer systems were battling for supremacy of the home computer market and no one was really making computer systems utilizing the 8086 that appealed to the mass market. Intel wasn't doing poorly with the 8086; its market share, when you compared it with the other microprocessors, was probably better than most. However, the situation certainly wasn't like it is today (circa 2001) where the 80x86 CPU family owns 85% of the general purpose computer market.

The 8086 CPU, and its smaller sibling, the eight-bit 8088, was happily raking in its portion of the microprocessor market and Intel naturally assumed that it was time to start working on a 32-bit processor to replace the 8086 in much the same way that the 8086 replaced the eight-bit 8085. As noted earlier, this new processor was the ill-fated iAPX 432 system. The iAPX 432 was such a dismal failure that Intel might not have survived had it not been for a big stroke of luck – IBM decided to use the 8088 microprocessor in their personal computer system.

To most computer historians, there were two watershed events in the history of the personal computer. The first was the introduction of the Visicalc spreadsheet program on the Apple II personal computer system. This single program demonstrated that there was a real reason for owning a computer beyond the nerdy "gee, I've got my own computer" excuse. Visicalc quickly (and, alas, briefly) made Apple Computer the largest PC company around. The second big event in the history of personal computers was, of course, the introduction of the IBM PC. The fact that IBM, a "real" computer company, would begin building PCs legitimized the market. Up to that point, businesses tended to ignore PCs and treated them as toys that nerdy engineers liked to play with. The introduction of the IBM PC caused a lot of businesses to take notice of these new devices. Not only did they take notice, but they liked what they saw. Although IBM cannot make the claim that they started the PC revolution, they certainly can take credit for giving it a big jumpstart early on in its life.

Once people began buying lots of PCs, it was only natural that people would start writing and selling software for these machines. The introduction of the IBM PC greatly expanded the marketplace for computer systems. Keep in mind that at the time of the IBM PC's introduction, most computer systems had only sold tens of thousands of units. The more popular models, like the TRS-80 and Apple II had only sold hundreds of thousands of units. Indeed, it wasn't until a couple of years after the introduction of the IBM PC that the first computer system sold one million units; and that was a Commodore 64 system, not the IBM PC.

For a brief period, the introduction of the IBM PC was a godsend to most of the other computer manufacturers. The original IBM PC was underpowered and quite a bit more expensive than its counterparts. For example, a dual-floppy disk drive PC with 64 Kilobytes of memory and a monochrome display sold for \$3,000. A comparable Apple II system with a color display sold for under \$2,000. The original IBM PC with its 4.77 MHz 8088 processor (that's four-point-seven-seven, not four hundred seventy-seven!) was only about two to three times as fast as the Apple II with its paltry 1 MHz eight-bit 6502 processor. The fact that most Apple II software was written by expert assembly language programmers while most (early) IBM software was written in a high level language (often interpreted) or by inexperienced 8086 assembly language programmers narrowed the gap even more.

Nonetheless, software development on PCs accelerated. The wide range of different (and incompatible) systems made software development somewhat risky. Those who did not have an emotional attachment to one particular company (and didn't have the resources to develop for more than one platform) generally decided to go with IBM's PC when developing their software.

One problem with the 8086's architecture was beginning to show through by 1983 (remember, this is five years after Intel introduced the 8086). The *segmented memory architecture* that allowed them to extend their 16-bit addressing scheme to 20 bits (allowing the 8086 to address a megabyte of memory) was being attacked on two fronts. First, this segmented addressing scheme was difficult to use in a program, especially if a program needed to access more than 64 kilobytes of data or, worse yet, needed to access a single data structure that was larger than 64K long. By 1983 software had reached the level of sophistication that most programs were using this much memory and many needed large data structures. The software community as a whole began to grumble and complain about this segmented memory architecture and what a stupid thing it was.

The second problem with Intel's segmented architecture is that it only supported a maximum of a one megabyte address space. Worse, the design of the IBM PC effectively limited the amount of RAM the system could have to 640 kilobytes. This limitation was also beginning to create problems for more sophisticated programs running on the PC. Once again, the software development community grumbled and complained about Intel's segmented architecture and the limitations it imposed upon their software.

About the time people began complaining about Intel's architecture, Intel began running an ad campaign bragging about how great their chip was. They quoted top executives at companies like Visicorp (the outfit selling Visicalc) who claimed that the segmented architecture was great. They also made a big deal about the fact that over a billion dollars worth of software had been written for their chip. This was all marketing hype, of course. Their chip was not particularly special. Indeed, the 8086's contemporaries (Z8000, 68000, and 16032) were architecturally superior. However, Intel was quite right about one thing – people had written a lot of software for the 8086 and most of the really good stuff was written in 8086 assembly language and could not be easily ported to the other processors. Worse, the software that people were writing for the 8086 was starting to get large; making it even more difficult to port it to the other chips. As a result, software developers were becoming locked into using the 8086 CPU.

About this time Intel undoubtedly realized that they were getting locked into the 80x86 architecture, as well. The iAPX 432 project was on its death bed. People were no more interested in the iAPX 432 than they were the other processors (in fact, they were less interested). So Intel decided to do the only reasonable thing – extend the 8086 family so they could continue to make more money off their cash cow.

The first real extension to the 8086 family that found its way into general purpose PCs was the 80286 that appeared in 1982. This CPU answered the second complaint by adding the ability to address up to 16 MBytes of RAM (a formidable amount in 1982). Unfortunately, it did not extend the segment size beyond 64 kilobytes. In 1985 Intel introduced the 80386 microprocessor. This chip answered most of the complaints about the x86 family, and then some, but people still complained about these problems for nearly ten years after the introduction of the 80386.

Intel was suffering at the hands of Microsoft and the installed base of existing PCs. When IBM introduced the floppy disk drive for the IBM PC they didn't choose an operating system to ship with it. Instead, they offered their customers a choice of the widely available operating systems at the time. Of course, Digital Research had ported CP/M to the PC, UCSD/Softech had ported UCSD Pascal (a very popular language/operating system at the time) to the PC, and Microsoft had quickly purchased a CP/M knock-off named QD DOS (for Quick and Dirty DOS) from Seattle Microsystems, relabelled it "MS-DOS", and offered this as well. CP/M-86 cost somewhere in the vicinity of \$595. UCSD Pascal was selling for something like \$795. MS-DOS was selling for \$50. Guess which one sold more copies! Within a year, almost no one ran CP/M or UCSD Pascal on PCs. Microsoft and MS-DOS (also called IBM DOS) ruled the PC.

MS-DOS v1.0 lived up to its "quick and dirty" heritage. Working furiously, Microsoft's engineers added lots of new features (many taken from the UNIX operating system and shell program) and MS-DOS v2.0 appeared shortly thereafter. Although still crude, MS-DOS v2.0 was a substantial improvement and people started writing tons of software for it.

Unfortunately, MS-DOS, even in its final version, wasn't the best operating system design. In particular, it left all but rudimentary control of the hardware to the application programmer. It provided a file system so application writers didn't have to deal with the disk drive and it provided mediocre support for keyboard input and character display. It provided nearly useless support for other devices. As a result, most application programmers (and most high level languages) bypassed MS-DOS' device control and used MS-DOS primarily as a file system module.

In addition to poor device management, MS-DOS provided nearly non-existent memory management. For all intents and purposes, once MS-DOS started a program running, it was that program's responsibility to manage the system's resources. Not only did this create extra work for application programmers, but it was one of the main reasons most software could not take advantage of the new features Intel was adding to their microprocessors.

When Intel introduced the 80286 and, later, the 80386, the only way to take advantage of their extra addressing capabilities and the larger segments of the 80386 was to operate in a so-called *protected mode*. Unfortunately, neither MS-DOS nor most applications (that managed memory themselves) were capable of operating in protected mode without substantial change (actually, it would have been easy to modify

MS-DOS to use protected mode, but it would have broken all the existing software that ran under MS-DOS; Microsoft, like Intel, couldn't afford to alienate the software developers in this manner).

Even if Microsoft could magically make MS-DOS run under protected mode, they couldn't afford to do so. When Intel introduced the 80386 microprocessor it was a very expensive device (the chip itself cost over \$1,000 at initial introduction). Although the 80286 had been out for three years, systems built around the 8088 were still extremely popular (since they were much lower cost than systems using the 80386). Software developers had a choice: they could solve their memory addressing problems and use the new features of the 80386 chip but limit their market to the few who had 80386 systems, or they could continue to suffer with the 64K segment limitation imposed by the 8088 and MS-DOS and be able to sell their software to millions of users who owned one of the earlier machines. The marketing departments of these companies ruled the day, all software was written to run on plain 8088 boxes so that it had a larger market. It wasn't until 1995, when Microsoft introduced Windows 95 that people finally felt they could abandon processors earlier than the 80386. The end result was the people were still complaining about the Intel architecture and its 64K segment limitation ten years after Intel had corrected the problem. The concept of upwards compatibility was clearly a double-edged sword in this case.

Segmentation had developed such a bad name over the years that Microsoft abandoned the use of segments in their 32-bit versions of Windows (95, 98, NT, 2000, ME, etc.). In a couple of respects, this was a real shame because Intel finally did segmentation right (or, at least, pretty good) in the 80386 and later processors. By not allowing the use of segmentation in Win32 programs Microsoft limited the use of this powerful feature. They also limited their users to a maximum address space of 4GB (the Pentium Pro and later processors were capable of addressing 64GB of physical memory). Considering that many applications are starting to push the 4GB barrier, this limitation on Microsoft's part was ill-considered. Nevertheless, the "flat" memory model that Microsoft employs is easier to write software for, undoubtedly a big part of their decision not to use segmentation.

The introduction of Windows NT, that actually ran on CPUs other than Intel's, must have given Intel a major scare. Fortunately for Intel, NT was an abysmal failure on non-Intel architectures like the Alpha and the PowerPC. On the other hand, the new Windows architecture does make it easier to move existing applications to 64-bit processors like the IA-64; so maybe WinNT's flexibility will work to Intel's advantage after all.

The 8086 software legacy has both advanced and retarded the 80x86 architecture. On the one hand, had software developers not written so much software for the 80x86, Intel would have abandoned the family in favor of something better a long time ago (not an altogether bad thing, in many people's opinions). On the other hand, however, the general acceptance of the 80386 and later processors was greatly delayed by the fact that software developers were writing software for the installed base of processors.

Around 1996, two types of software actually accelerated the design and acceptance of Intel's newer processors: multimedia software and games. When Intel introduced the MMX extensions to the 80x86 instruction set, software developers ignored the installed base and immediately began writing software to take advantage of these new instructions. This change of heart took place because the MMX instructions allowed developers to do things they hadn't been able to do before - not simply run faster, but run fast enough to display actual video and quick render 3D images. Combined with a change in pricing policy by Intel on new processor technology, the public quickly accepted these new systems.

Hard-core gamers, multimedia artists, and others quickly grabbed new machines and software as it became available. More often than not, each new generation of software would only run on the latest hardware, forcing these individuals to upgrade their equipment far more rapidly than ever before.

Intel, sensing an opportunity here, began developing CPUs with additional instruction targeted at specific applications. For example, the Pentium III introduced the SIMD (pronounced SIM-DEE) instructions that did for floating point calculations what the MMX instructions did for integer applications. Intel also hired lots of software engineers and began funding research into topic areas like speech recognition and (visual) pattern recognition in order to drive the new technologies that would require the new instructions their Pentium IV and later processors would offer. As this is being written, Intel is busy developing new uses for their specialized instructions so that system designers and software developers continue to use the 80x86 (and, perhaps, IA-64) family chips.

However, this discussion of fancy instruction sets is getting way ahead of the game. Let's take a long step back to the original 8086 chip and take a look at how system designers put a CPU together.

4.4 Basic CPU Design

A fair question to ask at this point is “How exactly does a CPU perform assigned chores?” This is accomplished by giving the CPU a fixed set of commands, or instructions, to work on. Keep in mind that CPU designers construct these processors using logic gates to execute these instructions. To keep the number of logic gates to a reasonably small set CPU designers must necessarily restrict the number and complexity of the commands the CPU recognizes. This small set of commands is the CPU’s instruction set.

Programs in early (pre-Von Neumann) computer systems were often “hard-wired” into the circuitry. That is, the computer’s wiring determined what problem the computer would solve. One had to rewire the circuitry in order to change the program. A very difficult task. The next advance in computer design was the programmable computer system, one that allowed a computer programmer to easily “rewire” the computer system using a sequence of sockets and plug wires. A computer program consisted of a set of rows of holes (sockets), each row representing one operation during the execution of the program. The programmer could select one of several instructions by plugging a wire into the particular socket for the desired instruction (see Figure 4.1).

Figure 4.1 Patch Panel Programming

Of course, a major difficulty with this scheme is that the number of possible instructions is severely limited by the number of sockets one could physically place on each row. However, CPU designers quickly discovered that with a small amount of additional logic circuitry, they could reduce the number of sockets required from n holes for n instructions to $\log_2(n)$ holes for n instructions. They did this by assigning a numeric code to each instruction and then encode that instruction as a binary number using $\log_2(n)$ holes (see Figure 4.2).

Figure 4.2 Encoding Instructions

This addition requires eight logic functions to decode the A, B, and C bits from the patch panel, but the extra circuitry is well worth the cost because it reduces the number of sockets that must be repeated for each instruction (this circuitry, by the way, is nothing more than a single three-line to eight-line decoder).

Of course, many CPU instructions are not stand-alone. For example, the move instruction is a command that moves data from one location in the computer to another (e.g., from one register to another). Therefore, the move instruction requires two operands: a source operand and a destination operand. The CPU's designer usually encodes these source and destination operands as part of the machine instruction, certain sockets correspond to the source operand and certain sockets correspond to the destination operand. Figure 4.3 shows one possible combination of sockets to handle this. The move instruction would move data from the source register to the destination register, the add instruction would add the value of the source register to the destination register, etc.

Figure 4.3 Encoding Instructions with Source and Destination Fields

One of the primary advances in computer design that the VNA provides is the concept of a stored program. One big problem with the patch panel programming method is that the number of program steps (machine instructions) is limited by the number of rows of sockets available on the machine. John Von Neumann and others recognized a relationship between the sockets on the patch panel and bits in memory; they figured they could store the binary equivalents of a machine program in main memory and fetch each program from memory, load it into a special decoding register that connected directly to the instruction decoding circuitry of the CPU.

The trick, of course, was to add yet more circuitry to the CPU. This circuitry, the control unit (CU), fetches instruction codes (also known as operation codes or opcodes) from memory and moves them to the instruction decoding register. The control unit contains a special register, the instruction pointer that contains the address of an executable instruction. The control unit fetches this instruction's opcode from memory and places it in the decoding register for execution. After executing the instruction, the control unit increments the instruction pointer and fetches the next instruction from memory for execution, and so on.

When designing an instruction set, the CPU's designers generally choose opcodes that are a multiple of eight bits long so the CPU can easily fetch complete instructions from memory. The goal of the CPU's designer is to assign an appropriate number of bits to the instruction class field (move, add, subtract, etc.) and to the operand fields. Choosing more bits for the instruction field lets you have more instructions, choosing additional bits for the operand fields lets you select a larger number of operands (e.g., memory locations or registers). There are additional complications. Some instructions have only one operand or, perhaps, they don't have any operands at all. Rather than waste the bits associated with these fields, the CPU designers

often reuse these fields to encode additional opcodes, once again with some additional circuitry. The Intel 80x86 CPU family takes this to an extreme with instructions ranging from one to almost 15 bytes long⁸.

4.5 Decoding and Executing Instructions: Random Logic Versus Microcode

Once the control unit fetches an instruction from memory, you may wonder "exactly how does the CPU execute this instruction?" In traditional CPU design there have been two common approaches: hardwired logic and emulation. The 80x86 family uses both of these techniques.

A hardwired, or *random logic*⁹, approach uses decoders, latches, counters, and other logic devices to move data around and operate on that data. The microcode approach uses a very fast but simple internal processor that uses the CPU's opcodes as an index into a table of operations (the *microcode*) and executes a sequence of *microinstructions* that do the work of the *macroinstruction* (i.e., the CPU instruction) they are emulating.

The random logic approach has the advantage that it is possible to devise faster CPUs if typical CPU speeds are faster than typical memory speeds (a situation that has been true for quite some time). The drawback to random logic is that it is difficult to design CPUs with large and complex instruction sets using a random logic approach. The logic to execute the instructions winds up requiring large percentage of the chip's real estate and it becomes difficult to properly lay out the logic so that related circuits are close to one another in the two-dimensional space of the chip,

CPUs based on microcode contain a small, very fast, execution unit that fetches instructions from the microcode bank (which is really nothing more than fast ROM on the CPU chip). This microcode executes one microinstruction per clock cycle and a sequence of microinstructions decode the instruction, fetch its operands, move the operands to appropriate functional units that do whatever calculations are necessary, store away necessary results, and then update appropriate registers and flags in anticipation of the next instruction.

The microcode approach may appear to be substantially slower than the random logic approach because of all the steps involved. Actually, this isn't necessarily true. Keep in mind that with a random logic approach to instruction execution, part of the random logic is often a sequencer that steps through several states (one state per clock cycle). Whether you use your clock cycles executing microinstructions or stepping through a random logic state machine, you're still burning up clock cycles.

One advantage of microcode is that it makes better reuse of existing silicon on the CPU. Many CPU instructions (macroinstructions) execute some of the same microinstructions as many other instructions. This allows the CPU designer to use microcode subroutines to implement many common operations, thus saving silicon on the CPU. While it is certainly possible to share circuitry in a random logic device, this is often difficult if two circuits could otherwise share some logic but are across the chip from one another.

Another advantage of microcode is that it lets you create some very complex instructions that consist of several different operations. This provides programmers (especially assembly language programmers) with the ability to do more work with fewer instructions in their programs. In theory, this lets them write faster programs since they now execute half as many instructions, each doing twice the work of a simpler instruction set (the 80x86 MMX instruction set extension is a good example of this theory in action, although the MMX instructions do not use a microcode implementation).

Microcode does suffer from one disadvantage compared to random logic: the speed of the processor is tied to the speed of the internal microcode execution unit. Although the "microengine" itself is usually quite fast, the microengine must fetch its instruction from the microcode ROM. Therefore, if memory technology is slower than the execution logic, the microcode ROM will slow the microengine down because the system will have to introduce wait states into the microcode ROM access. Actually, microengines generally don't support the use of wait states, so this means that the microengine will have to run at the same speed as the

8. Though this is, by no means, the most complex instruction set. The VAX, for example, has instructions up to 150 bytes long!

9. There is actually nothing random about this logic at all. This design technique gets its name from the fact that if you view a photomicrograph of a CPU die that uses microcode, the microcode section looks very regular; the same photograph of a CPU that utilizes random logic contains no such easily discernable patterns.

microcode ROM. This effectively limits the speed at which the microengine, and therefore the CPU, can run.

Which approach is better for CPU design? That depends entirely on the current state of memory technology. If memory technology is faster than CPU technology, then the microcode approach tends to make more sense. If memory technology is slower than CPU technology, then random logic tends to produce the faster CPUs.

When Intel first began designing the 8086 CPU sometime between 1976 and 1978, memory technology was faster so they used microcode. Today, CPU technology is much faster than memory technology, so random logic CPUs tend to be faster. Most modern (non-x86) processors use random logic. The 80x86 family uses a combination of these technologies to improve performance while maintaining compatibility with the complex instruction set that relied on microcode way back in 1978.

4.6 RISC vs. CISC vs. VLIW

In the 1970's, CPU designers were busy extending their instruction sets to make their chips easier to program. It was very common to find a CPU designer poring over the assembly output of some high level language compiler searching for common two and three instruction sequences the compiler would emit. The designer would then create a single instruction that did the work of this two or three instruction sequence, the compiler writer would modify the compiler to use this new instruction, and a recompilation of the program would, presumably, produce a faster and shorter program than before.

Digital Equipment Corporation (now part of Compaq Computer) raised this process to a new level in their VAX minicomputer series. It is not surprising, therefore, that many research papers appearing in the 1980's would commonly use the VAX as an example of what not to do.

The problem is, these designers lost track of what they were trying to do, or to use the old cliché, they couldn't see the forest for the trees. They assumed that there were making their processors faster by executing a single instruction that previously required two or more. They also assumed that they were making the programs smaller, for exactly the same reason. They also assumed that they were making the processors easier to program because programmers (or compilers) could write a single instruction instead of using multiple instructions. In many cases, they assumed wrong.

In the early 80's, researchers at IBM and several institutions like Stanford and UC Berkeley challenged the assumptions of these designers. They wrote several papers showing how complex instructions on the VAX minicomputer could actually be done faster (and sometimes in less space) using a sequence of simpler instructions. As a result, most compiler writers did not use the fancy new instructions on the VAX (nor did assembly language programmers). Some might argue that having an unused instruction doesn't hurt anything, but these researchers argued otherwise. They claimed that any unnecessary instructions required additional logic to implement and as the complexity of the logic grows it becomes more and more difficult to produce a high clock speed CPU.

This research led to the development of the RISC, or Reduced Instruction Set Computer, CPU. The basic idea behind RISC was to go in the opposite direction of the VAX. Decide what the smallest reasonable instruction set could be and implement that. By throwing out all the complex instructions, RISC CPU designers could use random logic rather than microcode (by this time, CPU speeds were outpacing memory speeds). Rather than making an individual instruction more complex, they could move the complexity to the system level and add many on-chip features to improve the overall system performance (like caches, pipelines, and other advanced mainframe features of the time). Thus, the great "RISC vs. CISC¹⁰" debate was born.

Before commenting further on the result of this debate, you should realize that RISC actually means "(Reduced Instruction) Set Computer," not "Reduced (Instruction Set) Computer." That is, the goal of RISC was to reduce the complexity of individual instructions, not necessarily reduce the number of instructions a RISC CPU supports. It was often the case that RISC CPUs had fewer instructions than their CISC counter-

10. CISC stands for Complex Instruction Set Computer and defines those CPUs that were popular at the time like the VAX and the 80x86.

parts, but this was not a precondition for calling a CPU a RISC device. Many RISC CPUs had more instructions than some of their CISC contemporaries, depending on how you count instructions.

First, there is no debate about one thing: if you have two CPUs, one RISC and one CISC and they both run at the same clock frequency and they execute the same average number of instructions per clock cycle, CISC is the clear winner. Since CISC processors do more work with each instruction, if the two CPUs execute the same number of instructions in the same amount of time, the CISC processor usually gets more work done.

However, RISC performance claims were based on the fact that RISC's simpler design would allow the CPU designers to reduce the overall complexity of the chip, thereby allowing it to run at a higher clock frequency. Further, with a little added complexity, they could easily execute more instructions per clock cycle, on the average, than their CISC contemporaries.

One drawback to RISC CPUs is that their code density was much lower than CISC CPUs. Although memory devices were dropping in price and the need to keep programs small was decreasing, low code density requires larger caches to maintain the same number of instructions in the cache. Further, since memory speeds were not keeping up with CPU speeds, the larger instruction sizes found in the RISC CPUs meant that the system spent more time bringing in those instructions from memory to cache since they could transfer fewer instructions per bus transaction. For many years, CPU architects argued to and fro about whether RISC or CISC was the better approach. With one big footnote, the RISC approach has generally won the argument. Most of the popular CISC systems, e.g., the VAX, the Z8000, the 16032/32016, and the 68000, have quietly faded away to be replaced by the likes of the PowerPC, the MIPS CPUs, the Alpha, and the SPARC. The one footnote here is, of course, the 80x86 family. Intel has proven that if you really want to keep extending a CISC architecture, and you're willing to throw a lot of money at it, you can extend it far beyond what anyone ever expected. As of late 2000/early 2001 the 80x86 is the raw performance leader. The CPU runs at a higher clock frequency than the competing RISC chips; it executes fairly close to the same number of instructions per clock cycle as the competing RISC chips; it has about the same "average instruction size to cache size" ratio as the RISC chips; and it is a CISC, so many of the instructions do more work than their RISC equivalents. So overall, the 80x86 is, on the average, faster than contemporary RISC chips¹¹.

To achieve this raw performance advantage, the 80x86 has borrowed heavily from RISC research. Intel has divided the instruction set into a set of simple instructions that Intel calls the "RISC core" and the remaining, complex instructions. The complex instructions do not execute as rapidly as the RISC core instructions. In fact, it is often the case that the task of a complex instruction can be accomplished faster using multiple RISC core instructions. Intel supports the complex instructions to provide full compatibility with older software, but compiler writers and assembly language programmers tend to avoid the use of these instructions. Note that Intel moves instructions between these two sets over time. As Intel improves the processor they tend to speed up some of the slower, complex, instructions. Therefore, it is not possible to give a static list of instructions you should avoid; instead, you will have to refer to Intel's documentation for the specific processor you use.

Later Pentium processors do not use an interpretive engine and microcode like the earlier 80x86 processors. Instead, the Pentium core processors execute a set of "micro-operations" (or "micro-ops"). The Pentium processors translate the 80x86 instruction set into a sequence of micro-ops on the fly. The RISC core instructions typically generate a single micro-op while the CISC instructions generate a sequence of two or more micro-ops. For the purposes of determining the performance of a section of code, we can treat each micro-op as a single instruction. Therefore, the CISC instructions are really nothing more than "macro-instructions" that the CPU automatically translates into a sequence of simpler instructions. This is the reason the complex instructions take longer to execute.

Unfortunately, as the x86 nears its 25th birthday, it's clear (to Intel, at least) that it's been pushed to its limits. This is why Intel is working with HP to base their IA-64 architecture on the PA-RISC instruction set. The IA-64 architecture is an interesting blend. On the one hand, it (supposedly) supports object-code compatibility with the previous generation x86 family (though at reduced performance levels). Obviously, it's a

11. Note, by the way, that this doesn't imply that 80x86 systems are faster than computer systems built around RISC chips. Many RISC systems gain additional speed by supporting multiple processors better than the x86 or by having faster bus throughput. This is one reason, for example, why Internet companies select Sun equipment for their web servers.

RISC architecture since it was originally based on Hewlet-Packard's PA-RISC (PA=Precision Architecture) design. However, Intel and HP have extended on the RISC design by using another technology: Very Long Instruction Word (VLIW) computing. The idea behind VLIW computing is to use a very long opcode that handle multiple operations in parallel. In some respects, this is similar to CISC computing since a single VLIW "instruction" can do some very complex things. However, unlike CISC instructions, a VLIW instruction word can actually complete several independent tasks simultaneously. Effectively, this allows the CPU to execute some number of instructions in parallel.

Intel's VLIW approach is risky. To succeed, they are depending on compiler technology that doesn't yet exist. They made this same mistake with the iAPX 432. It remains to be seen whether history is about to repeat itself or if Intel has a winner on their hands.

4.7 Instruction Execution, Step-By-Step

To understand the problems with developing an efficient CPU, let's consider four representative 80x86 instructions: MOV, ADD, LOOP, and JNZ (jump if not zero). These instructions will allow us to explore many of the issues facing the x86 CPU designer.

You've seen the MOV and ADD instructions in previous chapters so there is no need to review them here. The LOOP and JNZ instructions are new, so it's probably a good idea to explain what they do before proceeding. Both of these instructions are *conditional jump* instructions. A conditional jump instruction tests some condition and jumps to some other instruction in memory if the condition is true and they fall through to the next instruction if the condition is false. This is basically the opposite of HLA's IF statement (which falls through if the condition is true and jumps to the else section if the condition is false). The JNZ (jump if not zero) instruction tests the CPU's zero flag and transfers control to some target location if the zero flag contains zero; JNZ falls through to the next instruction if the zero flag contains one. The program specifies the target instruction to jump to by specifying the distance from the JNZ instruction to the target instruction as a small signed integer (for our purposes here, we'll assume that the distance is within the range ± 128 bytes so the instruction uses a single byte to specify the distance to the target location).

The last instruction of interest to us here is the LOOP instruction. The LOOP instruction decrements the value of the ECX register and transfers control to a target instruction within ± 128 bytes if ECX does not contain zero (after the decrement). This is a good example of a CISC instruction since it does multiple operations: (1) it subtracts one from ECX and then it (2) does a conditional jump if ECX does not contain zero. That is, LOOP is equivalent to the following two 80x86 instructions¹²:

```
loop SomeLabel;
```

-is roughly equivalent to-

```
dec( ecx );
jnz SomeLabel;
```

Note that *SomeLabel* specifies the address of the target instruction that must be within about ± 128 bytes of the LOOP or JNZ instructions above. The LOOP instruction is a good example of a complex (vs. RISC core) instruction on the Pentium processors. It is actually faster to execute a DEC and a JNZ instruction¹³ than it is to execute a LOOP instruction. In this section we will not concern ourselves with this issue; we will assume that the LOOP instruction operates as though it were a RISC core instruction.

The 80x86 CPUs do not execute instructions in a single clock cycle. For example, the MOV instruction (which is relatively simple) could use the following execution steps¹⁴:

- Fetch the instruction byte from memory.
- Update the EIP register to point at the next byte.
- Decode the instruction to see what it does.

12. This sequence is not exactly equivalent to LOOP since this sequence affects the flags while LOOP does not.

13. Actually, you'll see a little later that there is a *decrement* instruction you can use to subtract one from ECX. The decrement instruction is better because it is shorter.

14. It is not possible to state exactly what steps each CPU requires since many CPUs are different from one another.

- If required, fetch a 16-bit instruction operand from memory.
- If required, update EIP to point beyond the operand.
- If required, compute the address of the operand (e.g., EBX+disp) .
- Fetch the operand.
- Store the fetched value into the destination register

If we allocate one clock cycle for each of the above steps, an instruction could take as many as eight clock cycles to complete (note that three of the steps above are optional, depending on the MOV instruction's addressing mode, so a simple MOV instruction could complete in as few as five clock cycles).

The ADD instruction is a little more complex. Here's a typical set of operations the ADD(reg, reg) instruction must complete:

- Fetch the instruction byte from memory.
- Update EIP to point at the next byte.
- Decode the instruction.
- Get the value of the source operand and send it to the ALU.
- Fetch the value of the destination operand (a register) and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the first register operand.
- Update the flags register with the result of the addition operation.

If the source operand is a memory location, the operation is slightly more complicated:

- Fetch the instruction byte from memory.
- Update EIP to point at the next byte.
- Decode the instruction.
- If required, fetch a displacement for use in the effective address calculation
- If required, update EIP to point beyond the displacement value.
- Get the value of the source operand from memory and send it to the ALU.
- Fetch the value of the destination operand (a register) and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the register operand.
- Update the flags register with the result of the addition operation.

ADD(const, memory) is the messiest of all, this code sequence looks something like the following:

- Fetch the instruction byte from memory.
- Update EIP to point at the next byte.
- Decode the instruction.
- If required, fetch a displacement for use in the effective address calculation
- If required, update EIP to point beyond the displacement value.
- Fetch the constant value from memory and send it to the ALU.
- Update EIP to point beyond the constant's value (at the next instruction in memory).
- Get the value of the source operand from memory and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the memory operand.
- Update the flags register with the result of the addition operation.

Note that there are other forms of the ADD instruction requiring their own special processing. These are just representative examples. As you see in these examples, the ADD instruction could take as many as ten steps (or cycles) to complete. Note that this is one advantage of a RISC design. Most RISC design have only one or two forms of the ADD instruction (that add registers together and, perhaps, that add constants to registers). Since register to register adds are often the fastest (and constant to register adds are probably the second fastest), the RISC CPUs force you to use the fastest forms of these instructions.

The JNZ instruction might use the following sequence of steps:

- Fetch the instruction byte from memory.
- Update EIP to point at the next byte.
- Decode the instruction.

- Fetch a displacement byte to determine the jump distance send this to the ALU
- Update EIP to point at the next byte.
- Test the zero flag to see if it is clear.
- If the zero flag was clear, copy the EIP register to the ALU.
- If the zero flag was clear, instruct the ALU to add the displacement and EIP register values.
- If the zero flag was clear, copy the result of the addition above back to the EIP register.

Notice how the JNZ instruction requires fewer steps if the jump is not taken. This is very typical for conditional jump instructions. If each step above corresponds to one clock cycle, the JNZ instruction would take six or nine clock cycles, depending on whether the branch is taken. Because the 80x86 JNZ instruction does not allow different types of operands, there is only one sequence of steps needed for this application.

The 80x86 LOOP instruction might use an execution sequence like the following:

- Fetch the instruction byte from memory.
- Update EIP to point at the next byte.
- Decode the instruction.
- Fetch the value of the ECX register and send it to the ALU.
- Instruct the ALU to decrement the value.
- Send the result back to the ECX register. Set a special internal flag if this value is non-zero.
- Fetch a displacement byte to determine the jump distance send this to the ALU
- Update EIP to point at the next byte.
- Test the special flag to see if ECX was non-zero.
- If the flag was set, copy the EIP register to the ALU.
- If the flag was set, instruct the ALU to add the displacement and EIP register values.
- If the flag was set, copy the result of the addition above back to the EIP register.

Although a given 80x86 CPU might not execute the steps for the instructions above, they all execute some sequence of operations. Each operation requires a finite amount of time to execute (generally, one clock cycle per operation or *stage* as we usually refer to each of the above steps). Obviously, the more steps needed for an instruction, the slower it will run. This is why complex instructions generally run slower than simple instructions, complex instructions usually have lots of execution stages.

4.8 Parallelism – the Key to Faster Processors

An early goal of the RISC processors was to execute one instruction per clock cycle, on the average. However, even if a RISC instruction is simplified, the actual execution of the instruction still requires multiple steps. So how could they achieve this goal? And how do later members the 80x86 family with their complex instruction sets also achieve this goal? The answer is parallelism.

Consider the following steps for a MOV(reg, reg) instruction:

- Fetch the instruction byte from memory.
- Update the EIP register to point at the next byte.
- Decode the instruction to see what it does.
- Fetch the source register.
- Store the fetched value into the destination register

There are five stages in the execution of this instruction with certain dependencies between each stage. For example, the CPU must fetch the instruction byte from memory before it updates EIP to point at the next byte in memory. Likewise, the CPU must decode the instruction before it can fetch the source register (since it doesn't know it needs to fetch a source register until it decodes the instruction). As a final example, the CPU must fetch the source register before it can store the fetched value in the destination register.

Most of the stages in the execution of this MOV instruction are *serial*. That is, the CPU must execute one stage before proceeding to the next. The one exception is the "Update EIP" step. Although this stage must follow the first stage, none of the following stages in the instruction depend upon this step. Therefore, this could be the third, fourth, or fifth step in the calculation and it wouldn't affect the outcome of the instruc-

tion. Further, we could execute this step concurrently with any of the other steps and it wouldn't affect the operation of the MOV instruction, e.g.,

- Fetch the instruction byte from memory.
- Decode the instruction to see what it does.
- Fetch the source register and update the EIP register to point at the next byte.
- Store the fetched value into the destination register

By doing two of the stages in parallel, we can reduce the execution time of this instruction by one clock cycle. Although the remaining stages in the "mov(reg, reg);" instruction must remain serialized (that is, they must take place in exactly this order), other forms of the MOV instruction offer similar opportunities to overlapped portions of their execution to save some cycles. For example, consider the "mov([ebx+disp], eax);" instruction:

- Fetch the instruction byte from memory.
- Update the EIP register to point at the next byte.
- Decode the instruction to see what it does.
- Fetch a displacement operand from memory.
- Update EIP to point beyond the displacement.
- Compute the address of the operand (e.g., EBX+disp) .
- Fetch the operand.
- Store the fetched value into the destination register

Once again there is the opportunity to overlap the execution of several stages in this instruction, for example:

- Fetch the instruction byte from memory.
- Decode the instruction to see what it does and update the EIP register to point at the next byte.
- Fetch a displacement operand from memory.
- Compute the address of the operand (e.g., EBX+disp) and update EIP to point beyond the displacement..
- Fetch the operand.
- Store the fetched value into the destination register

In this example, we reduced the number of execution steps from eight to six by overlapping the update of EIP with two other operations.

As a last example, consider the "add(const, [ebx+disp]);" instruction (the instruction with the largest number of steps we've considered thus far). It's non-overlapped execution looks like this:

- Fetch the instruction byte from memory.
- Update EIP to point at the next byte.
- Decode the instruction.
- Fetch a displacement for use in the effective address calculation
- Update EIP to point beyond the displacement value.
- Fetch the constant value from memory and send it to the ALU.
- Compute the address of the memory operand (EBX+disp).
- Get the value of the source operand from memory and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the memory operand.
- Update the flags register with the result of the addition operation.
- Update EIP to point beyond the constant's value (at the next instruction in memory).

We can overlap at least three steps in this instruction by noting that certain stages don't depend on the result of their immediate predecessor

- Fetch the instruction byte from memory.
- Decode the instruction and update EIP to point at the next byte.
- Fetch a displacement for use in the effective address calculation
- Update EIP to point beyond the displacement value.
- Fetch the constant value from memory and send it to the ALU.
- Compute the address of the memory operand (EBX+disp).

- Get the value of the source operand from memory and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the memory operand and update the flags register with the result of the addition operation and update EIP to point beyond the constant's value.

Note that we could not merge one of the "Update EIP" operations because the previous stage and following stages of the instruction both use the value of EIP before and after the update.

Unlike the MOV instruction, the steps in the ADD instruction above are not all dependent upon the previous stage in the instruction's execution. For example, the sequence above fetches the constant from memory and then computes the effective address (EBX+disp) of the memory operand. Neither operation depends upon the other, so we could easily swap their positions above to yield the following:

- Fetch the instruction byte from memory.
- Decode the instruction and update EIP to point at the next byte.
- Fetch a displacement for use in the effective address calculation
- Update EIP to point beyond the displacement value.
- Compute the address of the memory operand (EBX+disp).
- Fetch the constant value from memory and send it to the ALU.
- Get the value of the source operand from memory and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the memory operand and update the flags register with the result of the addition operation and update EIP to point beyond the constant's value.

This doesn't save any steps, but it does reduce some dependencies between certain stages and their immediate predecessors, allowing additional parallel operation. For example, we can now merge the "Update EIP" operation with the effective address calculation:

- Fetch the instruction byte from memory.
- Decode the instruction and update EIP to point at the next byte.
- Fetch a displacement for use in the effective address calculation
- Compute the address of the memory operand (EBX+disp) and update EIP to point beyond the displacement value.
- Fetch the constant value from memory and send it to the ALU.
- Get the value of the source operand from memory and send it to the ALU.
- Instruct the ALU to add the values.
- Store the result back into the memory operand and update the flags register with the result of the addition operation and update EIP to point beyond the constant's value.

Although it might seem possible to fetch the constant and the memory operand in the same step (since their values do not depend upon one another), the CPU can't actually do this (yet!) because it has only a single data bus. Since both of these values are coming from memory, we can't bring them into the CPU during the same step because the CPU uses the data bus to fetch these two values. In the next section you'll see how we can overcome this problem.

By overlapping various stages in the execution of these instructions we've been able to substantially reduce the number of steps (i.e., clock cycles) that the instructions need to complete execution. This process of executing various steps of the instruction in parallel with other steps is a major key to improving CPU performance without cranking up the clock speed on the chip. In this section we've seen how to speed up the execution of an instruction by doing many of the internal operations of that instruction in parallel. However, there's only so much to be gained from this approach. In this approach, the instructions themselves are still serialized (one instruction completes before the next instruction begins execution). Starting with the next section we'll start to see how to overlap the execution of adjacent instructions in order to save additional cycles.

4.8.1 The Prefetch Queue – Using Unused Bus Cycles

The key to improving the speed of a processor is to perform operations in parallel. If we were able to do two operations on each clock cycle, the CPU would execute instructions twice as fast when running at the same clock speed. However, simply deciding to execute two operations per clock cycle is not so easy. Many steps in the execution of an instruction share *functional units* in the CPU (functional units are groups of logic that perform a common operation, e.g., the ALU and the CU). A functional unit is only capable of one operation at a time. Therefore, you cannot do two operations that use the same functional unit concurrently (e.g., incrementing the EIP register and adding two values together). Another difficulty with doing certain operations concurrently is that one operation may depend on the other's result. For example, the two steps of the ADD instruction that involve adding two values and then storing their sum. You cannot store the sum into a register until after you've computed the sum. There are also some other resources the CPU cannot share between steps in an instruction. For example, there is only one data bus; the CPU cannot fetch an instruction opcode at the same time it is trying to store some data to memory. The trick in designing a CPU that executes several steps in parallel is to arrange those steps to reduce conflicts or add additional logic so the two (or more) operations can occur simultaneously by executing in different functional units.

Consider again the steps the MOV(mem/reg, reg) instruction requires:

- Fetch the instruction byte from memory.
- Update the EIP register to point at the next byte.
- Decode the instruction to see what it does.
- If required, fetch a displacement operand from memory.
- If required, update EIP to point beyond the displacement.
- Compute the address of the operand, if required (i.e., EBX+xxxx) .
- Fetch the operand.
- Store the fetched value into the destination register

The first operation uses the value of the EIP register (so we cannot overlap incrementing EIP with it) and it uses the bus to fetch the instruction opcode from memory. Every step that follows this one depends upon the opcode it fetches from memory, so it is unlikely we will be able to overlap the execution of this step with any other.

The second and third operations do not share any functional units, nor does decoding an opcode depend upon the value of the EIP register. Therefore, we can easily modify the control unit so that it increments the EIP register at the same time it decodes the instruction. This will shave one cycle off the execution of the MOV instruction.

The third and fourth operations above (decoding and optionally fetching the displacement operand) do not look like they can be done in parallel since you must decode the instruction to determine if the CPU needs to fetch an operand from memory. However, we could design the CPU to go ahead and fetch the operand anyway, so that it's available if we need it. There is one problem with this idea, though, we must have the address of the operand to fetch (the value in the EIP register) and if we must wait until we are done incrementing the EIP register before fetching this operand. If we are incrementing EIP at the same time we're decoding the instruction, we will have to wait until the next cycle to fetch this operand.

Since the next three steps are optional, there are several possible instruction sequences at this point:

- #1 (step 4, step 5, step 6, and step 7) – e.g., MOV([ebx+1000], eax)
- #2 (step 4, step 5, and step 7) – e.g., MOV(disp, eax) -- assume disp's address is 1000
- #3 (step 6 and step 7) – e.g., MOV([ebx], eax)
- #4 (step 7) – e.g., MOV(ebx, eax)

In the sequences above, step seven always relies on the previous steps in the sequence. Therefore, step seven cannot execute in parallel with any of the other steps. Step six also relies upon step four. Step five cannot execute in parallel with step four since step four uses the value in the EIP register, however, step five can execute in parallel with any other step. Therefore, we can shave one cycle off the first two sequences above as follows:

- #1 (step 4, step 5/6, and step 7)
- #2 (step 4, step 5/7)
- #3 (step 6 and step 7)
- #4 (step 7)

Of course, there is no way to overlap the execution of steps seven and eight in the MOV instruction since it must surely fetch the value before storing it away. By combining these steps, we obtain the following steps for the MOV instruction:

- Fetch the instruction byte from memory.
- Decode the instruction and update ip
- If required, fetch a displacement operand from memory.
- Compute the address of the operand, if required (i.e., $ebx+xxxx$).
- Fetch the operand, if required update EIP to point beyond $xxxx$.
- Store the fetched value into the destination register

By adding a small amount of logic to the CPU, we've shaved one or two cycles off the execution of the MOV instruction. This simple optimization works with most of the other instructions as well.

Consider what happens with the MOV instruction above executes on a CPU with a 32-bit data bus. If the MOV instruction fetches an eight-bit displacement from memory, the CPU may actually wind up fetching the following three bytes after the displacement along with the displacement value (since the 32-bit data bus lets us fetch four bytes in a single bus cycle). The second byte on the data bus is actually the opcode of the next instruction. If we could save this opcode until the execution of the next instruction, we could shave a cycle of its execution time since it would not have to fetch the opcode byte. Furthermore, since the instruction decoder is idle while the CPU is executing the MOV instruction, we can actually decode the next instruction while the current instruction is executing, thereby shaving yet another cycle off the execution of the next instruction. This, effectively, overlaps a portion of the MOV instruction with the beginning of the execution of the next instruction, allowing additional parallelism.

Can we improve on this? The answer is yes. Note that during the execution of the MOV instruction the CPU is not accessing memory on every clock cycle. For example, while storing the data into the destination register the bus is idle. During time periods when the bus is idle we can pre-fetch instruction opcodes and operands and save these values for executing the next instruction.

The hardware to do this is the prefetch queue. Figure 4.4 shows the internal organization of a CPU with a prefetch queue. The Bus Interface Unit, as its name implies, is responsible for controlling access to the address and data busses. Whenever some component inside the CPU wishes to access main memory, it sends this request to the bus interface unit (or BIU) that acts as a "traffic cop" and handles simultaneous requests for bus access by different modules (e.g., the execution unit and the prefetch queue).

Figure 4.4 CPU Design with a Prefetch Queue

Whenever the execution unit is not using the Bus Interface Unit, the BIU can fetch additional bytes from the instruction stream. Whenever the CPU needs an instruction or operand byte, it grabs the next available byte from the prefetch queue. Since the BIU grabs four bytes at a time from memory (assuming a 32-bit data bus) and it generally consumes fewer than four bytes per clock cycle, any bytes the CPU would normally fetch from the instruction stream will already be sitting in the prefetch queue.

Note, however, that we're not guaranteed that all instructions and operands will be sitting in the prefetch queue when we need them. For example, consider the "JNZ Label;" instruction, if it transfers control to *Label*, will invalidate the contents of the prefetch queue. If this instruction appears at locations 400 and 401 in memory (it is a two-byte instruction), the prefetch queue will contain the bytes at addresses 402, 403, 404, 405, 406, 407, etc. If the target address of the JNZ instruction is 480, the bytes at addresses 402, 403, 404, etc., won't do us any good. So the system has to pause for a moment to fetch the double word at address 480 before it can go on.

Another improvement we can make is to overlap instruction decoding with the last step of the previous instruction. After the CPU processes the operand, the next available byte in the prefetch queue is an opcode, and the CPU can decode it in anticipation of its execution. Of course, if the current instruction modifies the EIP register then any time spent decoding the next instruction goes to waste, but since this occurs in parallel with other operations, it does not slow down the system (though it does require extra circuitry to do this).

The instruction execution sequence now assumes that the following events occur in the background:
CPU Prefetch Events:

- If the prefetch queue is not full (generally it can hold between eight and thirty-two bytes, depending on the processor) and the BIU is idle on the current clock cycle, fetch the next double word from memory at the address in EIP at the beginning of the clock cycle¹⁵.
- If the instruction decoder is idle and the current instruction does not require an instruction operand, begin decoding the opcode at the front of the prefetch queue (if present), otherwise begin decoding the byte beyond the current operand in the prefetch queue (if present). If the desired byte is not in the prefetch queue, do not execute this event.

15. This operation fetches only a byte if ip contains an odd value.

Now let's reconsider our "mov(reg, reg);" instruction from the previous section. With the addition of the prefetch queue and the bus interface unit, fetching and decoding opcode bytes, as well as updating the EIP register, takes place in parallel with the previous instruction. Without the BIU and the prefetch queue, the "mov(reg, reg);" requires the following steps:

- Fetch the instruction byte from memory.
- Decode the instruction to see what it does.
- Fetch the source register and update the EIP register to point at the next byte.
- Store the fetched value into the destination register

However, now that we can overlap the instruction fetch and decode with the previous instruction, we now get the following steps:

- Fetch and Decode Instruction - overlapped with previous instruction
- Fetch the source register and update the EIP register to point at the next byte.
- Store the fetched value into the destination register

The instruction execution timings make a few optimistic assumptions, namely that the opcode is already present in the prefetch queue and that the CPU has already decoded it. If either case is not true, additional cycles will be necessary so the system can fetch the opcode from memory and/or decode the instruction.

Because they invalidate the prefetch queue, jump and conditional jump instructions (when actually taken) are much slower than other instructions. This is because the CPU cannot overlap fetching and decoding the opcode for the next instruction with the execution of the jump instruction since the opcode is (probably) not in the prefetch queue. Therefore, it may take several cycles after the execution of one of these instructions for the prefetch queue to recover and the CPU is decoding opcodes in parallel with the execution of previous instructions. This has one very important implication to your programs: if you want to write fast code, make sure to avoid jumping around in your program as much as possible.

Note that the conditional jump instructions only invalidate the prefetch queue if they actually make the jump. If the condition is false, they fall through to the next instruction and continue to use the values in the prefetch queue as well as any pre-decoded instruction opcodes. Therefore, if you can determine, while writing the program, which condition is most likely (e.g., less than vs. not less than), you should arrange your program so that the most common case falls through and conditional jump rather than take the branch.

Instruction size (in bytes) can also affect the performance of the prefetch queue. The longer the instruction, the faster the CPU will empty the prefetch queue. Instructions involving constants and memory operands tend to be the largest. If you place a string of these in a row, the CPU may wind up having to wait because it is removing instructions from the prefetch queue faster than the BIU is copying data to the prefetch queue. Therefore, you should attempt to use shorter instructions whenever possible since they will improve the performance of the prefetch queue.

Usually, including the prefetch queue improves performance. That's why Intel provides the prefetch queue on every model of the 80x86, from the 8088 on up. On these processors, the BIU is constantly fetching data for the prefetch queue whenever the program is not actively reading or writing data.

Prefetch queues work best when you have a wide data bus. The 8086 processor runs much faster than the 8088 because it can keep the prefetch queue full with fewer bus accesses. Don't forget, the CPU needs to use the bus for other purposes than fetching opcodes, displacements, and immediate constants. Instructions that access memory compete with the prefetch queue for access to the bus (and, therefore, have priority). If you have a sequence of instructions that all access memory, the prefetch queue may become empty if there are only a few bus cycles available for filling the prefetch queue during the execution of these instructions. Of course, once the prefetch queue is empty, the CPU must wait for the BIU to fetch new opcodes from memory, slowing the program.

A wider data bus allows the BIU to pull in more prefetch queue data in the few bus cycles available for this purpose, so it is less likely the prefetch queue will ever empty out with a wider data bus. Executing shorter instructions also helps keep the prefetch queue full. The reason is that the prefetch queue has time to refill itself with the shorter instructions. Moral of the story: when programming a processor with a prefetch queue, always use the shortest instructions possible to accomplish a given task.

4.8.2 Pipelining – Overlapping the Execution of Multiple Instructions

Executing instructions in parallel using a bus interface unit and an execution unit is a special case of pipelining. The 80x86 family, starting with the 80486, incorporates pipelining to improve performance. With just a few exceptions, we'll see that pipelining allows us to execute one instruction per clock cycle.

The advantage of the prefetch queue was that it let the CPU overlap instruction fetching and decoding with instruction execution. That is, while one instruction is executing, the BIU is fetching and decoding the next instruction. Assuming you're willing to add hardware, you can execute almost all operations in parallel. That is the idea behind pipelining.

4.8.2.1 A Typical Pipeline

Consider the steps necessary to do a generic operation:

- Fetch opcode.
- Decode opcode and (in parallel) prefetch a possible displacement or constant operand (or both)
- Compute complex addressing mode (e.g., [ebx+xxxx]), if applicable.
- Fetch the source value from memory (if a memory operand) and the destination register value (if applicable).
- Compute the result.
- Store result into destination register.

Assuming you're willing to pay for some extra silicon, you can build a little “mini-processor” to handle each of the above steps. The organization would look something like Figure 4.5.

Figure 4.5 A Pipelined Implementation of Instruction Execution

Note how we've combined some stages from the previous section. For example, in stage four of Figure 4.5 the CPU fetches the source and destination operands in the same step. You can do this by putting multiple data paths inside the CPU (e.g., from the registers to the ALU) and ensuring that no two operands ever compete for simultaneous use of the data bus (i.e., no memory-to-memory operations).

If you design a separate piece of hardware for each stage in the pipeline above, almost all these steps can take place in parallel. Of course, you cannot fetch and decode the opcode for more than one instruction at the same time, but you can fetch one opcode while decoding the previous instruction. If you have an n-stage pipeline, you will usually have n instructions executing concurrently.

Figure 4.6 Instruction Execution in a Pipeline

Figure 4.6 shows pipelining in operation. T1, T2, T3, etc., represent consecutive “ticks” of the system clock. At T=T1 the CPU fetches the opcode byte for the first instruction.

At T=T2, the CPU begins decoding the opcode for the first instruction. In parallel, it fetches a block of bytes from the prefetch queue in the event the instruction has an operand. Since the first instruction no longer needs the opcode fetching circuitry, the CPU instructs it to fetch the opcode of the second instruction in parallel with the decoding of the first instruction. Note there is a minor conflict here. The CPU is attempting to fetch the next byte from the prefetch queue for use as an operand, at the same time it is fetching operand data from the prefetch queue for use as an opcode. How can it do both at once? You’ll see the solution in a few moments.

At T=T3 the CPU computes an operand address for the first instruction, if any. The CPU does nothing on the first instruction if it does not use an addressing mode requiring such computation. During T3, the CPU also decodes the opcode of the second instruction and fetches any necessary operand. Finally the CPU also fetches the opcode for the third instruction. With each advancing tick of the clock, another step in the execution of each instruction in the pipeline completes, and the CPU fetches yet another instruction from memory.

This process continues until at T=T6 the CPU completes the execution of the first instruction, computes the result for the second, etc., and, finally, fetches the opcode for the sixth instruction in the pipeline. The important thing to see is that after T=T5 the CPU completes an instruction on every clock cycle. Once the CPU fills the pipeline, it completes one instruction on each cycle. Note that this is true even if there are complex addressing modes to be computed, memory operands to fetch, or other operations which use cycles on a non-pipelined processor. All you need to do is add more stages to the pipeline, and you can still effectively process each instruction in one clock cycle.

A bit earlier you saw a small conflict in the pipeline organization. At T=T2, for example, the CPU is attempting to prefetch a block of bytes for an operand and at the same time it is trying to fetch the next opcode byte. Until the CPU decodes the first instruction it doesn’t know how many operands the instruction requires nor does it know their length. However, the CPU needs to know this information to determine the length of the instruction so it knows what byte to fetch as the opcode of the next instruction. So how can the pipeline fetch an instruction opcode in parallel with an address operand?

One solution is to disallow this. If an instruction has an address or constant operand, we simply delay the start of the next instruction (this is known as a *hazard* as you shall soon see). Unfortunately, many instructions have these additional operands, so this approach will have a substantial negative impact on the execution speed of the CPU.

The second solution is to throw (a lot) more hardware at the problem. Operand and constant sizes usually come in one, two, and four-byte lengths. Therefore, if we actually fetch three bytes from memory, at offsets one, three, and five, beyond the current opcode we are decoding, we know that one of these bytes will probably contain the opcode of the next instruction. Once we are through decoding the current instruction we know how long it will be and, therefore, we know the offset of the next opcode. We can use a simple data selector circuit to choose which of the three opcode bytes we want to use.

In actual practice, we have to select the next opcode byte from more than three candidates because 80x86 instructions take many different lengths. For example, an instruction that moves a 32-bit constant to a memory location can be ten or more bytes long. And there are instruction lengths for nearly every value

between one and fifteen bytes. Also, some opcodes on the 80x86 are longer than one byte, so the CPU may have to fetch multiple bytes in order to properly decode the current instruction. Nevertheless, by throwing more hardware at the problem we can decode the current opcode at the same time we're fetching the next.

4.8.2.2 Stalls in a Pipeline

Unfortunately, the scenario presented in the previous section is a little too simplistic. There are two drawbacks to that simple pipeline: bus contention among instructions and non-sequential program execution. Both problems may increase the average execution time of the instructions in the pipeline.

Bus contention occurs whenever an instruction needs to access some item in memory. For example, if a "mov(reg, mem);" instruction needs to store data in memory and a "mov(mem, reg);" instruction is reading data from memory, contention for the address and data bus may develop since the CPU will be trying to simultaneously fetch data and write data in memory.

One simplistic way to handle bus contention is through a *pipeline stall*. The CPU, when faced with contention for the bus, gives priority to the instruction furthest along in the pipeline. The CPU suspends fetching opcodes until the current instruction fetches (or stores) its operand. This causes the new instruction in the pipeline to take two clock cycles to execute rather than one (see Figure 4.7).

Figure 4.7 A Pipeline Stall

This example is but one case of bus contention. There are many others. For example, as noted earlier, fetching instruction operands requires access to the prefetch queue at the same time the CPU needs to fetch an opcode. Given the simple scheme above, it's unlikely that most instructions would execute at one clock per instruction (CPI).

Fortunately, the intelligent use of a cache system can eliminate many pipeline stalls like the ones discussed above. The next section on caching will describe how this is done. However, it is not always possible, even with a cache, to avoid stalling the pipeline. What you cannot fix in hardware, you can take care of with software. If you avoid using memory, you can reduce bus contention and your programs will execute faster. Likewise, using shorter instructions also reduces bus contention and the possibility of a pipeline stall.

What happens when an instruction *modifies* the EIP register? This, of course, implies that the next set of instructions to execute do not immediately follow the instruction that modifies EIP. By the time the instruction

```
JNZ Label;
```

completes execution (assuming the zero flag is clear so the branch is taken), we've already started five other instructions and we're only one clock cycle away from the completion of the first of these. Obviously, the CPU must not execute those instructions or it will compute improper results.

The only reasonable solution is to *flush* the entire pipeline and begin fetching opcodes anew. However, doing so causes a severe execution time penalty. It will take six clock cycles (the length of the pipeline in our examples) before the next instruction completes execution. Clearly, you should avoid the use of instructions which interrupt the sequential execution of a program. This also shows another problem – pipeline length. The longer the pipeline is, the more you can accomplish per cycle in the system. However, lengthening a pipeline may slow a program if it jumps around quite a bit. Unfortunately, you cannot control the number of stages in the pipeline¹⁶. You can, however, control the number of transfer instructions which appear in your programs. Obviously you should keep these to a minimum in a pipelined system.

4.8.3 Instruction Caches – Providing Multiple Paths to Memory

System designers can resolve many problems with bus contention through the intelligent use of the prefetch queue and the cache memory subsystem. They can design the prefetch queue to buffer up data from the instruction stream, and they can design the cache with separate data and code areas. Both techniques can improve system performance by eliminating some conflicts for the bus.

The prefetch queue simply acts as a buffer between the instruction stream in memory and the opcode fetching circuitry. The prefetch queue works well when the CPU isn't constantly accessing memory. When the CPU isn't accessing memory, the BIU can fetch additional instruction opcodes for the prefetch queue. Alas, the pipelined 80x86 CPUs are constantly accessing memory since they fetch an opcode byte on every clock cycle. Therefore, the prefetch queue cannot take advantage of any "dead" bus cycles to fetch additional opcode bytes – there aren't any "dead" bus cycles. However, the prefetch queue is still valuable for a very simple reason: the BIU fetches multiple bytes on each memory access and most instructions are shorter. Without the prefetch queue, the system would have to explicitly fetch each opcode, even if the BIU had already "accidentally" fetched the opcode along with the previous instruction. With the prefetch queue, however, the system will not refetch any opcodes. It fetches them once and saves them for use by the opcode fetch unit.

For example, if you execute two one-byte instructions in a row, the BIU can fetch both opcodes in one memory cycle, freeing up the bus for other operations. The CPU can use these available bus cycles to fetch additional opcodes or to deal with other memory accesses.

Of course, not all instructions are one byte long. The 80x86 has a large number of different instruction sizes. If you execute several large instructions in a row, you're going to run slower. Once again we return to that same rule: *the fastest programs are the ones which use the shortest instructions*. If you can use shorter instructions to accomplish some task, do so.

Suppose, for a moment, that the CPU has two separate memory spaces, one for instructions and one for data, each with their own bus. This is called the *Harvard Architecture* since the first such machine was built at Harvard. On a Harvard machine there would be no contention for the bus. The BIU could continue to fetch opcodes on the instruction bus while accessing memory on the data/memory bus (see Figure 4.8),

16. Note, by the way, that the number of stages in an instruction pipeline varies among CPUs.

Figure 4.8 A Typical Harvard Machine

In the real world, there are very few true Harvard machines. The extra pins needed on the processor to support two physically separate busses increase the cost of the processor and introduce many other engineering problems. However, microprocessor designers have discovered that they can obtain many benefits of the Harvard architecture with few of the disadvantages by using separate on-chip caches for data and instructions. Advanced CPUs use an internal Harvard architecture and an external Von Neumann architecture. Figure 4.9 shows the structure of the 80x86 with separate data and instruction caches.

Figure 4.9 Using Separate Code and Data Caches

Each path inside the CPU represents an independent bus. Data can flow on all paths concurrently. This means that the prefetch queue can be pulling instruction opcodes from the instruction cache while the execution unit is writing data to the data cache. Now the BIU only fetches opcodes from memory whenever it cannot locate them in the instruction cache. Likewise, the data cache buffers memory. The CPU uses the data/address bus only when reading a value which is not in the cache or when flushing data back to main memory.

Although you cannot control the presence, size, or type of cache on a CPU, as an assembly language programmer you must be aware of how the cache operates to write the best programs. On-chip level one instruction caches are generally quite small (8,192 bytes on the 80486, for example). Therefore, the shorter your instructions, the more of them will fit in the cache (getting tired of “shorter instructions” yet?). The more instructions you have in the cache, the less often bus contention will occur. Likewise, using registers to hold temporary results places less strain on the data cache so it doesn’t need to flush data to memory or retrieve data from memory quite so often. *Use the registers wherever possible!*

4.8.4 Hazards

There is another problem with using a pipeline: the data hazard. Let’s look at the execution profile for the following instruction sequence:

```
mov( Somevar, ebx );
mov( [ebx], eax );
```

When these two instructions execute, the pipeline will look something like shown in Figure 4.10:

Figure 4.10 A Data Hazard

Note a major problem here. These two instructions fetch the 32 bit value whose address appears at location &SomeVar in memory. *But this sequence of instructions won’t work properly!* Unfortunately, the second instruction has already used the value in EBX before the first instruction loads the contents of memory location &SomeVar (T4 & T6 in the diagram above).

CISC processors, like the 80x86, handle hazards automatically¹⁷. However, they will stall the pipeline to synchronize the two instructions. The actual execution would look something like shown in Figure 4.11.

17. Some RISC chips do not. If you tried this sequence on certain RISC chips you would get an incorrect answer.

Figure 4.11 How the 80x86 Handles a Data Hazard

By delaying the second instruction two clock cycles, the CPU guarantees that the load instruction will load EAX from the proper address. Unfortunately, the second load instruction now executes in three clock cycles rather than one. However, requiring two extra clock cycles is better than producing incorrect results. Fortunately, you can reduce the impact of hazards on execution speed within your software.

Note that the data hazard occurs when the source operand of one instruction was a destination operand of a previous instruction. There is nothing wrong with loading EBX from SomeVar and then loading EAX from [EBX], *unless they occur one right after the other*. Suppose the code sequence had been:

```
mov( 2000, ecx );
mov( SomeVar, ebx );
mov( [ebx], eax );
```

We could reduce the effect of the hazard that exists in this code sequence by simply *rearranging the instructions*. Let's do that and obtain the following:

```
mov( SomeVar, ebx );
mov( 2000, ecx );
mov( [ebx], eax );
```

Now the "mov([ebx], eax);" instruction requires only one additional clock cycle rather than two. By inserting yet another instruction between the "mov(SomeVar, ebx);" and the "mov([ebx], eax);" instructions you can eliminate the effects of the hazard altogether¹⁸.

On a pipelined processor, the order of instructions in a program may dramatically affect the performance of that program. Always look for possible hazards in your instruction sequences. Eliminate them wherever possible by rearranging the instructions.

In addition to data hazards, there are also *control hazards*. We've actually discussed control hazards already, although we did not refer to them by that name. A control hazard occurs whenever the CPU branches to some new location in memory and the CPU has to flush the following instructions following the branch that are in various stages of execution.

4.8.5 Superscalar Operation— Executing Instructions in Parallel

With the pipelined architecture we could achieve, at best, execution times of one CPI (clock per instruction). Is it possible to execute instructions faster than this? At first glance you might think, "Of course not, we can do at most one operation per clock cycle. So there is no way we can execute more than one instruction per clock cycle." Keep in mind however, that a single instruction is *not* a single operation. In the examples presented earlier each instruction has taken between six and eight operations to complete. By adding seven or eight separate units to the CPU, we could effectively execute these eight operations in one clock

18. Of course, any instruction you insert at this point must *not* modify the values in the eax and ebx registers. Also note that the examples in this section are contrived to demonstrate pipeline stalls. Actual 80x86 CPUs have additional circuitry to help reduce the effect of pipeline stalls on the execution time.

cycle, yielding one CPI. If we add more hardware and execute, say, 16 operations at once, can we achieve 0.5 CPI? The answer is a qualified “yes.” A CPU including this additional hardware is a *superscalar* CPU and can execute more than one instruction during a single clock cycle. The 80x86 family began supporting superscalar execution with the introduction of the Pentium processor.

A superscalar CPU has, essentially, several execution units (see Figure 4.12). If it encounters two or more instructions in the instruction stream (i.e., the prefetch queue) which can execute independently, it will do so.

Figure 4.12 A CPU that Supports Superscalar Operation

There are a couple of advantages to going superscalar. Suppose you have the following instructions in the instruction stream:

```
mov( 1000, eax );
mov( 2000, ebx );
```

If there are no other problems or hazards in the surrounding code, and all six bytes for these two instructions are currently in the prefetch queue, there is no reason why the CPU cannot fetch and execute both instructions in parallel. All it takes is extra silicon on the CPU chip to implement two execution units.

Besides speeding up independent instructions, a superscalar CPU can also speed up program sequences which have hazards. One limitation of superscalar CPU is that once a hazard occurs, the offending instruction will completely stall the pipeline. Every instruction which follows will also have to wait for the CPU to synchronize the execution of the instructions. With a superscalar CPU, however, instructions following the hazard may continue execution through the pipeline as long as they don't have hazards of their own. This alleviates (though does not eliminate) some of the need for careful instruction scheduling.

As an assembly language programmer, the way you write software for a superscalar CPU can dramatically affect its performance. First and foremost is that rule you're probably sick of by now: *use short instructions*. The shorter your instructions are, the more instructions the CPU can fetch in a single operation and, therefore, the more likely the CPU will execute faster than one CPI. Most superscalar CPUs do not completely duplicate the execution unit. There might be multiple ALUs, floating point units, etc. This means that certain instruction sequences can execute very quickly while others won't. You have to study the exact composition of your CPU to decide which instruction sequences produce the best performance.

4.8.6 Out of Order Execution

In a standard superscalar CPU it is the programmer's (or compiler's) responsibility to schedule (arrange) the instructions to avoid hazards and pipeline stalls. Fancier CPUs can actually remove some of this burden and improve performance by automatically rescheduling instructions while the program executes. To understand how this is possible, consider the following instruction sequence:

```
mov( SomeVar, ebx );
mov( [ebx], eax );
mov( 2000, ecx );
```

A data hazard exists between the first and second instructions above. The second instruction must delay until the first instruction completes execution. This introduces a pipeline stall and increases the running time of the program. Typically, the stall affects every instruction that follows. However, note that the third instruction's execution does not depend on the result from either of the first two instructions. Therefore, there is no reason to stall the execution of the "mov(2000, ecx);" instruction. It may continue executing while the second instruction waits for the first to complete. This technique, appearing in later members of the Pentium line, is called "out of order execution" because the CPU completes the execution of some instruction prior to the execution of previous instructions appearing in the code stream.

Clearly, the CPU may only execute instruction out of sequence if doing so produces exactly the same results as in-order execution. While there are a lot of little technical issues that make this problem a little more difficult than it seems, with enough engineering effort it is quite possible to implement this feature.

Although you might think that this extra effort is not worth it (why not make it the programmer's or compiler's responsibility to schedule the instructions) there are some situations where out of order execution will improve performance that static scheduling could not handle.

4.8.7 Register Renaming

One problem that hampers the effectiveness of superscalar operation on the 80x86 CPU is the 80x86's limited number of general purpose registers. Suppose, for example, that the CPU had four different pipelines and, therefore, was capable of executing four instructions simultaneously. Actually achieving four instructions per clock cycle would be very difficult because most instructions (that can execute simultaneously with other instructions) operate on two register operands. For four instructions to execute concurrently, you'd need four separate destination registers and four source registers (and the two sets of registers must be disjoint, that is, a destination register for one instruction cannot be the source of another). CPUs that have lots of registers can handle this task quite easily, but the limited register set of the 80x86 makes this difficult. Fortunately, there is a way to alleviate part of the problem: through *register renaming*.

Register renaming is a sneaky way to give a CPU more registers than it actually has. Programmers will not have direct access to these extra registers, but the CPU can use these additional registers to prevent hazards in certain cases. For example, consider the following short instruction sequence:

```
mov( 0, eax );
mov( eax, i );
mov( 50, eax );
mov( eax, j );
```

Clearly a data hazard exists between the first and second instructions and, likewise, a data hazard exists between the third and fourth instructions in this sequence. Out of order execution in a superscalar CPU would normally allow the first and third instructions to execute concurrently and then the second and fourth instructions could also execute concurrently. However, a data hazard, of sorts, also exists between the first and third instructions since they use the same register. The programmer could have easily solved this problem by using a different register (say EBX) for the third and fourth instructions. However, let's assume that the programmer was unable to do this because the other registers are all holding important values. Is this sequence doomed to executing in four cycles on a superscalar CPU that should only require two?

One advanced trick a CPU can employ is to create a bank of registers for each of the general purpose registers on the CPU. That is, rather than having a single EAX register, the CPU could support an array of EAX registers; let's call these registers EAX[0], EAX[1], EAX[2], etc. Similarly, you could have an array of each of the registers, so we could also have EBX[0]..EBX[n], ECX[0]..ECX[n], etc. Now the instruction set does not give the programmer the ability to select one of these specific register array elements for a given instruction, but the CPU can automatically choose a different register array element if doing so would not change the overall computation and doing so could speed up the execution of the program. For example, consider the following sequence (with register array elements automatically chosen by the CPU):

```
mov( 0, eax[0] );
mov( eax[0], i );
mov( 50, eax[1] );
mov( eax[1], j );
```

Since EAX[0] and EAX[1] are different registers, the CPU can execute the first and third instructions concurrently. Likewise, the CPU can execute the second and fourth instructions concurrently.

The code above provides an example of *register renaming*. Dynamically, the CPU automatically selects one of several different elements from a register array in order to prevent data hazards. Although this is a simple example, and different CPUs implement register renaming in many different ways, this example does demonstrate how the CPU can improve performance in certain instances through the use of this technique.

4.8.8 Very Long Instruction Word Architecture (VLIW)

Superscalar operation attempts to schedule, in hardware, the execution of multiple instructions simultaneously. Another technique that Intel is using in their IA-64 architecture is the use of very long instruction words, or VLIW. In a VLIW computer system, the CPU fetches a large block of bytes (41 in the case of the IA-64 Itanium CPU) and decodes and executes this block all at once. This block of bytes usually contains two or more instructions (three in the case of the IA-64). VLIW computing requires the programmer or compiler to properly schedule the instructions in each block (so there are no hazards or other conflicts), but if properly scheduled, the CPU can execute three or more instructions per clock cycle.

The Intel IA-64 Architecture is not the only computer system to employ a VLIW architecture. Transmeta's Crusoe processor family also uses a VLIW architecture. The Crusoe processor is different than the IA-64 architecture insofar as it does not support native execution of IA-32 instructions. Instead, the Crusoe processor dynamically translates 80x86 instructions to Crusoe's VLIW instructions. This "code morphing" technology results in code running about 50% slower than native code, though the Crusoe processor has other advantages.

We will not consider VLIW computing any further since the IA-32 architecture does not support it. But keep this architectural advance in mind if you move towards the IA-64 family or the Crusoe family.

4.8.9 Parallel Processing

Most of the techniques for improving CPU performance via architectural advances involve the parallel (overlapped) execution of instructions. Most of the techniques of this chapter are transparent to the programmer. That is, the programmer does not have to do anything special to take minimal advantage of the parallel operation of pipelines and superscalar operations. True, if programmers are aware of the underlying architecture they can write code that runs even faster, but these architectural advances often improve performance even if programmers do not write special code to take advantage of them.

The only problem with this approach (attempting to dynamically parallelize an inherently sequential program) is that there is only so much you can do to parallelize a program that requires sequential execution for proper operation (which covers most programs). To truly produce a parallel program, the programmer must specifically write parallel code; of course, this does require architectural support from the CPU. This section and the next touches on the types of support a CPU can provide.

Typical CPUs use what is known as the SISD model: *Single Instruction, Single Data*. This means that the CPU executes one instruction at a time that operates on a single piece of data¹⁹. Two common parallel models are the so-called SIMD (*Single Instruction, Multiple Data*) and MIMD (*Multiple Instruction, Multiple Data*) models. As it turns out, x86 systems can support both of these parallel execution models.

In the SIMD model, the CPU executes a single instruction stream, just like the standard SISD model. However, the CPU executes the specified operation on multiple pieces of data concurrently rather than a single data object. For example, consider the 80x86 ADD instruction. This is a SISD instruction that operates on (that is, produces) a single piece of data; true, the instruction fetches values from two source operands and stores a sum into a destination operand but the end result is that the ADD instruction will only produce a single sum. An SIMD version of ADD, on the other hand, would compute the sum of several values simultaneously. The Pentium III's MMX and SIMD instruction extensions operate in exactly this fashion. With an MMX instruction, for example, you can add up to eight separate pairs of values with the execution of a single instruction. The aptly named SIMD instruction extensions operate in a similar fashion.

Note that SIMD instructions are only useful in specialized situations. Unless you have an algorithm that can take advantage of SIMD instructions, they're not that useful. Fortunately, high-speed 3-D graphics and multimedia applications benefit greatly from these SIMD (and MMX) instructions, so their inclusion in the 80x86 CPU offers a huge performance boost for these important applications.

The MIMD model uses multiple instructions, operating on multiple pieces of data (usually one instruction per data object, though one of these instructions could also operate on multiple data items). These multiple instructions execute independently of one another. Therefore, it's very rare that a single program (or, more specifically, a single thread of execution) would use the MIMD model. However, if you have a multi-programming environment with multiple programs attempting to execute concurrently in memory, the MIMD model does allow each of those programs to execute their own code stream concurrently. This type of parallel system is usually called a multiprocessor system. Multiprocessor systems are the subject of the next section.

The common computation models are SISD, SIMD, and MIMD. If you're wondering if there is a MISD model (Multiple Instruction, Single Data) the answer is no. Such an architecture doesn't really make sense.

4.8.10 Multiprocessing

Pipelining, superscalar operation, out of order execution, and VLIW design are techniques CPU designers use in order to execute several operations in parallel. These techniques support *fine-grained parallelism*²⁰ and are useful for speeding up adjacent instructions in a computer system. If adding more functional units increases parallelism (and, therefore, speeds up the system), you might wonder what would happen if you added two CPUs to the system. This technique, known as *multiprocessing*, can improve system performance, though not as uniformly as other techniques. As noted in the previous section, a multiprocessor system uses the MIMD parallel execution model.

The techniques we've considered to this point don't require special programming to realize a performance increase. True, if you do pay attention you will get better performance; but no special programming is necessary to activate these features. Multiprocessing, on the other hand, doesn't help a program one bit unless that program was specifically written to use multiprocessor (or runs under an O/S specifically written to support multiprocessing). If you build a system with two CPUs, those CPUs cannot trade off executing alternate instructions within a program. In fact, it is very expensive (timewise) to switch the execution of a program from one processor to another. Therefore, multiprocessor systems are really only effective in a system that execute multiple programs concurrently (i.e., a multitasking system)²¹. To differentiate this type of parallelism from that afforded by pipelining and superscalar operation, we'll call this kind of parallelism *coarse-grained parallelism*.

19. We will ignore the parallelism provided by pipelining and superscalar operation in this discussion.

20. For our purposes, fine-grained parallelism means that we are executing adjacent program instructions in parallel.

21. Technically, it only needs to execute multiple threads concurrently, but we'll ignore this distinction here since the technical distinction between threads and programs/processes is beyond the scope of this chapter.

Adding multiple processors to a system is not as simple as wiring the processor to the motherboard. A big problem with multiple processors is the *cache coherency* problem. To understand this problem, consider two separate programs running on separate processors in a multiprocessor system. Suppose also that these two processor communicate with one another by writing to a block of shared physical memory. Unfortunately, when CPU #1 writes to this block of addresses the CPU caches the data up and might not actually write the data to physical memory for some time. Simultaneously, CPU #2 might be attempting to read this block of shared memory but winds up reading the data out of its local cache rather than the data that CPU #1 wrote to the block of shared memory (assuming the data made it out of CPU #1's local cache). In order for these two functions to operate properly, the two CPU's must communicate writes to common memory addresses in cache between themselves. This is a very complex and involved process.

Currently, the Pentium III and IV processors directly support cache updates between two CPUs in a system. Intel also builds a more expensive processor, the XEON, that supports more than two CPUs in a system. However, one area where the RISC CPUs have a big advantage over Intel is in the support for multiple processors in a system. While Intel systems reach a point of diminishing returns at about 16 processors, Sun SPARC and other RISC processors easily support 64-CPU systems (with more arriving, it seems, every day). This is why large databases and large web server systems tend to use expensive UNIX-based RISC systems rather than x86 systems.

4.9 Putting It All Together

The performance of modern CPUs is intrinsically tied to the architecture of that CPU. Over the past half century there have been many major advances in CPU design that have dramatically improved performance. Although the clock frequency has improved by over four orders of magnitude during this time period, other improvements have added one or two orders of magnitude improvement as well. Over the 80x86's lifetime, performance has improved 10,000-fold.

Unfortunately, the 80x86 family has just about pushed the limits of what it can achieve by extending the architecture. Perhaps another order of magnitude is possible, but Intel is reaching the point of diminishing returns. Having realized this, Intel has chosen to implement a new architecture using VLIW for their IA-64 family. Only time will prove whether their approach is the correct one, but most people believe that the IA-32 has reached the end of its lifetime. On the other hand, people have been announcing the death of the IA-32 for the past decade, so we'll see what happens now.

5.1 Chapter Overview

This chapter discusses the low-level implementation of the 80x86 instruction set. It describes how the Intel engineers decided to encode the instructions in a numeric format (suitable for storage in memory) and it discusses the trade-offs they had to make when designing the CPU. This chapter also presents a historical background of the design effort so you can better understand the compromises they had to make.

5.2 The Importance of the Design of the Instruction Set

In this chapter we will be exploring one of the most interesting and important aspects of CPU design: the design of the CPU's instruction set. The instruction set architecture (or ISA) is one of the most important design issues that a CPU designer must get right from the start. Features like caches, pipelining, superscalar implementation, etc., can all be grafted on to a CPU design long after the original design is obsolete. However, it is very difficult to change the instructions a CPU executes once the CPU is in production and people are writing software that uses those instructions. Therefore, one must carefully choose the instructions for a CPU.

You might be tempted to take the "kitchen sink" approach to instruction set design¹ and include as many instructions as you can dream up in your instruction set. This approach fails for several reasons we'll discuss in the following paragraphs. Instruction set design is the epitome of compromise management. Good CPU design is the process of selecting what to throw out rather than what to leave in. It's easy enough to say "let's include everything." The hard part is deciding what to leave out once you realize you can't put everything on the chip.

Nasty reality #1: Silicon real estate. The first problem with "putting it all on the chip" is that each feature requires some number of transistors on the CPU's silicon die. CPU designers work with a "silicon budget" and are given a finite number of transistors to work with. This means that there aren't enough transistors to support "putting all the features" on a CPU. The original 8086 processor, for example, had a transistor budget of less than 30,000 transistors. The Pentium III processor had a budget of over eight million transistors. These two budgets reflect the differences in semiconductor technology in 1978 vs. 1998.

Nasty reality #2: Cost. Although it is possible to use millions of transistors on a CPU today, the more transistors you use the more expensive the CPU. Pentium III processors, for example, cost hundreds of dollars (circa 2000). A CPU with only 30,000 transistors (also circa 2000) would cost only a few dollars. For low-cost systems it may be more important to shave some features and use fewer transistors, thus lowering the CPU's cost.

Nasty reality #3: Expandability. One problem with the "kitchen sink" approach is that it's very difficult to anticipate all the features people will want. For example, Intel's MMX and SIMD instruction enhancements were added to make multimedia programming more practical on the Pentium processor. Back in 1978 very few people could have possibly anticipated the need for these instructions.

Nasty reality #4: Legacy Support. This is almost the opposite of expandability. Often it is the case that an instruction the CPU designer feels is important turns out to be less useful than anticipated. For example, the LOOP instruction on the 80x86 CPU sees very little use in modern high-performance programs. The 80x86 ENTER instruction is another good example. When designing a CPU using the "kitchen sink" approach, it is often common to discover that programs almost never use some of the available instructions. Unfortunately, you cannot easily remove instructions in later versions of a processor because this will break some existing programs that use those instructions. Generally, once you add an instruction you have to support it forever in the instruction set. Unless very few programs use the instruction (and you're willing to let

1. As in "Everything, including the kitchen sink."

them break) or you can automatically simulate the instruction in software, removing instructions is a very difficult thing to do.

Nasty reality #4: Complexity. The popularity of a new processor is easily measured by how much software people write for that processor. Most CPU designs die a quick death because no one writes software specific to that CPU. Therefore, a CPU designer must consider the assembly programmers and compiler writers who will be using the chip upon introduction. While a "kitchen sink" approach might seem to appeal to such programmers, the truth is no one wants to learn an overly complex system. If your CPU does everything under the sun, this might appeal to someone who is already familiar with the CPU. However, pity the poor soul who doesn't know the chip and has to learn it all at once.

These problems with the "kitchen sink" approach all have a common solution: design a simple instruction set to begin with and leave room for later expansion. This is one of the main reasons the 80x86 has proven to be so popular and long-lived. Intel started with a relatively simple CPU and figured out how to extend the instruction set over the years to accommodate new features.

5.3 Basic Instruction Design Goals

In a typical Von Neumann architecture CPU, the computer encodes CPU instructions as numeric values and stores these numeric values in memory. The encoding of these instructions is one of the major tasks in instruction set design and requires very careful thought.

To encode an instruction we must pick a unique numeric opcode value for each instruction (clearly, two different instructions cannot share the same numeric value or the CPU will not be able to differentiate them when it attempts to decode the opcode value). With an n -bit number, there are 2^n different possible opcodes, so to encode m instructions you will need an opcode that is at least $\log_2(m)$ bits long.

Encoding opcodes is a little more involved than assigning a unique numeric value to each instruction. Remember, we have to use actual hardware (i.e., decoder circuits) to figure out what each instruction does and command the rest of the hardware to do the specified task. Suppose you have a seven-bit opcode. With an opcode of this size we could encode 128 different instructions. To decode each instruction individually requires a seven-line to 128-line decoder – an expensive piece of circuitry. Assuming our instructions contain certain patterns, we can reduce the hardware by replacing this large decoder with three smaller decoders.

If you have 128 truly unique instructions, there's little you can do other than to decode each instruction individually. However, in most architectures the instructions are not completely independent of one another. For example, on the 80x86 CPUs the opcodes for "mov(eax, ebx);" and "mov(ecx, edx);" are different (because these are different instructions) but these instructions are not unrelated. They both move data from one register to another. In fact, the only difference between them is the source and destination operands. This suggests that we could encode instructions like MOV with a sub-opcode and encode the operands using other strings of bits within the opcode.

For example, if we really have only eight instructions, each instruction has two operands, and each operand can be one of four different values, then we can encode the opcode as three packed fields containing three, two, and two bits (see Figure 5.1). This encoding only requires the use of three simple decoders to completely determine what instruction the CPU should execute. While this is a bit of a trivial case, it does demonstrate one very important facet of instruction set design – it is important to make opcodes easy to decode and the easiest way to do this is to break up the opcode into several different bit fields, each field contributing part of the information necessary to execute the full instruction. The smaller these bit fields, the easier it will be for the hardware to decode and execute them².

2. Not to mention faster and less expensive.

Note: the circuitry attached to the destination register bits is identical to the circuitry for the source register bits.

Figure 5.1 Separating an Opcode into Separate Fields to Ease Decoding

Although Intel probably went a little overboard with the design of the original 8086 instruction set, an important design goal is to keep instruction sizes within a reasonable range. CPUs with unnecessarily long instructions consume extra memory for their programs. This tends to create more cache misses and, therefore, hurts the overall performance of the CPU. Therefore, we would like our instructions to be as compact as possible so our programs' code uses as little memory as possible.

It would seem that if we are encoding 2^n different instructions using n bits, there would be very little leeway in choosing the size of the instruction. It's going to take n bits to encode those 2^n instructions, you can't do it with any fewer. You may, of course, use more than n bits. And believe it or not, that's the secret to reducing the size of a typical program on the CPU.

Before discussing how to use longer instructions to generate shorter programs, a short digression is necessary. The first thing to note is that we generally cannot choose an arbitrary number of bits for our opcode length. Assuming that our CPU is capable of reading bytes from memory, the opcode will probably have to be some even multiple of eight bits long. If the CPU is not capable of reading bytes from memory (e.g., most RISC CPUs only read memory in 32 or 64 bit chunks) then the opcode is going to be the same size as

the smallest object the CPU can read from memory at one time (e.g., 32 bits on a typical RISC chip). Any attempt to shrink the opcode size below this data bus enforced lower limit is futile. Since we're discussing the 80x86 architecture in this text, we'll work with opcodes that must be an even multiple of eight bits long.

Another point to consider here is the size of an instruction's operands. Some CPU designers (specifically, RISC designers) include all operands in their opcode. Other CPU designers (typically CISC designers) do not count operands like immediate constants or address displacements as part of the opcode (though they do usually count register operand encodings as part of the opcode). We will take the CISC approach here and not count immediate constant or address displacement values as part of the actual opcode.

With an eight-bit opcode you can only encode 256 different instructions. Even if we don't count the instruction's operands as part of the opcode, having only 256 different instructions is somewhat limiting. It's not that you can't build a CPU with an eight-bit opcode, most of the eight-bit processors predating the 8086 had eight-bit opcodes, it's just that modern processors tend to have far more than 256 different instructions. The next step up is a two-byte opcode. With a two-byte opcode we can have up to 65,536 different instructions (which is probably enough) but our instructions have doubled in size (not counting the operands, of course).

If reducing the instruction size is an important design goal³ we can employ some techniques from data compression theory to reduce the average size of our instructions. The basic idea is this: first we analyze programs written for our CPU (or a CPU similar to ours if no one has written any programs for our CPU) and count the number of occurrences of each opcode in a large number of typical applications. We then create a sorted list of these opcodes from most-frequently-used to least-frequently-used. Then we attempt to design our instruction set using one-byte opcodes for the most-frequently-used instructions, two-byte opcodes for the next set of most-frequently-used instructions, and three (or more) byte opcodes for the rarely used instructions. Although our maximum instruction size is now three or more bytes, most of the actual instructions appearing in a program will use one or two byte opcodes, so the average opcode length will be somewhere between one and two bytes (let's call it 1.5 bytes) and a typical program will be shorter than had we chosen a two byte opcode for all instructions (see Figure 5.2).

3. To many CPU designers it is not; however, since this was a design goal for the 8086 we'll follow this path.

If the H.O. two bits of the first opcode byte are not both zero, then the whole opcode is one byte long and the remaining six bits let us encode 64 one-byte instructions. Since there are a total of three opcode bytes of these form, we can encode up to 192 different one-byte instructions.

If the H.O. three bits of our first opcode byte contain %001, then the opcode is two bytes long and the remaining 13 bits let us encode 8192 different instructions.

If the H.O. three bits of our first opcode byte contain all zeros, then the opcode is three bytes long and the remaining 21 bits let us encode two million (2^{21}) different instructions.

Figure 5.2 Encoding Instructions Using a Variable-Length Opcode

Although using variable-length instructions allows us to create smaller programs, it comes at a price. First of all, decoding the instructions is a bit more complicated. Before decoding an instruction field, the CPU must first decode the instruction's size. This extra step consumes time and may affect the overall performance of the CPU (by introducing delays in the decoding step and, thereby, limiting the maximum clock

frequency of the CPU). Another problem with variable length instructions is that it makes decoding multiple instructions in a pipeline quite difficult (since we cannot trivially determine the instruction boundaries in the prefetch queue). These reasons, along with some others, is why most popular RISC architectures avoid variable-sized instructions. However, for our purpose, we'll go with a variable length approach since saving memory is an admirable goal.

Before actually choosing the instructions you want to implement in your CPU, now would be a good time to plan for the future. Undoubtedly, you will discover the need for new instructions at some point in the future, so reserving some opcodes specifically for that purpose is a real good idea. If you were using the instruction encoding appearing in Figure 5.2 for your opcode format, it might not be a bad idea to reserve one block of 64 one-byte opcodes, half (4,096) of the two-byte instructions, and half (1,048,576) of the three-byte opcodes for future use. In particular, giving up 64 of the very valuable one-byte opcodes may seem extravagant, but history suggests that such foresight is rewarded.

The next step is to choose the instructions you want to implement. Note that although we've reserved nearly half the instructions for future expansion, we don't actually have to implement instructions for all the remaining opcodes. We can choose to leave a good number of these instructions unimplemented (and effectively reserve them for the future as well). The right approach is not to see how quickly we can use up all the opcodes, but rather to ensure that we have a consistent and complete instruction set given the compromises we have to live with (e.g., silicon limitations). The main point to keep in mind here is that it's much easier to add an instruction later than it is to remove an instruction later. So for the first go-around, it's generally better to go with a simpler design rather than a more complex design.

The first step is to choose some generic instruction types. For a first attempt, you should limit the instructions to some well-known and common instructions. The best place to look for help in choosing these instructions is the instruction sets of other processors. For example, most processors you find will have instructions like the following:

- Data movement instructions (e.g., MOV)
- Arithmetic and logical instructions (e.g., ADD, SUB, AND, OR, NOT)
- Comparison instructions
- A set of conditional jump instructions (generally used after the compare instructions)
- Input/Output instructions
- Other miscellaneous instructions

Your goal as the designer of the CPU's initial instruction set is to choose a reasonable set of instructions that will allow programmers to efficiently write programs (using as few instructions as possible) without adding so many instructions you exceed your silicon budget or violate other system compromises. This is a very strategic decision, one that CPU designers should base on careful research, experimentation, and simulation. The job of the CPU designer is not to create the best instruction set, but to create an instruction set that is optimal given all the constraints.

Once you've decided which instructions you want to include in your (initial) instruction set, the next step is to assign opcodes for them. The first step is to group your instructions into sets by common characteristics of those instructions. For example, an ADD instruction is probably going to support the exact same set of operands as the SUB instruction. So it makes sense to put these two instructions into the same group. On the other hand, the NOT instruction generally requires only a single operand⁴ as does a NEG instruction. So you'd probably put these two instructions in the same group but a different group than ADD and SUB.

Once you've grouped all your instructions, the next step is to encode them. A typical encoding will use some bits to select the group the instruction falls into, it will use some bits to select a particular instruction from that group, and it will use some bits to determine the types of operands the instruction allows (e.g., registers, memory locations, and constants). The number of bits needed to encode all this information may have a direct impact on the instruction's size, regardless of the frequency of the instruction. For example, if you need two bits to select a group, four bits to select an instruction within that group, and six bits to specify the instruction's operand types, you're not going to fit this instruction into an eight-bit opcode. On the other hand, if all you really want to do is push one of eight different registers onto the stack, you can use four bits

4. Assuming this operation treats its single operand as both a source and destination operand, a common way of handling this instruction.

to select the PUSH instruction and three bits to select the register (assuming the encoding in Figure 5.2 the eighth and H.O. bit would have to contain zero).

Encoding operands is always a problem because many instructions allow a large number of operands. For example, the generic 80x86 MOV instruction requires a two-byte opcode⁵. However, Intel noticed that the "mov(disp, eax);" and "mov(eax, disp);" instructions occurred very frequently. So they created a special one byte version of this instruction to reduce its size and, therefore, the size of those programs that use this instruction frequently. Note that Intel did not remove the two-byte versions of these instructions. They have two different instructions that will store EAX into memory or load EAX from memory. A compiler or assembler would always emit the shorter of the two instructions when given an option of two or more instructions that wind up doing exactly the same thing.

Notice an important trade-off Intel made with the MOV instruction. They gave up an extra opcode in order to provide a shorter version of one of the MOV instructions. Actually, Intel used this trick all over the place to create shorter and easier to decode instructions. Back in 1978 this was a good compromise (reducing the total number of possible instructions while also reducing the program size). Today, a CPU designer would probably want to use those redundant opcodes for a different purpose, however, Intel's decision was reasonable at the time (given the high cost of memory in 1978).

To further this discussion, we need to work with an example. So the next section will go through the process of designing a very simple instruction set as a means of demonstrating this process.

5.4 The Y86 Hypothetical Processor

Because of enhancements made to the 80x86 processor family over the years, Intel's design goals in 1978, and advances in computer architecture occurring over the years, the encoding of 80x86 instructions is very complex and somewhat illogical. Therefore, the 80x86 is not a good candidate for an example architecture when discussing how to design and encode an instruction set. However, since this is a text about 80x86 assembly language programming, attempting to present the encoding for some simpler real-world processor doesn't make sense. Therefore, we will discuss instruction set design in two stages: first, we will develop a simple (trivial) instruction set for a hypothetical processor that is a small subset of the 80x86, then we will expand our discussion to the full 80x86 instruction set. Our hypothetical processor is not a true 80x86 CPU, so we will call it the Y86 processor to avoid any accidental association with the Intel x86 family.

The Y86 processor is a *very* stripped down version of the x86 CPUs. First of all, the Y86 only supports one operand size – 16 bits. This simplification frees us from having to encode the size of the operand as part of the opcode (thereby reducing the total number of opcodes we will need). Another simplification is that the Y86 processor only supports four 16-bit registers: AX, BX, CX, and DX. This lets us encode register operands with only two bits (versus the three bits the 80x86 family requires to encode eight registers). Finally, the Y86 processors only support a 16-bit address bus with a maximum of 65,536 bytes of addressable memory. These simplifications, plus a very limited instruction set will allow us to encode all Y86 instructions using a single byte opcode and a two-byte displacement/offset (if needed).

The Y86 CPU provides 20 instructions. Seven of these instructions have two operands, eight of these instructions have a single operand, and five instructions have no operands at all. The instructions are MOV (two forms), ADD, SUB, CMP, AND, OR, NOT, JE, JNE, JB, JBE, JA, JAE, JMP, BRK, IRET, HALT, GET, and PUT. The following paragraphs describe how each of these work.

The MOV instruction is actually two instruction classes merged into the same instruction. The two forms of the mov instruction take the following forms:

```
mov( reg/memory/constant, reg );
mov( reg, memory );
```

where *reg* is any of AX, BX, CX, or DX; *constant* is a numeric constant (using hexadecimal notation), and *memory* is an operand specifying a memory location. The next section describes the possible forms the

5. Actually, Intel claims it's a one byte opcode plus a one-byte "mod-reg-r/m" byte. For our purposes, we'll treat the mod-reg-r/m byte as part of the opcode.

memory operand can take. The “reg/memory/constant” operand tells you that this particular operand may be a register, memory location, or a constant.

The arithmetic and logical instructions take the following forms:

```
add( reg/memory/constant, reg );
sub( reg/memory/constant, reg );
cmp( reg/memory/constant, reg );
and( reg/memory/constant, reg );
or( reg/memory/constant, reg );

not( reg/memory );
```

Note: the NOT instruction appears separately because it is in a different class than the other arithmetic instructions (since it supports only a single operand).

The ADD instruction adds the value of the first operand to the second (register) operand, leaving the sum in the second (register) operand. The SUB instruction subtracts the value of the first operand from the second, leaving the difference in the second operand. The CMP instruction compares the first operand against the second and saves the result of this comparison for use with one of the conditional jump instructions (described in a moment). The AND and OR instructions compute the corresponding bitwise logical operation on the two operands and store the result into the first operand. The NOT instruction inverts the bits in the single memory or register operand.

The *control transfer instructions* interrupt the sequential execution of instructions in memory and transfer control to some other point in memory either unconditionally, or after testing the result of the previous CMP instruction. These instructions include the following:

```
ja  dest;  -- Jump if above (i.e., greater than)
jae dest;  -- Jump if above or equal (i.e., greater than or equal)
jb  dest;  -- Jump if below (i.e., less than)
jbe dest;  -- Jump if below or equal (i.e., less than or equal)
je  dest;  -- Jump if equal
jne dest;  -- Jump if not equal

jmp dest;  -- Unconditional jump

iret;      -- Return from an interrupt
```

The first six instructions let you check the result of the previous CMP instruction for greater than, greater or equal, less than, less or equal, equality, or inequality⁶. For example, if you compare the AX and BX registers with a “cmp(ax, bx);” instruction and execute the JA instruction, the Y86 CPU will jump to the specified destination location if AX was greater than BX. If AX was not greater than BX, control will fall through to the next instruction in the program.

The JMP instruction unconditionally transfers control to the instruction at the destination address. The IRET instruction returns control from an interrupt service routine, which we will discuss later.

The GET and PUT instructions let you read and write integer values. GET will stop and prompt the user for a hexadecimal value and then store that value into the AX register. PUT displays (in hexadecimal) the value of the AX register.

The remaining instructions do not require any operands, they are HALT and BRK. HALT terminates program execution and BRK stops the program in a state that it can be restarted.

The Y86 processors require a unique opcode for every different instruction, not just the instruction classes. Although “mov(bx, ax);” and “mov(cx, ax);” are both in the same class, they must have different opcodes if the CPU is to differentiate them. However, before looking at all the possible opcodes, perhaps it would be a good idea to learn about all the possible operands for these instructions.

6. The Y86 processor only performs *unsigned* comparisons.

5.4.1 Addressing Modes on the Y86

The Y86 instructions use five different operand types: registers, constants, and three memory addressing schemes. Each form is called an *addressing mode*. The Y86 processor supports the *register* addressing mode⁷, the *immediate* addressing mode, the *indirect* addressing mode, the *indexed* addressing mode, and the *direct* addressing mode. The following paragraphs explain each of these modes.

Register operands are the easiest to understand. Consider the following forms of the MOV instruction:

```
mov( ax, ax );
mov( bx, ax );
mov( cx, ax );
mov( dx, ax );
```

The first instruction accomplishes absolutely nothing. It copies the value from the AX register back into the AX register. The remaining three instructions copy the values of BX, CX and DX into AX. Note that these instructions leave BX, CX, and DX unchanged. The second operand (the destination) is not limited to AX; you can move values to any of these registers.

Constants are also pretty easy to deal with. Consider the following instructions:

```
mov( 25, ax );
mov( 195, bx );
mov( 2056, cx );
mov( 1000, dx );
```

These instructions are all pretty straightforward; they load their respective registers with the specified hexadecimal constant⁸.

There are three addressing modes which deal with accessing data in memory. The following instructions demonstrate the use of these addressing modes:

```
mov( [1000], ax );
mov( [bx], ax );
mov( [1000+bx], ax );
```

The first instruction above uses the direct addressing mode to load AX with the 16 bit value stored in memory starting at location \$1000.

The "mov([bx], ax);" instruction loads AX from the memory location specified by the contents of the bx register. This is an indirect addressing mode. Rather than using the value in BX, this instruction accesses to the memory location whose address appears in BX. Note that the following two instructions:

```
mov( 1000, bx );
mov( [bx], ax );
```

are equivalent to the single instruction:

```
mov( [1000], ax );
```

Of course, the second sequence is preferable. However, there are many cases where the use of indirection is faster, shorter, and better. We'll see some examples of this a little later.

The last memory addressing mode is the *indexed* addressing mode. An example of this memory addressing mode is

```
mov( [1000+bx], ax );
```

This instruction adds the contents of BX with \$1000 to produce the address of the memory value to fetch. This instruction is useful for accessing elements of arrays, records, and other data structures.

7. Technically, registers do not have an address, but we apply the term *addressing mode* to registers nonetheless.

8. All numeric constants in Y86 assembly language are given in hexadecimal. The "\$" prefix is not necessary.

an *iii* field of %101. The source operand is CX, so the *mmm* field is %010 and the destination operand is DX so the *rr* field is %11. Merging these bits produces the opcode %10111010 or \$BA.

Figure 5.7 Encoding ADD(*cx*, *dx*);

Now consider the "add(5, ax);" instruction. Since this instruction has an immediate source operand, the *mmm* field will be %111. The destination register operand is AX (%00) so the full opcode becomes \$10100111 or \$A7. Note, however, that this does not complete the encoding of the instruction. We also have to include the 16-bit constant \$0005 as part of the instruction. The binary encoding of the constant must immediately follow the opcode in memory, so the sequence of bytes in memory (from lowest address to highest address) is \$A7, \$05, \$00. Note that the L.O. byte of the constant follows the opcode and the H.O. byte of the constant follows the L.O. byte. This sequence appears backwards because the bytes are arranged in order of increasing memory address and the H.O. byte of a constant always appears in the highest memory address.

Figure 5.8 Encoding ADD(5, *ax*);

The "add([2ff+bx], *cx*);" instruction also contains a 16-bit constant associated with the instruction's encoding – the displacement portion of the indexed addressing mode. To encode this instruction we use the following field values: *iii*=%101, *rr*=%10, and *mmm*=%101. This produces the opcode byte %10110101 or \$B5. The complete instruction also requires the constant \$2FF so the full instruction is the three-byte sequence \$B5, \$FF, \$02.

Figure 5.9 Encoding ADD([2ff+bx], *cx*);

Now consider the "add([1000], ax);" instruction. This instruction adds the 16-bit contents of memory locations \$1000 and \$1001 to the value in the AX register. Once again, $iii = \%101$ for the ADD instruction. The destination register is AX so $rr = \%00$. Finally, the addressing mode is the displacement-only addressing mode, so $mmm = \%110$. This forms the opcode $\%10100110$ or \$A6. The instruction is three bytes long since it must encode the displacement (address) of the memory location in the two bytes following the opcode. Therefore, the complete three-byte sequence is \$A6, \$00, \$10.

Figure 5.10 Encoding ADD([1000], ax);

The last addressing mode to consider is the register indirect addressing mode, [bx]. The "add([bx], bx);" instruction uses the following encoded values: $mmm = \%101$, $rr = \%01$ (bx), and $mmm = \%100$ ([bx]). Since the value in the BX register completely specifies the memory address, there is no need for a displacement field. Hence, this instruction is only one byte long.

Figure 5.11 Encoding the ADD([bx], bx); Instruction

You use a similar approach to encode the SUB, CMP, AND, and OR instructions as you do the ADD instruction. The only difference is that you use different values for the iii field in the opcode.

The MOV instruction is special because there are two forms of the MOV instruction. You encode the first form ($iii = \%110$) exactly as you do the ADD instruction. This form copies a constant or data from memory or a register (the mmm field) into a destination register (the rr field).

The second form of the MOV instruction ($iii = \%111$) copies data from a source register (rr) to a destination memory location (that the mmm field specifies). In this form of the MOV instruction, the source/destination meanings of the rr and mmm fields are reversed so that rr is the source field and mmm is the destination field. Another difference is that the mmm field may only contain the values $\%100$ ([bx]), $\%101$ ([disp+bx]), and $\%110$ ([disp]). The destination values cannot be $\%000$.. $\%011$ (registers) or $\%111$ (constant). These latter five encodings are illegal (the register destination instructions are handled by the other MOV instruction and storing data into a constant doesn't make any sense).

The Y86 processor supports a single instruction with a single memory/register operand – the NOT instruction. The NOT instruction has the syntax: "not(reg);" or "not(mem);" where mem represents one of the memory addressing modes ([bx], [disp+bx], or [disp]). Note that you may not specify a constant as the operand of the NOT instruction.

Since the NOT instruction has only a single operand, it only uses the mmm field to encode this operand. The rr field, combined with the iii field, selects the NOT instruction ($iii = \%000$ and $rr = \%10$). Whenever the

iii field contains zero this tells the CPU that special decoding is necessary for the instruction. In this case, the *rr* field specifies whether we have the NOT instruction or one of the other specially decoded instructions.

To encode an instruction like "not(ax);" you would simply specify %000 for *iii* and %10 for the *rr* fields. Then you would encode the *mmm* field the same way you would encode this field for the ADD instruction. Since *mmm*=%000 for AX, the encoding of "not(ax);" would be %00010000 or \$10.

Figure 5.12 Encoding the NOT(ax); Instruction

The NOT instruction does not allow an immediate (constant) operand, hence the opcode %00010111 (\$17) is an illegal opcode.

The Y86 conditional jump instructions also use a special encoding. These instructions are always three bytes long. The first byte (the opcode) specifies which conditional jump instruction to execute and the next two bytes specify where the CPU transfers if the condition is met. There are seven different Y86 jump instructions, six conditional jumps and one unconditional jump. These instructions set *mmm*=%000, *rr*=%01, and use the *mmm* field to select one of the seven possible jumps; the eighth possible opcode is an illegal opcode (see Figure 5.6). Encoding these instructions is relatively straight-forward. Once you pick the instruction you want to encode, you've determined the opcode (since there is a single opcode for each instruction). The opcode values fall in the range \$08..\$0E (\$0F is the illegal opcode).

The only field that requires some thought is the 16-bit operand that follows the opcode. This field holds the address of the target instruction to which the (un)conditional jump transfers if the condition is true (e.g., JE transfers control to this address if the previous CMP instruction found that its two operands were equal). To properly encode this field you must know the address of the opcode byte of the target instruction. If you've already converted the instruction to binary form and stored it into memory, this isn't a problem; just specify the address of that instruction as the operand of the condition jump. On the other hand, if you haven't yet written, converted, and placed that instruction into memory, knowing its address would seem to require a bit of divination. Fortunately, you can figure out the target address by computing the lengths of all the instructions between the current jump instruction you're encoding and the target instruction. Unfortunately, this is an arduous task. The best solution is to write all your instructions down on paper, compute their lengths (which is easy, all instructions are one or three bytes long depending on the presence of a 16-bit operand), and then assign an appropriate address to each instruction. Once you've done this (and, assuming you haven't made any mistakes) you'll know the starting address for each instruction and you can fill in target address operands in your (un)conditional jump instructions as you encode them. Fortunately, there is a better way to do this, as you'll see in the next section.

The last group of instructions, the zero operand instructions, are the easiest to encode. Since they have no operands they are always one byte long and the instruction uniquely specifies the opcode for the instruction. These instructions always have *iii*=%000, *rr*=%00, and *mmm* specifies the particular instruction opcode (see Figure 5.5). Note that the Y86 CPU leaves three of these instructions undefined (so we can use these opcodes for future expansion).

5.4.4 Using an Assembler to Encode Instructions

Of course, hand coding machine language programs as demonstrated in the previous section is impractical for all but the smallest programs. Certainly you haven't had to do anything like this when writing HLA

programs. The HLA compiler lets you create a text file containing human readable forms of the instructions. You might wonder why we can write such code for the 80x86 but not for the Y86. The answer is to use an assembler or compiler for the Y86. The job of an assembler/compiler is to read a text file containing human readable text and translate that text into the binary encoded representation for the corresponding machine language program.

An assembler or compiler is nothing special. It's just another program that executes on your computer system. The only thing special about an assembler or compiler is that it translates programs from one form (source code) to another (machine code). A typical Y86 assembler, for example, would read lines of text with each line containing a Y86 instruction, it would *parse*⁹ each statement and then write the binary equivalent of each instruction to memory or to a file for later execution. In the laboratory exercises associated with this chapter, you'll get the opportunity to use a simple Y86 assembler to translate Y86 source programs into Y86 machine code.

Assemblers have two big advantages over coding in machine code. First, they automatically translate strings like "ADD(ax, bx);" and "MOV(ax, [1000]);" to their corresponding binary form. Second, and probably even more important, assemblers let you attach labels to statements and refer to those labels within jump instructions; this means that you don't have to know the target address of an instruction in order to specify that instruction as the target of a jump or conditional jump instruction. The laboratory exercises associated with this chapter provide a very simple Y86 assembler that lets you specify up to 26 labels in a program (using the symbols 'A'..'Z'). To attach a label to a statement, you simply preface the instruction with the label and a colon, e.g.,

```
L: mov( 0, ax );
```

To transfer control to a statement with a label attached to it, you simply specify the label name as the operand of the jump instruction, e.g.,

```
jmp L;
```

The assembler will compute the address of the label and fill in the address for you whenever you specify the label as the operand of a jump or conditional jump instruction. The assembler can do this even if it hasn't yet encountered the label in the program's source file (i.e., the label is attached to a later instruction in the source file). Most assemblers accomplish this magic by making two passes over the source file. During the first pass the assembler determines the starting address of each symbol and stores this information in a simple database called the *symbol table*. The assembler does not emit any machine code during this first pass. Then the assembler makes a second pass over the source file and actually emits the machine code. During this second pass it looks up all label references in the symbol table and uses the information it retrieves from this database to fill in the operand fields of the instructions that refer to some symbol.

5.4.5 Extending the Y86 Instruction Set

The Y86 CPU is a trivial CPU, suitable only for demonstrating how to encode machine instructions. However, like any good CPU the Y86 design does provide the capability for expansion. So if you wanted to improve the CPU by adding new instructions, the ability to accomplish this exists in the instruction set.

There are two standard ways to increase the number of instructions in a CPU's instruction set. Both mechanisms require the presence of undefined (or illegal) opcodes on the CPU. Since the Y86 CPU has several of these, we can expand the instruction set.

The first method is to directly use the undefined opcodes to define new instructions. This works best when there are undefined bit patterns within an opcode group and the new instruction you want to add falls into that same group. For example, the opcode %00011mmm falls into the same group as the NOT instruction. If you decided that you really needed a NEG (negate, take the two's complement) instruction, using this particular opcode for this purpose makes a lot of sense because you'd probably expect the NEG instruction to use the same syntax (and, therefore, decoding) as the NOT instruction.

9. "Parse" means to figure out the meaning of the statement.

Likewise, if you want to add a zero-operand instruction to the instruction set, there are three undefined zero-operand instructions that you could use for this purpose. You'd just appropriate one of these opcodes and assign your instruction to it.

Unfortunately, the Y86 CPU doesn't have that many illegal opcodes open. For example, if you wanted to add the SHL, SHR, ROL, and ROR instructions (shift and rotate left and right) as single-operand instructions, there is insufficient space in the single operand instruction opcodes to add these instructions (there is currently only one open opcode you could use). Likewise, there are no two-operand opcodes open, so if you wanted to add an XOR instruction or some other two-operand instruction, you'd be out of luck.

A common way to handle this dilemma (one the Intel designers have employed) is to use a prefix opcode byte. This opcode expansion scheme uses one of the undefined opcodes as an opcode prefix byte. Whenever the CPU encounters a prefix byte in memory, it reads and decodes the next byte in memory as the actual opcode. However, it does not treat this second byte as it would any other opcode. Instead, this second opcode byte uses a completely different encoding scheme and, therefore, lets you specify as many new instructions as you can encode in that byte (or bytes, if you prefer). For example, the opcode \$FF is illegal (it corresponds to a "mov(dx, const);" instruction) so we can use this byte as a special prefix byte to further expand the instruction set¹⁰.

Figure 5.13 Using a Prefix Byte to Extend the Instruction Set

5.5 Encoding 80x86 Instructions

The Y86 processor is simple to understand, easy to hand encode instructions for it, and a great vehicle for learning how to assign opcodes. It's also a purely hypothetical device intended only as a teaching tool. Therefore, you can now forget all about the Y86, it's served its purpose. Now it's time to take a look at the actual machine instruction format for the 80x86 CPU family.

They don't call the 80x86 CPU a *Complex Instruction Set Computer* for nothing. Although more complex instruction encodings do exist, no one is going to challenge the assertion that the 80x86 has a complex instruction encoding. The generic 80x86 instruction takes the form shown in Figure 5.14. Although this diagram seems to imply that instructions can be up to 16 bytes long, in actuality the 80x86 will not allow instructions greater than 15 bytes in length.

10. We could also have used values \$F7, \$EF, and \$E7 since they also correspond to an attempt to store a register into a constant. However, \$FF is easier to decode. On the other hand, if you need even more prefix bytes for instruction expansion, you can use these three values as well.

Figure 5.14 80x86 Instruction Encoding

The prefix bytes are not the "opcode expansion prefix" that the previous sections in this chapter discussed. Instead, these are special bytes to modify the behavior of existing instructions (rather than define new instructions). We'll take a look at a couple of these prefix bytes in a little bit, others we'll leave for discussion in later chapters. The 80x86 certainly supports more than four prefix values, however, an instruction may have a maximum of four prefix bytes attached to it. Also note that the behavior of many prefix bytes are mutually exclusive and the results are undefined if you put a pair of mutually exclusive prefix bytes in front of an instruction.

The 80x86 supports two basic opcode sizes: a standard one-byte opcode and a two-byte opcode consisting of a \$0F opcode expansion prefix byte and a second byte specifying the actual instruction. One way to view these opcode bytes is as an eight-bit extension of the *iii* field in the Y86 encoding. This provides for up to 512 different instruction classes (although the 80x86 does not yet use them all). In reality, various instruction classes use certain bits in this opcode for decidedly non-instruction-class purposes. For example, consider the ADD instruction opcode. It takes the form shown in Figure 5.15.

Note that bit number zero specifies the size of the operands the ADD instruction operates upon. If this field contains zero then the operands are eight bit registers and memory locations. If this bit contains one then the operands are either 16-bits or 32-bits. Under Win32 the default is 32-bit operands if this field contains a one. To specify a 16-bit operand (under Win32) you must insert a special "operand-size prefix byte" in front of the instruction.

Bit number one specifies the direction of the transfer. If this bit is zero, then the destination operand is a memory location (e.g., "add(al, [ebx]);" If this bit is one, then the destination operand is a register (e.g., "add([ebx], al);" You'll soon see that this direction bit creates a problem that results in one instruction have two different possible opcodes.

ADD opcode.

d = 0 if adding from register to memory.

d = 1 if adding from memory to register.

s = 0 if adding eight-bit operands.

s = 1 if adding 16-bit or 32-bit operands

5.5.1 Encoding Instruction Operands

The "mod-reg-r/m" byte (in Figure 5.14) specifies a basic addressing mode. This byte contains the following fields:

Figure 5.16 MOD-REG-R/M Byte

The REG field specifies an 80x86 register. Depending on the instruction, this can be either the source or the destination operand. Many instructions have the "d" (direction) field in their opcode to choose whether this operand is the source (d=0) or the destination (d=1) operand. This field is encoded using the bit patterns found in Table 26

For certain (single operand) instructions, the REG field may contain an opcode extension rather than a register value (the R/M field will specify the operand in this case).

The MOD and R/M fields combine to specify the other operand in a two-operand instruction (or the only operand in a single-operand instruction like NOT or NEG). Remember, the "d" bit in the opcode determines which operand is the source and which is the destination. The MOD and R/M fields together specify the following addressing modes:

a. The size bit in the opcode specifies eight or 32-bit register size. To select a 16-bit register requires a prefix byte.

There are a couple of interesting things to note about this table. First of all, note that there are two forms of the [reg+disp] addressing modes: one form with an eight-bit displacement and one form with a 32-bit displacement. Addressing modes whose displacement falls in the range -128..+127 require only a single byte displacement after the opcode; hence these instructions will be shorter (and sometimes faster) than

instructions whose displacement value is outside this range. It turns out that many offsets are within this range, so the assembler/compiler can generate shorter instructions for a large percentage of the instructions.

The second thing to note is that there is no [ebp] addressing mode. If you look in the table above where this addressing mode logically belongs, you'll find that it's slot is occupied by the 32-bit displacement only addressing mode. The basic encoding scheme for addressing modes didn't allow for a displacement only addressing mode, so Intel "stole" the encoding for [ebp] and used that for the displacement only mode. Fortunately, anything you can do with the [ebp] addressing mode you can do with the [ebp+disp₈] addressing mode by setting the eight-bit displacement to zero. True, the instruction is a bit longer, but the capabilities are still there. Intel (wisely) chose to replace this addressing mode because they anticipated that programmers would use this addressing mode less often than the other register indirect addressing modes (for reasons you'll discover in a later chapter).

Another thing you'll notice missing from this table are addressing modes of the form [ebx+edx*4], the so-called scaled indexed addressing modes. You'll also notice that the table is missing addressing modes of the form [esp], [esp+disp₈], and [esp+disp₃₂]. In the slots where you would normally expect these addressing modes you'll find the SIB (scaled index byte) modes. If these values appear in the MOD and R/M fields then the addressing mode is a scaled indexed addressing mode with a second byte (the SIB byte) following the MOD-REG-R/M byte that specifies the registers to use (note that the MOD field still specifies the displacement size of zero, one, or four bytes). The following diagram shows the layout of this SIB byte and the following tables explain the values for each field.

Figure 5.17 SIB (Scaled Index Byte) Layout

| %111 | EDI |

The MOD-REG-R/M and SIB bytes are complex and convoluted, no question about that. The reason these addressing mode bytes are so convoluted is because Intel reused their 16-bit addressing circuitry in the 32-bit mode rather than simply abandoning the 16-bit format in the 32-bit mode. There are good hardware reasons for this, but the end result is a complex scheme for specifying addressing modes.

Part of the reason the addressing scheme is so convoluted is because of the special cases for the SIB and displacement-only modes. You will note that the intuitive encoding of the MOD-REG-R/M byte does not allow for a displacement-only mode. Intel added a quick kludge to the addressing scheme replacing the [EBP] addressing mode with the displacement-only mode. Programmers who actually want to use the [EBP] addressing mode have to use [EBP+0] instead. Semantically, this mode produces the same result but the instruction is one byte longer since it requires a displacement byte containing zero.

You will also note that if the REG field of the MOD-REG-R/M byte contains %100 and MOD does not contain %11 then the addressing mode is an "SIB" mode rather than the expected [ESP], [ESP+disp₈], or [ESP+disp₃₂] mode. The SIB mode is used when an addressing mode uses one of the scaled indexed registers, i.e., one of the following addressing modes:

| | |
|----------------------------|--------------------------|
| [reg ₃₂ +eax*n] | MOD = %00 |
| [reg ₃₂ +ebx*n] | Note: n = 1, 2, 4, or 8. |
| [reg ₃₂ +ecx*n] | |
| [reg ₃₂ +edx*n] | |
| [reg ₃₂ +ebp*n] | |
| [reg ₃₂ +esi*n] | |

```

[disp+reg32+ebx*n]
[disp+reg32+ecx*n]
[disp+reg32+edx*n]
[disp+reg32+ebp*n]
[disp+reg32+esi*n]
[disp+reg32+edi*n]

[disp+eax*n]           MOD = %00 and BASE field contains %101
[disp+ebx*n]
[disp+ecx*n]
[disp+edx*n]
[disp+ebp*n]
[disp+esi*n]
[disp+edi*n]

```

In each of these addressing modes, the MOD field of the MOD-REG-R/M byte specifies the size of the displacement (zero, one, or four bytes). This is indicated in Table 28 via the modes "SIB Mode," "SIB + disp₈ Mode," and "SIB + disp₃₂ Mode." The Base and Index fields of the SIB byte select the base and index registers, respectively. Note that this addressing mode does not allow the use of the ESP register as an index register. Presumably, Intel left this particular mode undefined to provide the ability to extend the addressing modes in a future version of the CPU (although extending the addressing mode sequence to three bytes seems a bit extreme).

Like the MOD-REG-R/M encoding, the SIB format redefines the [EBP+index*scale] mode as a displacement plus index mode. Once again, if you really need this addressing mode, you will have to use a single byte displacement value containing zero to achieve the same result.

5.5.2 Encoding the ADD Instruction: Some Examples

To figure out how to encode an instruction using this complex scheme, some examples are warranted. So let's take a look at how to encode the 80x86 ADD instruction using various addressing modes. The ADD opcode is \$00, \$01, \$02, or \$03, depending on the direction and size bits in the opcode (see Figure 5.15). The following figures each describe how to encode various forms of the ADD instruction using different addressing modes.

Figure 5.18 Encoding the ADD(al, cl); Instruction

There is an interesting side effect of the operation of the direction bit and the MOD-REG-R/M organization: some instructions have two different opcodes (and both are legal). For example, we could encode the "add(al, cl);" instruction from Figure 5.18 as \$02, \$C8 by reversing the AL and CL registers in the REG and R/M fields and then setting the *d* bit in the opcode (bit #1). This issue applies to instructions with two register operands.

Note that we can also encode "add(eax, ecx);" using the bytes \$03, \$C8.

Figure 5.25 Encoding the ADD([ebx + edi * 4], ecx); Instruction

5.5.3 Encoding Immediate Operands

You may have noticed that the MOD-REG-R/M and SIB bytes don't contain any bit combinations you can use to specify an immediate operand. The 80x86 uses a completely different opcode to specify an immediate operand. Figure 5.26 shows the basic encoding for an ADD immediate instruction.

Figure 5.26 Encoding an ADD Immediate Instruction

There are three major differences between the encoding of the ADD immediate and the standard ADD instruction. First, and most important, the opcode has a one in the H.O. bit position. This tells the CPU that the instruction has an immediate constant. This individual change, however, does not tell the CPU that it must execute an ADD instruction, as you'll see momentarily.

The second difference is that there is no direction bit in the opcode. This makes sense because you cannot specify a constant as a destination operand. Therefore, the destination operand is always the location the MOD and R/M bits specify in the MOD-REG-R/M field.

In place of the direction bit, the opcode has a sign extension (*x*) bit. For eight-bit operands, the CPU ignores this bit. For 16-bit and 32-bit operands, this bit specifies the size of the constant following the ADD instruction. If this bit contains zero then the constant is the same size as the operand (i.e., 16 or 32 bits). If this bit contains one then the constant is a signed eight-bit value and the CPU sign extends this value to the appropriate size before adding it to the operand. This little trick often makes programs quite a bit shorter because one commonly adds small valued constants to 16 or 32 bit operands.

The third difference between the ADD immediate and the standard ADD instruction is the meaning of the REG field in the MOD-REG-R/M byte. Since the instruction implies that the source operand is a constant and the MOD-R/M fields specify the destination operand, the instruction does not need to use the REG field to specify an operand. Instead, the 80x86 CPU uses these three bits as an opcode extension. For the ADD immediate instruction these three bits must contain zero (other bit patterns would correspond to a different instruction).

Note that when adding a constant to a memory location, the displacement (if any) associated with the memory location immediately precedes the immediate (constant) data in the opcode sequence.

5.5.4 Encoding Eight, Sixteen, and Thirty-Two Bit Operands

When Intel designed the 8086 they used one bit (*s*) to select between eight and sixteen bit integer operand sizes in the opcode. Later, when they extended the 80x86 architecture to 32 bits with the introduction of the 80386, they had a problem, with this single bit they could only encode two sizes but they needed to encode three (8, 16, and 32 bits). To solve this problem, they used a *operand size prefix byte*.

Intel studied their instruction set and came to the conclusion that in a 32-bit environment, programs were more likely to use eight-bit and 32-bit operands far more often than 16-bit operands. So Intel decided to let the size bit (*s*) in the opcode select between eight and thirty-two bit operands, as the previous sections describe. Although modern 32-bit programs don't use 16-bit operands that often, they do need them now and then. To allow for 16-bit operands, Intel lets you prefix a 32-bit instruction with the operand size prefix byte, whose value is \$66. This prefix byte tells the CPU to operand on 16-bit data rather than 32-bit data.

You do not have to explicitly put an operand size prefix byte in front of your 16-bit instructions; the assembler will take care of this automatically for you whenever you use a 16-bit operand in an instruction. However, do keep in mind that whenever you use a 16-bit operand in a 32-bit program, the instruction is longer (by one byte) because of the prefix value. Therefore, you should be careful about using 16-bit instructions if size (and to a lesser extent, speed) are important because these instructions are longer (and may be slower because of their effect on the cache).

5.5.5 Alternate Encodings for Instructions

As noted earlier in this chapter, one of Intel's primary design goals for the 80x86 was to create an instruction set to allow programmers to write very short programs in order to save precious (at the time) memory. One way they did this was to create alternate encodings of some very commonly used instructions. These alternate instructions were shorter than the standard counterparts and Intel hoped that programmers would make extensive use of these instructions, thus creating shorter programs.

A good example of these alternate instructions are the "add(constant, accumulator);" instructions (the accumulator is AL, AX, or EAX). The 80x86 provides a single byte opcode for "add(constant, al);" and "add(constant, eax);" (the opcodes are \$04 and \$05, respectively). With a one-byte opcode and no MOD-REG-R/M byte, these instructions are one byte shorter than their standard ADD immediate counterparts. Note that the "add(constant, ax);" instruction requires an operand size prefix (as does the standard "add(constant, ax);" instruction, so it's opcode is effectively two bytes if you count the prefix byte. This, however, is still one byte shorter than the corresponding standard ADD immediate.

You do not have to specify anything special to use these instructions. Any decent assembler will automatically choose the shortest possible instruction it can use when translating your source code into machine code. However, you should note that Intel only provides alternate encodings for the accumulator registers. Therefore, if you have a choice of several instructions to use and the accumulator registers are among these choices, the AL/AX/EAX registers almost always make the best bet. This is a good reason why you should take some time and scan through the encodings of the 80x86 instructions some time. By familiarizing yourself with the instruction encodings, you'll know which instructions have special (and, therefore, shorter) encodings.

5.6 Putting It All Together

Designing an instruction set that can stand the test of time is a true intellectual challenge. An engineer must balance several compromises when choosing an instruction set and assigning opcodes for the instructions. The Intel 80x86 instruction set is a classic example of a kludge that people are currently using for purposes the original designers never intended. However, the 80x86 is also a marvelous testament to the ingenuity of Intel's engineers who were faced with the difficult task of extending the CPU in ways it was never intended. The end result, though functional, is extremely complex. Clearly, no one designing a CPU (from scratch) today would choose the encoding that Intel's engineers are using. Nevertheless, the 80x86

CPU does demonstrate that careful planning (or just plain luck) does give the designer the ability to extend the CPU far beyond it's original design.

Historically, an important fact we've learned from the 80x86 family is that it's very poor planning to assume that your CPU will last only a short time period and that users will replace the chip and their software when something better comes along. Software developers usually don't have a problem adapting to a new architecture when they write new software (assuming financial incentive to do so), but they are very resistant to moving existing software from one platform to another. This is the primary reason the Intel 80x86 platform remains popular to this day.

Choosing which instructions you want to incorporate into the initial design of a new CPU is a difficult task. You must balance the desire to provide lots of useful instructions with the silicon budget and you must also be careful not to include lots of irrelevant instructions that programmers wind up ignoring for one reason or another. Remember, all future versions of the CPU will probably have to support all the instructions in the initial instruction set, so it's better to err on the side of supplying too few instructions rather than too many. Remember, you can always expand the instruction set in a later version of the chip.

Hand in hand with selecting the optimal instruction set is allowing for easy future expansion of the chip. You must leave some undefined opcodes available so you can easily expand the instruction set later on. However, you must balance the number of undefined opcodes with the number of initial instructions and the size of your opcodes. For efficiency reasons, we want the opcodes to be as short as possible. We also need a reasonable set of instructions in the initial instruction set. A reasonable instruction set may consume most of the legal bit patterns in small opcode. So a hard decision has to be made: reduce the number of instructions in the initial instruction set, increase the size of the opcode, or rely on an opcode prefix byte (which makes the newer instructions (you add later) longer. There is no easy answer to this problem, as the CPU designer, you must carefully weigh these choices during the initial CPU design. Unfortunately, you can't easily change your mind later on.

Most CPUs (Von Neumann architecture) use a binary encoding of instructions and fetch these instructions from memory. This chapter introduces the concept of binary instruction encoding via the hypothetical "Y86" processor. This is a trivial (and not very practical) CPU design that makes it easy to demonstrate how to choose opcodes for a simple instruction set, encode operands, and leave room for future expansion. Some of the more interesting features the Y86 demonstrates includes the fact that an opcode often contains sub-fields and we usually group instructions by the number of types of operands they support. The Y86 encoding also demonstrates how to use special opcodes to differentiate one group of instructions from another and to provide undefined (illegal) opcodes that we can use for future expansion.

The Y86 CPU is purely hypothetical and useful only as an educational tool. After exploring the design of a simple instruction set with the Y86, this chapter began to discuss the encoding of instructions on the 80x86 platform. While the full 80x86 instruction set is far too complex to discuss this early in this text (i.e., there are lots of instructions we still have to discuss later in this text), this chapter was able to discuss basic instruction encoding using the ADD instruction as an example. Note that this chapter only touches on the 80x86 instruction encoding scheme. For a full discussion of 80x86 encoding, see the appendices in this text and the Intel 80x86 documentation.

Memory Architecture

Chapter Six

6.1 Chapter Overview

This chapter discusses the memory hierarchy – the different types and performance levels of memory found on a typical 80x86 computer system. Many programmers tend to view memory as this big nebulous block of storage that holds values for future use. From a semantic point of view, this is a reasonable view. However, from a performance point of view there are many different kinds of memory and using the wrong one or using one form improperly can have a dramatically negative impact on the performance of a program. This chapter discusses the memory hierarchy and how to best use it within your programs.

6.2 The Memory Hierarchy

Most modern programs can benefit greatly from a large amount of very fast memory. A physical reality, however, is that as a memory device gets larger, it tends to get slower. For example, cache memories (see “Cache Memory” on page 147) are very fast but are also small and expensive. Main memory is inexpensive and large, but is slow (requiring wait states, see “Wait States” on page 146). The memory hierarchy is a mechanism of comparing the cost and performance of the various places we can store data and instructions. Figure 6.1 provides a look at one possible form of the memory hierarchy.

Figure 6.1 The Memory Hierarchy

At the top level of the memory hierarchy are the CPU’s general purpose registers. The registers provide the fastest access to data possible on the 80x86 CPU. The register file is also the smallest memory object in the memory hierarchy (with just eight general purpose registers available). By virtue of the fact that it is virtually impossible to add more registers to the 80x86, registers are also the most expensive memory locations. Note that we can include FPU, MMX, SIMD, and other CPU registers in this class as well. These additional

registers do not change the fact that there are a very limited number of registers and the cost per byte is quite high (figuring the cost of the CPU divided by the number of bytes of register available).

Working our way down, the Level One Cache system is the next highest performance subsystem in the memory hierarchy. On the 80x86 CPUs, the Level One Cache is provided on-chip by Intel and cannot be expanded. The size is usually quite small (typically between 4Kbytes and 32Kbytes), though much larger than the registers available on the CPU chip. Although the Level One Cache size is fixed on the CPU and you cannot expand it, the cost per byte of cache memory is much lower than that of the registers because the cache contains far more storage than is available in all the combined registers.

The Level Two Cache is present on some CPUs, on other CPUs it is the system designer's task to incorporate this cache (if it is present at all). For example, most Pentium II, III, and IV CPUs have a level two cache as part of the CPU package, but many of Intel's Celeron chips do not¹. The Level Two Cache is generally much larger than the level one cache (e.g., 256 or 512KBytes versus 16 Kilobytes). On CPUs where Intel includes the Level Two Cache as part of the CPU package, the cache is not expandable. It is still lower cost than the Level One Cache because we amortize the cost of the CPU across all the bytes in the Level Two Cache. On systems where the Level Two Cache is external, many system designers let the end user select the cache size and upgrade the size. For economic reasons, external caches are actually more expensive than caches that are part of the CPU package, but the cost per bit at the transistor level is still equivalent to the in-package caches.

Below the Level Two Cache system in the memory hierarchy falls the main memory subsystem. This is the general-purpose, relatively low-cost memory found in most computer systems. Typically, this is DRAM or some similar inexpensive memory technology.

Below main memory is the NUMA category. NUMA, which stands for NonUniform Memory Access is a bit of a misnomer here. NUMA means that different types of memory have different access times. Therefore, the term NUMA is fairly descriptive of the entire memory hierarchy. In Figure 6.1a, however, we'll use the term NUMA to describe blocks of memory that are electronically similar to main memory but for one reason or another operate significantly slower than main memory. A good example is the memory on a video display card. Access to memory on video display cards is often an order of magnitude slower than access to main memory. Other peripheral devices that provide a block of shared memory between the CPU and the peripheral probably have similar access times as this video card example. Another example of NUMA includes certain slower memory technologies like Flash Memory that have significant slower access and transfers times than standard semiconductor RAM. We'll use the term NUMA in this chapter to describe these blocks of memory that look like main memory but run at slower speeds.

Most modern computer systems implement a Virtual Memory scheme that lets them simulate main memory using storage on a disk drive. While disks are significantly slower than main memory, the cost per bit is also significantly lower. Therefore, it is far less expensive (by three orders of magnitude) to keep some data on magnetic storage rather than in main memory. A Virtual Memory subsystem is responsible for transparently copying data between the disk and main memory as needed by a program.

File Storage also uses disk media to store program data. However, it is the program's responsibility to store and retrieve file data. In many instances, this is a bit slower than using Virtual Memory, hence the lower position in the memory hierarchy².

Below File Storage in the memory hierarchy comes Network Storage. At this level a program is keeping data on a different system that connects the program's system via a network. With Network Storage you can implement Virtual Memory, File Storage, and a system known as Distributed Shared Memory (where processes running on different computer systems share data in a common block of memory and communicate changes to that block across the network).

Virtual Memory, File Storage, and Network Storage are examples of so-called *on-line memory subsystems*. Memory access via these mechanism is slower than main memory access, but when a program requests data from one of these memory devices, the device is ready and able to respond to the request as quickly as is physically possible. This is not true for the remaining levels in the memory hierarchy.

1. Note, by the way, that the level two cache on the Pentium CPUs is typically not on the same chip as the CPU. Instead, Intel packages a separate chip inside the box housing the Pentium CPU and wires this second chip (containing the level two cache) directly to the Pentium CPU inside the package.

2. Note, however, that in some degenerate cases Virtual Memory can be much slower than file access.

The Near-Line and Off-Line Storage subsystems are not immediately ready to respond to a program's request for data. An Off-Line Storage system keeps its data in electronic form (usually magnetic or optical) but on media that is not (necessarily) connected to the computer system while the program that needs the data is running. Examples of Off-Line Storage include magnetic tapes, disk cartridges, optical disks, and floppy diskettes. When a program needs data from an off-line medium, the program must stop and wait for a someone or something to mount the appropriate media on the computer system. This delay can be quite long (perhaps the computer operator decided to take a coffee break?). Near-Line Storage uses the same media as Off-Line Storage, the difference is that the system holds the media in a special robotic jukebox device that can automatically mount the desired media when some program requests it. Tapes and removable media are among the most inexpensive electronic data storage formats available. Hence, these media are great for storing large amounts of data for long time periods.

Hard Copy storage is simply a print-out (in one form or another) of some data. If a program requests some data and that data is present only in hard copy form, someone will have to manually enter the data into the computer. Paper (or other hard copy media) is probably the least expensive form of memory, at least for certain data types.

6.3 How the Memory Hierarchy Operates

The whole point of the memory hierarchy is to allow reasonably fast access to a large amount of memory. If only a little memory was necessary, we'd use fast static RAM (i.e., the stuff they make cache memory out of) for everything. If speed wasn't necessary, we'd just use low-cost dynamic RAM for everything. The whole idea of the memory hierarchy is that we can take advantage of the principle of locality of reference (see "Cache Memory" on page 147) to move often-referenced data into fast memory and leave less-used data in slower memory. Unfortunately, the selection of often-used versus lesser-used data varies over the execution of any given program. Therefore, we cannot simply place our data at various levels in the memory hierarchy and leave the data alone throughout the execution of the program. Instead, the memory subsystems need to be able to move data between themselves dynamically to adjust for changes in locality of reference during the program's execution.

Moving data between the registers and the rest of the memory hierarchy is strictly a program function. The program, of course, loads data into registers and stores register data into memory using instructions like MOV. It is strictly the programmer's or compiler's responsibility to select an instruction sequence that keeps heavily referenced data in the registers as long as possible.

The program is largely unaware of the memory hierarchy. In fact, the program only explicitly controls access to main memory and those components of the memory hierarchy at the file storage level and below (since manipulating files is a program-specific operation). In particular, cache access and virtual memory operation are generally transparent to the program. That is, access to these levels of the memory hierarchy usually take place without any intervention on the program's part. The program just accesses main memory and the hardware (and operating system) take care of the rest.

Of course, if the program really accessed main memory on each access, the program would run quite slowly since modern DRAM main memory subsystems are much slower than the CPU. The job of the cache memory subsystems (and the cache controller) is to move data between main memory and the cache so that the CPU can quickly access data in the cache. Likewise, if data is not available in main memory, but is available in slower virtual memory, the virtual memory subsystem is responsible for moving the data from hard disk to main memory (and then the caching subsystem may move the data from main memory to cache for even faster access by the CPU).

With few exceptions, most transparent memory subsystem accesses always take place between one level of the memory hierarchy and the level immediately below or above it. For example, the CPU rarely accesses main memory directly. Instead, when the CPU requests data from memory, the Level One Cache subsystem takes over. If the requested data is in the cache, then the Level One Cache subsystem returns the data and that's the end of the memory access. On the other hand if the data is not present in the level one cache, then it passes the request on down to the Level Two Cache subsystem. If the Level Two Cache subsystem has the data, it returns this data to the Level One Cache, which then returns the data to the CPU. Note that requests

for this same data in the near future will come from the Level One Cache rather than the Level Two Cache since the Level One Cache now has a copy of the data.

If neither the Level One nor Level Two Cache subsystems have a copy of the data, then the memory subsystem goes to main memory to get the data. If found in main memory, then the memory subsystems copy this data to the Level Two Cache which passes it to the Level One Cache which gives it to the CPU. Once again, the data is now in the Level One Cache, so any references to this data in the near future will come from the Level One Cache.

If the data is not present in main memory, but is present in Virtual Memory on some storage device, the operating system takes over, reads the data from disk (or other devices, such as a network storage server) and places this data in main memory. Main memory then passes this data through the caches to the CPU.

Because of locality of reference, the largest percentage of memory accesses take place in the Level One Cache system. The next largest percentage of accesses occur in the Level Two Cache subsystems. The most infrequent accesses take place in Virtual Memory.

6.4 Relative Performance of Memory Subsystems

If you take another look at Figure 6.1 you'll notice that the speed of the various levels increases at the higher levels of the memory hierarchy. A good question to ask, and one we'll hope to answer in this section, is "how much faster is each successive level in the memory hierarchy?" It actually ranges from "almost no difference" to "four orders of magnitude" as you'll seem momentarily.

Registers are, unquestionably, the best place to store data you need to access quickly. Accessing a register never requires any extra time³. Further, instructions that access data can almost always access that data in a register. Such instructions already encode the register "address" as part of the MOD-REG-R/M byte (see "Encoding Instruction Operands" on page 279). Therefore, it never takes any extra bits in an instruction to use a register. Instructions that access memory often require extra bytes (i.e., displacement bytes) as part of the instruction encoding. This makes the instruction longer which means fewer of them can sit in the cache or in a prefetch queue. Hence, the program may run slower if it uses memory operands more often than register operands simply due to the instruction size difference.

If you read Intel's instruction timing tables, you'll see that they claim that an instruction like "mov(someVar, ecx);" is supposed to run as fast as an instruction of the form "mov(ebx, ecx);" However, if you read the fine print, you'll find that they make several assumptions about the former instruction. First, they assume that *someVar*'s value is present in the level one cache memory. If it is not, then the cache controller needs to look in the level two cache, in main memory, or worse, on disk in the virtual memory subsystem. All of a sudden, this instruction that should execute in one cycle (e.g., one nanosecond on a one gigahertz processor) requires several milliseconds to execution. That's over six orders of magnitude difference, if you're counting. Now granted, locality of reference suggests that future accesses to this variable will take place in one cycle. However, if you access *someVar*'s value one million times immediately thereafter, the average access time of each instruction will be two cycles because of the large amount of time needed to access *someVar* the very first time (when it was on a disk in the virtual memory system). Now granted, the likelihood that some variable will be on disk in the virtual memory subsystem is quite low. But there is a three orders of magnitude difference in performance between the level one cache subsystem and the main memory subsystem. So if the program has to bring in the data from main memory, 999 accesses later you're still paying an average cost of two cycles for the instruction that Intel's documentation claims should execute in one cycle. Note that register accesses never suffer from this problem. Hence, register accesses are much faster.

The difference between the level one and level two cache systems is not so dramatic. Usually, a level two caching subsystem introduces between one and eight wait states (see "Wait States" on page 146). The difference is usually much greater, though, if the secondary cache is not packaged together with the CPU.

On a one gigahertz processor the level one cache must respond within one nanosecond if the cache operates with zero wait states (note that some processors actually introduce wait states in accesses to the level

3. Okay, strictly speaking this is not true. However, we'll ignore data hazards in this discussion and assume that the programmer or compiler has scheduled their instructions properly to avoid pipeline stalls due to data hazards with register data.

one cache, but system designers try not to do this). Accessing data in the level two cache is always slower than in the level one cache and there is always the equivalent of at least one wait state, perhaps more, when accessing data in the level two cache. The reason is quite simple – it takes the CPU time to determine that the data it is seeking is not in the L1 (level one) cache; by the time it determines that the data is not present, the memory access cycle is nearly complete and there is no time to access the data in the L2 (level two) cache.

It may also be that the L2 cache is slower than the L1 cache. This is usually done in order to make the L2 cache less expensive. Also, larger memory subsystems tend to be slower than smaller ones, and L2 caches are usually 16 to 64 times larger than the L1 cache, hence they are usually slower as well. Finally, because L2 caches are not usually on the same silicon chip as the CPU, there are some delays associated with getting data in and out of the cache. All this adds up to additional wait states when accessing data in the L2 cache. As noted above, the L2 cache can be as much as an order of magnitude slower than the L1 cache.

Another difference between the L1 and L2 caches is the amount of data the system fetches when there is an L1 cache miss. When the CPU fetches data from the L1 cache, it generally fetches (or writes) only the data requested. If you execute a "mov(al, memory);" instruction, the CPU writes only a single byte to the cache. Likewise, if you execute "mov(mem32, eax);" then the CPU reads 32 bits from the L1 cache. Access to memory subsystems below the L1 cache, however, do not work in small chunks like this. Usually, memory subsystems read blocks (or *cache lines*) of data whenever accessing lower levels of the memory hierarchy. For example, if you execute the "mov(mem32, eax);" instruction and *mem32*'s value is not in the L1 cache, the cache controller doesn't simply read *mem32*'s value from the L2 cache (assuming it's present there). Instead, the cache controller will actually read a block of bytes (generally 16, 32, or 64 bytes, this depends on the particular processor) from the lower memory levels. The hope is that spatial locality exists and reading a block of bytes will speed up accesses to adjacent objects in memory⁴. The bad news, however, is that the "mov(mem32, eax);" instruction doesn't complete until the L1 cache reads the entire cache line (of 16, 32, 64, etc., bytes) from the L2 cache. Although the program may amortize the cost of reading this block of bytes over future accesses to adjacent memory locations, there is a large passage of time between the request for *mem32* and the actual completion of the "mov(mem32, eax);" instruction. This excess time is known as latency. As noted, the hope is that extra time will be worth the cost when future accesses to adjacent memory locations occur; however, if the program does not access memory objects adjacent to *mem32*, this latency is lost time.

A similar performance gulf separates the L2 cache and main memory. Main memory is typically an order of magnitude slower than the L2 cache. Again the L2 cache reads data from main memory in blocks (cache lines) to speed up access to adjacent memory elements.

There is a three to four order of magnitude difference in performance between standard DRAM and disk storage. To overcome this difference, there is usually a two to three orders of magnitude difference in size between the L2 cache and the main memory. In other words, the idea is "if the access time difference between main memory and virtual memory is two orders of magnitude greater than the difference between the L2 cache and main memory, then we'd better make sure we have two orders of magnitude more main memory than we have L2 cache." This keeps the performance loss to a reasonable level since we access virtual memory on disk two orders of magnitude less often.

We will not consider the performance of the other memory hierarchy subsystems since they are more or less under programmer control (their access is not automatic by the CPU or operating system). Hence, very little can be said about how frequently a program will access them.

6.5 Cache Architecture

Up to this point, cache has been this magical place that automatically stores data when we need it, perhaps fetching new data as the CPU requires it. However, a good question is "how exactly does the cache do this?" Another might be "what happens when the cache is full and the CPU is requesting additional data not

4. Note that reading a block of *n* bytes is much faster than *n* reads of one byte. So this scheme is many times faster if spatial locality does occur in the program. For information about spatial locality, see "Cache Memory" on page 147.

in the cache?" In this section, we'll take a look at the internal cache organization and try to answer these questions along with a few others.

The basic idea behind a cache is that a program only access a small amount of data at a given time. If the cache is the same size as the typical amount of data the program access at any one given time, then we can put that data into the cache and access most of the data at a very high speed. Unfortunately, the data rarely sits in contiguous memory locations; usually, there's a few bytes here, a few bytes there, and some bytes somewhere else. In general, the data is spread out all over the address space. Therefore, the cache design has got to accommodate the fact that it must map data objects at widely varying addresses in memory.

As noted in the previous section, cache memory is not organized as a group of bytes. Instead, cache organization is usually in blocks of cache lines with each line containing some number of bytes (typically a small number that is a power of two like 16, 32, or 64), see Figure 6.2.

Figure 6.2 Possible Organization of an 8 Kilobyte Cache

The idea of a cache system is that we can attach a different (non-contiguous) address to each of the cache lines. So cache line #0 might correspond to addresses \$10000..\$1000F and cache line #1 might correspond to addresses \$21400..\$2140F. Generally, if a cache line is n bytes long (n is usually some power of two) then that cache line will hold n bytes from main memory that fall on an n -byte boundary. In this example, the cache lines are 16 bytes long, so a cache line holds blocks of 16 bytes whose addresses fall on 16-byte boundaries in main memory (i.e., the L.O. four bits of the address of the first byte in the cache line are always zero).

When the cache controller reads a cache line from a lower level in the memory hierarchy, a good question is "where does the data go in the cache?" The most flexible cache system is the *fully associative cache*. In a fully associative cache subsystem, the caching controller can place a block of bytes in any one of the cache lines present in the cache memory. While this is a very flexible system, the flexibility is not without cost. The extra circuitry to achieve full associativity is expensive and, worse, can slow down the memory subsystem. Most L1 and L2 caches are not fully associative for this reason.

At the other extreme is the *direct mapped cache* (also known as the *one-way set associative cache*). In a direct mapped cache, a block of main memory is always loaded into the same cache line in the cache. Generally, some number of bits in the main memory address select the cache line. For example, Figure 6.3 shows how the cache controller could select a cache line for an 8 Kilobyte cache with 16-byte cache lines and a 32-bit main memory address. Since there are 512 cache lines, this example uses bits four through twelve to select one of the cache lines (bits zero through three select a particular byte within the 16-byte cache line). The direct-mapped cache scheme is very easy to implement. Extracting nine (or some other number of) bits from the address and using this as an index into the array of cache lines is trivial and fast. However, direct-mapped caches to suffer from some other problems.

Figure 6.3 Selecting a Cache Line in a Direct-mapped Cache

Perhaps the biggest problem with a direct-mapped cache is that it may not make effective use of all the cache memory. For example, the cache scheme in Figure 6.3 maps address zero to cache line #0. It also maps address \$2000 (8K), \$4000 (16K), \$6000 (24K), \$8000 (32K), and, in fact, it maps every address that is an even multiple of eight kilobytes to cache line #0. This means that if a program is constantly accessing data at addresses that are even multiples of 8K and not accessing any other locations, the system will only use cache line #0, leaving all the other cache lines unused. Each time the CPU requests data at an address that is not at an address within cache line #0, the CPU will have to go down to a lower level in the memory hierarchy to access the data. In this pathological case, the cache is effectively limited to the size of one cache line. Had we used a fully associative cache organization, each access (up to 512 cache lines' worth) could have their own cache line, thus improving performance.

If a fully associative cache organization is too complex, expensive, and slow to implement, but a direct-mapped cache organization isn't as good as we'd like, one might ask if there is a compromise that gives us more capability than a direct-mapped approach without all the complexity of a fully associative cache. The answer is yes, we can create an *n-way set associative cache* which is a compromise between these two extremes. The idea here is to break up the cache into sets of cache lines. The CPU selects a particular set using some subset of the address bits, just as for direct-mapping. Within each set there are *n* cache lines. The caching controller uses a fully associative mapping algorithm to select one of the *n* cache lines within the set.

As an example, an 8 kilobyte two-way set associative cache subsystem with 16-byte cache lines organizes the cache as a set of 256 sets with each set containing two cache lines ("two-way" means each set contains two cache lines). Eight bits from the memory address select one of these 256 different sets. Then the cache controller can map the block of bytes to either cache line within the set (see Figure 6.4). The advantage of a two-way set associative cache over a direct mapped cache is that you can have two accesses on 8 Kilobyte boundaries (using the current example) and still get different cache lines for both accesses. However, once you attempt to access a third memory location at an address that is an even multiple of eight kilobytes you will have a conflict.

Figure 6.4 A Two-Way Set Associative Cache

A two-way set associative cache is much better than a direct-mapped cache and considerably less complex than a fully associative cache. However, if you're still getting too many conflicts, you might consider using a four-way set associative cache. A four-way set associative cache puts four associative cache lines in each block. In the current 8K cache example, a four-way set associative example would have 128 sets with each set containing four cache lines. This would allow up to four accesses to an address that is an even multiple of eight kilobytes before a conflict would occur.

Obviously, we can create an arbitrary m -way set associative cache (well, m does have to be a power of two). However, if m is equal to n , where n is the number of cache lines, then you've got a fully associative cache with all the attendant problems (complexity and speed). Most cache designs are direct-mapped, two-way set associative, or four-way set associative. The 80x86 family CPUs use all three (depending on the CPU and cache).

Although this section has made direct-mapped cache look bad, they are, in fact, very effective for many types of data. In particular, they are very good for data that you access in a sequential rather than random fashion. Since the CPU typically executes instructions in a sequential fashion, instructions are a good thing to put into a direct-mapped cache. Data access is probably a bit more random access, so a two-way or four-way set associative cache probably makes a better choice.

Because access to data and instructions is different, many CPU designers will use separate caches for instructions and data. For example, the CPU designer could choose to implement an 8K instruction cache and an 8K data cache rather than a 16K unified cache. The advantage is that the CPU designer could choose a more appropriate caching scheme for instructions versus data. The drawback is that the two caches are now each half the size of a unified cache and you may get fewer cache misses from a unified cache. The choice of an appropriate cache organization is a difficult one and can only be made after analyzing lots of running programs on the target processor. How to choose an appropriate cache format is beyond the scope of this text, just be aware that it's not an easy choice you can make by reading some textbook.

Thus far, we've answered the question "where do we put a block of data when we read it into the cache?" An equally important question we ignored until now is "what happens if a cache line isn't available when we need to read data from memory?" Clearly, if all the lines in a set of cache lines contain data, we're going to have to replace one of these lines with the new data. The question is, "how do we choose the cache line to replace?"

For a direct-mapped (one-way set associative) cache architecture, the answer is trivial. We replace exactly the block that the memory data maps to in the cache. The cache controller replaces whatever data

was formerly in the cache line with the new data. Any reference to the old data will result in a cache miss and the cache controller will have to bring that data into the cache replacing whatever data is in that block at that time.

For a two-way set associative cache, the replacement algorithm is a bit more complex. Whenever the CPU references a memory location, the cache controller uses some number of the address bits to select the set that should contain the cache line. Using some fancy circuitry, the caching controller determines if the data is already present in one of the two cache lines in the set. If not, then the CPU has to bring the data in from memory. Since the main memory data can go into either cache line, somehow the controller has to pick one or the other. If either (or both) cache lines are currently unused, the selection is trivial: pick an unused cache line. If both cache lines are currently in use, then the cache controller must pick one of the cache lines and replace its data with the new data. Ideally, we'd like to keep the cache line that will be referenced first (that is, we want to replace the one whose next reference is later in time). Unfortunately, neither the cache controller nor the CPU is omniscient, they cannot predict which is the best one to replace. However, remember the principle of temporal locality (see "Cache Memory" on page 147): if a memory location has been referenced recently, it is likely to be referenced again in the very near future. A corollary to this is "if a memory location has not been accessed in a while, it is likely to be a long time before the CPU accesses it again." Therefore, a good replacement policy that many caching controllers use is the "least recently used" or LRU algorithm. The idea is to pick the cache line that was not most frequently accessed and replace that cache line with the new data. An LRU policy is fairly easy to implement in a two-way set associative cache system. All you need is a bit that is set to zero whenever the CPU accessing one cache line and set it to one when you access the other cache line. This bit will indicate which cache line to replace when a replacement is necessary. For four-way (and greater) set associative caches, maintaining the LRU information is a bit more difficult, which is one of the reasons the circuitry for such caches is more complex. Other possible replacement policies include First-in, First-out⁵ (FIFO) and random. These are easier to implement than LRU, but they have their own little problems.

The replacement policies for four-way and n-way set associative caches are roughly the same as for two-way set associative caches. The major difference is in the complexity of the circuit needed to implement the replacement policy (see the comments on LRU in the previous paragraph).

Another problem we've overlooked in this discussion on caches is "what happens when the CPU writes data to memory?" The simple answer is trivial, the CPU writes the data to the cache. However, what happens when the cache line containing this data is replaced by incoming data? If the contents of the cache line is not written back to main memory, then the data that was written will be lost. The next time the CPU reads that data, it will fetch the original data values from main memory and the value written is lost.

Clearly any data written to the cache must ultimately be written to main memory as well. There are two common write policies that caches use: write-back and write-through. Interestingly enough, it is sometimes possible to set the write policy under software control; these aren't hardwired into the cache controller like most of the rest of the cache design. However, don't get your hopes up. Generally the CPU only allows the BIOS or operating system to set the cache write policy, your applications don't get to mess with this. However, if you're the one writing the operating system...

The write-through policy states that any time data is written to the cache, the cache immediately turns around and writes a copy of that cache line to main memory. Note that the CPU does not have to halt while the cache controller writes the data to memory. So unless the CPU needs to access main memory shortly after the write occurs, this writing takes place in parallel with the execution of the program. Still, writing a cache line to memory takes some time and it is likely that the CPU (or some CPU in a multiprocessor system) will want to access main memory during this time, so the write-through policy may not be a high performance solution to the problem. Worse, suppose the CPU reads and writes the value in a memory location several times in succession. With a write-through policy in place the CPU will saturate the bus with cache line writes and this will have a very negative impact on the program's performance. On the positive side, the write-through policy does update main memory with the new value as rapidly as possible. So if two different CPUs are communicating through the use of shared memory, the write-through policy is probably better because the second CPU will see the change to memory as rapidly as possible when using this policy.

5. This policy does exhibit some anomalies. These problems are beyond the scope of this chapter, but a good text on architecture or operating systems will discuss the problems with the FIFO replacement policy.

The second common cache write policy is the write-back policy. In this mode, writes to the cache are not immediately written to main memory; instead, the cache controller updates memory at a later time. This scheme tends to be higher performance because several writes to the same variable (or cache line) only update the cache line, they do not generate multiple writes to main memory.

Of course, at some point the cache controller must write the data in cache to memory. To determine which cache lines must be written back to main memory, the cache controller usually maintains a *dirty bit* with each cache line. The cache system sets this bit whenever it writes data to the cache. At some later time the cache controller checks this dirty bit to determine if it must write the cache line to memory. Of course, whenever the cache controller replaces a cache line with other data from memory, it must first write that cache line to memory if the dirty bit is set. Note that this increases the latency time when replacing a cache line. If the cache controller were able to write dirty cache lines to main memory while no other bus access was occurring, the system could reduce this latency during cache line replacement.

A cache subsystem is not a panacea for slow memory access. In order for a cache system to be effective the software must exhibit locality of reference. If a program accesses memory in a random fashion (or in a fashion guaranteed to exploit the caching controller's weaknesses) then the caching subsystem will actually cause a big performance drop. Fortunately, real-world programs do exhibit locality of reference, so most programs will benefit from the presence of a cache in the memory subsystem.

6.6 Virtual Memory, Protection, and Paging

In a modern operating system such as Windows, it is very common to have several different programs running concurrently in memory. This presents several problems. First, how do you keep the programs from interfering with one another? Second, if one program expects to load into memory at address \$1000 and a second program also expects to load into memory at address \$1000, how can you load and execute both programs at the same time? One last question we might ask is what happens if our computer has 64 megabytes of memory and we decide to load and execute three different applications, two of which require 32 megabytes and one that requires 16 megabytes (not to mention the memory the operating system requires for its own purposes)? The answer to all these questions lies in the virtual memory subsystem the 80x86 processors support⁶.

Virtual memory on the 80x86 gives each process its own 32-bit address space⁷. This means that address \$1000 in one program is physically different than address \$1000 in a separate program. The 80x86 achieves this sleight of hand by using *paging* to remap *virtual addresses* within one program to different *physical addresses* in memory. A virtual address is the memory address that the program uses. A physical address is the bit pattern that actually appears on the CPU's address bus. The two don't have to be the same (and usually, they aren't). For example, program #1's virtual address \$1000 might actually correspond to physical address \$215000 while program #2's virtual address \$1000 might correspond to physical memory address \$300000. How can the CPU do this? Easy, by using *paging*.

The concept behind paging is quite simple. First, you break up memory into blocks of bytes called pages. A page in main memory is comparable to a cache line in a cache subsystem, although pages are usually much larger than cache lines. For example, the 80x86 CPUs use a page size of 4,096 bytes.

After breaking up memory into pages, you use a lookup table to translate the H.O. bits of a virtual address to select a page; you use the L.O. bits of the virtual address as an index into the page. For example, with a 4,096-byte page, you'd use the L.O. 12 bits of the virtual address as the offset within the page in physical memory. The upper 20 bits of the address you would use as an index into a lookup table that returns the actual upper 20 bits of the physical address (see Figure 6.5).

6. Actually, virtual memory is really only supported by the 80386 and later processors. We'll ignore this issue here since most people have an 80386 or later processor.

7. Strictly speaking, you actually get a 36-bit address space on Pentium Pro and later processors, but Windows limits you to 32-bits so we'll use that limitation here.

Figure 6.5 Translating a Virtual Address to a Physical Address

Of course, a 20-bit index into the page table would require over one million entries in the page table. If each entry is 32 bits (20 bits for the offset plus 12 bits for other purposes), then the page table would be four megabytes long. This would be larger than most of the programs that would run in memory! However, using what is known as a multi-level page table, it is very easy to create a page table that is only 8 kilobytes long for most small programs. The details are unimportant here, just rest assured that you don't need a four megabyte page table unless your program consumes the entire four gigabyte address space.

If you study Figure 6.5 for a few moments, you'll probably discover one problem with using a page table – it requires two memory accesses in order to access an address in memory: one access to fetch a value from the page table and one access to read or write the desired memory location. To prevent cluttering the data (or instruction) cache with page table entries (thus increasing the number of cache misses), the page table uses its own cache known as the *Translation Lookaside Buffer*, or TLB. This cache typically has 32 entries on a Pentium family processor. This provides a sufficient lookup capability to handle 128 kilobytes of memory (32 pages) without a miss. Since a program typically works with less data than this at any given time, most page table accesses come from the cache rather than main memory.

As noted, each entry in the page table is 32 bits even though the system really only needs 20 bits to remap the addresses. Intel uses some of the remaining 12 bits to provide some memory protection information. For example, one bit marks whether a page is read/write or read-only. Another bit determines if you can execute code on that page. Some bits determine if the application can access that page or if only the operating system can do so. Some bits determine if the page is "dirty" (that is, if the CPU has written to the page) and whether the CPU has accessed the page recently (these bits have the same meaning as for cache lines). Another bit determines whether the page is actually present in physical memory or if it's stored on secondary storage somewhere. Note that your applications do not have access to the page table, and therefore they cannot modify these bits. However, Windows does provide some functions you can call if you want to change certain bits in the page table (e.g., Windows will allow you to set a page to read-only if you want to do so).

Beyond remapping memory so multiple programs can coexist in memory even though they access the same virtual addresses, paging also provides a mechanism whereby the operating system can move infrequently used pages to secondary storage (i.e., a disk drive). Just as locality of reference applies to cache lines, it applies to pages in memory as well. At any one given time a program will only access a small per-

centage of the pages in memory that contain data and code (this set of pages is known as the *working set*). While this working set of pages varies (slowly) over time, for a reasonable time period the working set remains constant. Therefore, there is little need to have the remainder of the program in memory consuming valuable physical memory that some other process could be using. If the operating system can save those (currently unused) pages to disk, the physical memory they consume would be available for other programs that need it.

Of course, the problem with moving data out of physical memory is that sooner or later the program might actually need it. If you attempt to access a page of memory and the page table bit tells the MMU (memory management unit) that this page is not present in physical memory, then the CPU interrupts the program and passes control to the operating system. The operating system analyzes the memory access request and reads the corresponding page of data from the disk drive to some available page in memory. The process is nearly identical to that used by a fully associative cache subsystem except, of course, accessing the disk is much slower than main memory. In fact, you can think of main memory as a fully associative write-back cache with 4,096 byte cache lines that caches the data on the disk drive. Placement and replacement policies and other issues are very similar to those we've discussed for caches. Discussing how the virtual memory subsystem works beyond equating it to a cache is well beyond the scope of this text. If you're interested, any decent text on operating system design will explain how a virtual memory subsystem swaps pages between main memory and the disk. Our main goal here is to realize that this process takes place in operating systems like Windows and that accessing the disk is very slow.

One important issue resulting from the fact that each program has a separate page table and the programs themselves don't have access to the page table is that programs cannot interfere with the operation of other programs by overwriting those other program's data (assuming, of course, that the operating system is properly written). Further, if your program crashes by overwriting itself, it cannot crash other programs at the same time. This is a big benefit of a paging memory system.

Note that if two programs want to cooperate and share data, they can do so. All they've got to do is to tell the operating system that they want to share some blocks of memory. The operating system will map their corresponding virtual addresses (of the shared memory area) to the same physical addresses in memory. Under Windows, you can achieve this use *memory mapped files*; see the Windows documentation for more details.

6.7 Thrashing

Thrashing is a degenerate case that occurs when there is insufficient memory at one level in the memory hierarchy to properly contain the working set required by the upper levels of the memory hierarchy. This can result in the overall performance of the system dropping to the speed of a lower level in the memory hierarchy. Therefore, thrashing can quickly reduce the performance of the system to the speed of main memory or, worse yet, the speed of the disk drive.

There are two primary causes of thrashing: (1) insufficient memory at a given level in the memory hierarchy, and (2) the program does not exhibit locality of reference. If there is insufficient memory to hold a working set of pages or cache lines, then the memory system is constantly replacing one block (cache line or page) with another. As a result, the system winds up operating at the speed of the slower memory in the hierarchy. A common example occurs with virtual memory. A user may have several applications running at the same time and the sum total of these programs' working sets is greater than all of physical memory available to the program. As a result, as the operating system switches between the applications it has to copy each application's data to and from disk and it may also have to copy the code from disk to memory. Since a context switch between programs is often much faster than retrieving data from the disk, this slows the programs down by a tremendous factor since thrashing slows the context switch down to the speed of swapping the applications to and from disk.

If the program does not exhibit locality of reference and the lower memory subsystems are not fully associative, then thrashing can occur even if there is free memory at the current level in the memory hierarchy. For example, suppose an eight kilobyte L1 caching system uses a direct-mapped cache with 16-byte cache lines (i.e., 512 cache lines). If a program references data objects 8K apart on each access then the sys-

tem will have to replace the same line in the cache over and over again with each access. This occurs even though the other 511 cache lines are currently unused.

If insufficient memory is the cause of thrashing, an easy solution is to add more memory (if possible, it is rather hard to add more L1 cache when the cache is on the same chip as the processor). Another alternative is to run fewer processes concurrently or modify the program so that it references less memory over a given time period. If lack of locality of reference is causing the problem, then you should restructure your program and its data structures to make references local to one another.

6.8 NUMA and Peripheral Devices

Although most of the RAM memory in a system is based on high-speed DRAM interfaced directly to the processor's bus, not all memory is connected to the CPU in this manner. Sometimes a large block of RAM is part of a peripheral device and you communicate with that device by writing data to the RAM on the peripheral. Video display cards are probably the most common example, but some network interface cards and USB controllers also work this way (as well as other peripherals). Unfortunately, the access time to the RAM on these peripheral devices is often much slower than access to normal memory. We'll call such access NUMA⁸ access to indicate that access to such memory isn't uniform (that is, not all memory locations have the same access times). In this section we'll use the video card as an example, although NUMA performance applies to other devices and memory technologies as well.

A typical video card interfaces to the CPU via the PCI (or much worse, ISA) bus inside the computer system. The PCI bus nominally runs at 33 MHz and is capable of transferring four bytes per bus cycle. In burst mode, a video controller card, therefore, is capable of transferring 132 megabytes per second (though few would ever come close to achieving this for technical reasons). Now compare this with main memory access. Main memory usually connects directly to the CPU's bus and modern CPUs have a 100 MHz 64-bit wide bus. Technically (if memory were fast enough), the CPU's bus could transfer 800 MBytes/sec. between memory and the CPU. This is six times faster than transferring data across the PCI bus. Game programmers long ago discovered that it's much faster to manipulate a copy of the screen data in main memory and only copy that data to the video display memory when a vertical retrace occurs (about 60 times/sec.). This mechanism is much faster than writing directly to the video memory every time you want to make a change.

Unlike caches and the virtual memory subsystem that operate in a transparent fashion, programs that write to NUMA devices must be aware of this and minimize the accesses whenever possible (e.g., by using an off-screen bitmap to hold temporary results). If you're actually storing and retrieving data on a NUMA device, like a Flash memory card, then you must explicitly cache the data yourself. Later in this text you'll learn about hash tables and searching. Those techniques will help you create your own caching system for NUMA devices.

6.9 Segmentation

Segmentation is another memory management scheme, like paging, that provides memory protection and virtual memory capabilities. Windows does not support the use of segments, nor does HLA provide any instructions that let you manipulate segment registers or use segment override prefixes on an instruction. The Win32 operating system employs the flat memory model that, essentially, ignores segments on the 80x86. Furthermore, the remainder of this text also ignores segmentation. What this means is that you don't really need to know anything about segmentation in order to write assembly language programs that run under Windows. However, it's unthinkable to write a book on 80x86 assembly language programming that doesn't at least mention segmentation. Hence this section.

The basic idea behind the segmentation model is that memory is managed using a set of segments. Each segment is, essentially, its own address space. A segment consists of two components: a base address that contains the address of some physical memory location and a length value that specifies the length of the

8. Remember, NUMA stands for NonUniform Memory Access.

segment. A segmented address also consists of two components: a segment selector and an offset into the segment. The segment selector specifies the segment to use (that is, the base address and length values) while the offset component specifies the offset from the base address for the actual memory access. The physical address of the actual memory location is the sum of the offset and the base address values. If the offset exceeds the length of the segment, the system generates a protection violation.

Segmentation on the 80x86 got a (deservedly) bad name back in the days of the 8086, 8088, and 80286 processors. The problem back then is that the offset into the segment was only a 16-bit value, effectively limiting segments to 64 kilobytes in length. By creating multiple segments in memory it was possible to address more than 64K within a single program; however, it was a major pain to do so, especially if a single data object exceeded 64 kilobytes in length. With the advent of the 80386, Intel solved this problem (and others) with their segmentation model. By then, however, the damage had been done; segmentation had developed a really bad name that it still bears to this day.

Segments are an especially powerful memory management system when a program needs to manipulate different variable sized objects and the program cannot determine the size of the objects before run time. For example, suppose you want to manipulate several different files using Windows' memory mapped file scheme. Under Win32, which doesn't support segmentation, you have to specify the maximum size of the file before you map it into memory. If you don't do this, then Windows can't leave sufficient space at the end of the first file in memory before the second file starts. On the other hand, if Windows supported segmentation, it could easily return segmented pointers to these two memory mapped files, each in their own logical address space. This would allow the files to grow to the size of the maximum offset within a segment (or the maximum file size, whichever is smaller). Likewise, if two programs wanted to share some common data, a segmented system could allow the two programs to put the shared data in a segment. This would allow both programs to reference objects in the shared area using like-valued pointer (offset) values. This makes it easier to pass pointer data (within the shared segment) between the two programs, a very difficult thing to do when using a flat memory model without segmentation as Windows currently does.

One of the more interesting features of the 80386 and later processors is the fact that Intel combined both segmentation and paging in the same memory management unit. Prior to the 80386 most real-world CPUs used paging or segmentation but not both. The 80386 processor merged both of these memory management mechanisms into the same chip, offering the advantages of both systems on a single chip. Unfortunately, most 32-bit operating systems (e.g., Linux and Windows) fail to take advantage of segmentation so this feature goes wasted on the chip.

6.10 Segments and HLA

Although HLA creates programs use the flat memory model under Win32, HLA does provide limited support for segments in your code. However, HLA's (and Window's) segments are not the same thing as 80x86 segments; HLA segments are a logical organization of memory that has very little to do with segmentation on the 80x86. HLA's segments provide a simple way to organize variables and other objects in memory.

Logically, a segment is a block of memory where you place related objects. By default, HLA supports five different segments: a segment that holds machine instructions, a read-only segment that holds constant objects that HLA creates, a readonly segment that holds values you declare in the `READONLY` section, a data segment that holds variables and other objects you declare in the `STATIC` section, and a "BSS" section that holds uninitialized variables you declare in the `STORAGE` section⁹.

Normally you are completely unaware of the fact that HLA creates these segments in memory. The use of these segments is automatic and generally transparent to your HLA programs. In a few cases, however, you may need access to this segment information. For example, when linking your HLA programs with high level languages like C/C++ or Delphi you may need to tell HLA to use different names for the five segments it create (as imposed by the high level language). By default, HLA uses the following segment names for its five segments:

9. In theory, there is also a stack and a heap segment. However, the linker, not HLA, defines and allocates these two segments. You cannot explicitly declare static objects in these two segments during compilation.

- `_TEXT` for the code segment (corresponds to the `".code"` segment).
- `_DATA` for the STATIC section (corresponds to the `".data"` segment).
- `_BSS` for the STORAGE section (corresponds to the `".bss"` segment).
- `"CONST"` for the HLA constant segment (corresponds to the `".edata"` segment).
- `"readonly"` for the HLA READONLY segment (this is not a standardized segment name).

The `_TEXT`, `_DATA`, `_BSS`, and `"CONST"` segment names are quite standard under Win32. Most common compilers that generate Win32 code use these segment names for the code, data, uninitialized, and constant data sections. There does not seem to be a common segment that high level language compilers use for read-only data (other than `CONST`), so HLA creates a separate specifically for this purpose: the `"readonly"` segment where HLA puts the objects you declare in the `READONLY` section.

Examples of objects HLA puts in the `"CONST"` segment include string literal constants for string variables, constants HLA emits for extended syntax forms of the `mul`, `imul`, `div`, `idiv`, `bounds`, and other instructions, floating point constants that HLA automatically emits (e.g., for the `"fld(1.234);"` instruction) and so on. Generally, you do not explicitly declare values that wind up in this section (other than through the use of one of the aforementioned instructions).

HLA provides special directives that let you change the default names for these segments. Although `_TEXT`, `_DATA`, `_BSS` and `"CONST"` are very standard names, some compilers may use different names and expect HLA to put its code and data in those different segments. The `"readonly"` segment is definitely non-standard, some compilers may not allow you to use it (indeed, some compilers may not even allow read-only segments in memory). Should you encounter a language that wants different segment names or doesn't allow `readonly` segments, you can tell HLA to use a different segment name or to map the read-only segments to the static data segment. Here are the directives to achieve this:

```
#code( "codeSegmentName", "alignment", "class" )
#static( "dataSegmentName", "alignment", "class" )
#storage( "bssSegmentName", "alignment", "class" )
#readonly( "readOnlySegmentName", "alignment", "class" )
#const( "constSegmentName", "alignment", "class" )
```

The `#code` directive tells HLA to rename the code segment (`_TEXT`) or use different alignment or classification options. The `#static` directive renames the data segment (`_DATA`, the segment the `STATIC` section uses). The `#storage` directive renames the uninitialized data segment (`_BSS`, the segment the `STORAGE` section uses). The `#readonly` directive renames the `"readonly"` segment (where HLA places data you declare in the `READONLY` section). Finally, the `#const` directive renames HLA's `"CONST"` segments (where HLA places constants that it emits internally).

Each of these directives contains three string expression operands. The first string operand specifies the name of the segment. The second string specifies the segment alignment; we'll return to a discussion of this operand in a moment. The third operand is the segment class; the linker uses this name to combine segments that have different names into a single memory block. Generally, the class name is some variant of the segment name, but this is not necessarily the case (e.g., the standard class name for the `_TEXT` segment is `"CODE"`).

The alignment operand must be a string that contains one of the following identifiers: `"byte"`, `"word"`, `"dword"`, `"para"`, or `"page"`. HLA will only allow a string constant containing one of these five strings. The alignment option specifies the boundary on which the linker will start a segment. This option is only meaningful if you combine two different segments by using the same string for the class parameter. The linker combines two segments by concatenating them in memory. When the linker combines the segments, it makes sure that the concatenated segments start on the boundary the alignment operand specifies. A `"byte"` alignment means that the segment can start at an arbitrary byte boundary. The `"word"` and `"dword"` alignment options tell the linker that the segment must start on a word or double word boundary (respectively). The `"para"` alignment option tells the linker to start the segment on a paragraph (16-byte) boundary. The `"page"` option tells the linker to align the segment on a 256-byte page boundary (this has nothing to do with 4K pages). Most systems expect paragraph alignment, so the most common option here is `"para"`¹⁰.

10. In fact, MASM requires `PARA` alignment for the standard segment names. You may only change the alignment if you specify different segment names.

By default, the linker will start each segment in memory on a 4K MMU page boundary. Therefore, if each segment in an HLA program uses only one byte, that program will consume at least 20K because each segment in memory will start on a different 4K boundary¹¹. This is why a simple "Hello World" application consumes so much memory – the five default HLA segments each consume 4K of the memory space whether or not the segments actually have 4K of data. The program isn't really 20K long, it's just spread out over the 20K. As you add more code to the "Hello World" program, you'll notice that the executable file doesn't grow in size until you reach some magic point. Then the program jumps in size by increments of 4K (each time a segment's length crosses a 4K boundary, the program grows in length by 4K). If you want the shortest possible executable file, you can tell HLA to combine all the segments into a single segment. However, saving 8K, 12K, or even 16K of data is hardly useful on modern computer systems. Combining segments only saves a significant percentage of the program's size on very tiny programs, so it's not worth the effort for most real applications.

To combine two segments you use the same name for the third parameter in the `#code`, `#data`, `#static`, `#readonly`, and `#const` directives. For example, if you want to combine the "CONST" and "readonly" segments into a single memory segment, you can do so with the following two statements (this is actually the default definition):

```
#readonly( "readonly", "para", "CONST" )
#const( "CONST", "para", "CONST" )
```

By using the same class names but different segment names you tell the linker to combine these two segments in memory. Of course, you can also combine the two segments by giving them the same segment name, e.g.,

```
#readonly( "readonly", "para", "readonly" )
#const( "readonly", "para", "readonly" )    // This is a bad idea, see below.
```

Generally, though, you should not give the `#const` ("CONST") segment the same name as other segments. This can create code generation problems. If you want to combine the "CONST" segment with a different segment, use the class parameter to achieve this. If you give the `#const` segment the same name as one of the other segments, HLA may interleave data objects between the other segment and the `#const` segment; HLA generally assumes this is not the case, so the combination of segments may introduce some subtle bugs in your programs.

If the particular language you are using doesn't support read-only segments, you should map the "readonly" and "CONST" segments to the "_TEXT" (or equivalent) segment using the "CODE" combine class parameter. Do not map the rename these segments to "_TEXT" because this will interleave data with code and that will most likely crash your program.

The segment renaming directives do not check the syntax of the strings you specify for the segment name and class fields. These should be legal MASM identifiers and should not be MASM keywords. Generally, legal HLA identifiers work just fine here (unless, of course, you just happen to pick a MASM reserved word). If you specify a syntactically incorrect segment name or class name, HLA will not complain until it attempts to assemble its output file with MASM.

You may only rename the HLA segments once and these directives must appear before the UNIT or PROGRAM statements in an HLA source file. HLA does not allow you to change the name of one of these segments after it has emitted any code for a specific segment. Since HLA emits segment declarations in response to a UNIT or PROGRAM statement, you must do any segment renaming prior to these statements in an HLA source file; i.e., these directives will typically be the very first statements in a source file.

Here are the default segment names, alignments, and class values that HLA uses:

```
#code( "_TEXT", "para", "CODE" )
#static( "_DATA", "para", "DATA" )
#storage( "_BSS", "para", "BSS" )
#const( "CONST", "para", "CONST" )
#readonly( "readonly", "para", "CONST" )
```

11. Actually, the smallest HLA program will probably be at least 24K or 28K because the Win32 libraries also consume a few pages in memory.

If you use the MASM-defined names "_TEXT", "_DATA", "_BSS", or "CONST" you must provide the alignment and class parameters given above or MASM will complain when it compiles HLA's output.

6.11 User Defined Segments in HLA

In addition to the five standard segments, HLA lets you declare your own segments in your assembly programs. Like the five standard segments, you should not confuse HLA segments with 80x86 segments. You do not use the 80x86 segment registers to access data in user-defined segments. Instead, user segments exist as a logical entity to group a set of related objects into the same physical block of memory. In this section we'll take a look at why you would want to use segments and how you declare them in HLA.

It should come as no surprise that when you declare two variables in adjacent statements in a declaration section (e.g., `STATIC`) that HLA allocates those objects in adjacent memory locations. What may be surprising is that HLA will probably not allocate two variables adjacently in memory if you declare those variables in two adjacent declaration sections. E.g., HLA will allocate *i* and *j* below in adjacent memory locations, but it probably will not allocate *j* and *k* in adjacent memory locations:

```
static
    i:uns32;
    j:int32;

storage
    k:dword;
```

The reason *k* does not immediately follow *j* in memory is because *k* is in the "_BSS" segment while *i* and *j* are in the "_DATA" segment. Since segments typically start on 4K boundaries, there may be a huge gap between *j* and *k*, assuming that the "_BSS" segment follows the "_DATA" segment in memory (and it may not).

Another somewhat surprising result is that HLA (and MASM and the linker) will combine declarations from declaration sections with the same segment name, even if those declarations are not adjacent. Consider the following code:

```
static
    i:uns32;
    j:int32;

storage
    k:dword;

static
    m:real32;
```

Although *j* and *k* probably won't occupy adjacent memory locations, nor will *k* and *m*, it is quite possible for *j* and *m* to occupy adjacent memory locations since HLA places both declarations in the "_DATA" segment. There is no requirement for HLA to allocate *m* immediately after *j*, but HLA will allocate both objects in the same block of physical memory. If you need allocate two variables in adjacent memory locations, or one variable must appear at a lower address than another in memory, you must allocate both objects in the same (physical) declaration sequence. I.e., *i* and *j* (in the declarations above) will be allocated in adjacent memory locations with *i* at the lower address. HLA allocates *m* in the same segment as *i* and *j*, but there's no guarantee that *m* will appear at a higher or lower address than *i* and *j*.

In addition to the five standard segments, HLA lets you define your own memory segments. You use the `SEGMENT` declaration statement to accomplish this. The `SEGMENT` statement takes the following form:

```
segment segName( "alignment", "class" );
    << Declarations >>
```

You would use this declaration anywhere a `STATIC`, `READONLY`, or `STORAGE`, declaration section is legal¹². Anything legal after a `STATIC` keyword is legal after the `SEGMENT` declaration.

The *segName* field in the declaration above is the name you're going to give this segment. You should choose a unique name and it probably shouldn't be *_TEXT*, *_BSS*, *_DATA*, *readonly*, or *CONST* (HLA doesn't prevent the use of these segment names; however, there is little purpose to using most of them since you can create objects in most of these segments using the standard declaration sections). This segment name will automatically be a public name, so you should use an identifier that doesn't conflict with any MASM keywords or other global symbols.

The alignment field must be one of the following strings: *"byte"*, *"word"*, *"dword"*, *"para"*, or *"page"*. This alignment directive has the same meaning as the corresponding string in the segment renaming directives.

The "class" operand specifies the combine class. This field has the same meaning as the combine class operand in the segment renaming directives. Note that, like those directives, this operand must be a string constant. HLA does not check the syntax of this string. It should be a legal identifier that doesn't conflict with any MASM reserved words (just like the segment renaming directives' class field).

Segment names are global, even if you define a segment within a procedure. You may use the same segment name in several different segment declaration sections throughout your program; if you do, HLA (and MASM and the linker) will physically combine all the objects you declare in such a segment.

One nice thing about using different segments for variable declarations is that you physically separate the objects in memory. This reduces the impact of errant programs on data unrelated to the task at hand. For example, if you put each procedure's static variables in their own separate segment, this will reduce the likelihood that one procedure will accidentally overwrite another procedure's data if it oversteps an array bounds by a few bytes. Of course, the procedure can still wipe out its own variables by doing this, however, keeping the values in their own segment localizes the impact and makes it easier to track down this defect in your code. One bad thing about using separate segments for each procedure is that each segment consumes a minimum of 4K of memory; so your program's executable will contain a lot of empty data if you have a large number of these segments and you don't declare 4K of data in each procedure.

6.12 Controlling the Placement and Attributes of Segments in Memory

Whenever you compile and HLA program, HLA produces several output files: in particular, HLA produces an ".ASM" file that HLA assembles via MASM, and a ".LINK" file that contains information for the linker. The ".LINK" file controls the placement of segments within memory (when the program actually executes) and it also controls other attributes of segments (such as whether they may contain executable code, whether the segment is writable, etc.). When HLA compiles a program to an executable, it first calls a program named "HLAPARSE.EXE" which is actually responsible for translating the HLA source code to a MASM-compatible ".ASM" file. Then HLA calls the LINK program to link the OBJ files that MASM produces with various library files to produce an executable file¹³. In addition to passing in the list of OBJ and LIB filenames, HLA also provides the linker with other useful information about segment placement. In this section we'll explore some of the linker options so you can run the linker separately should you want to exercise explicit control over the placement of segments in memory.

To get a (partial) list of the linker options, run the link.exe program with the "/"? command line option. The linker will respond with a list that looks something like the following:

```

```

```
usage: LINK [options] [files] [@commandfile]
```

```
options:
```

```
/ALIGN:#
```

12. Well, not really. segment declarations may not appear in classes or namespaces. See the appropriate sections later in this text for a discussion of classes and namespaces.

13. If you've got any resource files, HLA will also call the resource compiler, rc.exe, to compile these files. Resource files are beyond the scope of this chapter, so we will ignore them here.

Most of these options are very advanced, or of little use to us right now. However, a good number of them are useful on occasion so we'll discuss them here.

/ALIGN:number The number value must be a decimal number and it must be a power of two¹⁴. The default (which HLA uses) is 4096. This specifies the default alignment for each segment in the program. You should normally leave this at 4K, but if you write a lot of very short assembly programs you can shrink the size of the executable image by setting this to a smaller value. Note that this number should be at least as large as the largest alignment option (byte, word, dword, para, or page) that you specify for you segments.

14. You can use a hexadecimal value if you specify the number using C/C++ syntax, e.g., "0x123ABC".

The `/BASE:address` option lets you specify the starting address of the code segment ("`_TEXT`"). The linker defaults this address to `0x4000000` (i.e., `$400_0000`). HLA typically uses a default value of `0x3000000` (`$300_0000`). This leaves room for a 16 Mbyte unused block, a 16 Mbyte stack segment, and a 16 Mbyte heap segment below the code segment in memory (which is where the linker normally puts the stack and heap). If you want a larger heap or stack segment, you should specify a higher starting address with the `/BASE` linker option.

The `/ENTRY:name` options specifies the name of the main program. This is the location where program execution begins when Windows first executes the program. For HLA console window applications, the name of the main program is "`?HLAMain`". Unless you're linking HLA code with a main program written in another language, or you completely understand the HLA start up sequence, you should always use this identifier to specify the entry point of an HLA main program. Note that if you circumvent this entry point, HLA does not properly set up the exception handling facilities and other features of the language. So change this name at your own risk.

`/HEAP:reserve,commit` This option specifies the amount of memory that the system reserves for the heap. The first numeric value indicates the amount of heap space to reserve, the second parameter specifies the amount of that heap space to actual map into the address space. By default, HLA supplies `0x1000000` (`$100_0000`, or 16 Mbytes) for both values. This sets aside room for a 16 Mbyte heap and makes all of it available to your program. This is a rather large value for the heap, especially if you write short programs that don't allocate much memory dynamically. For most small applications you may want to set this to a more reasonable (smaller) value. The Windows default is one megabyte (`0x100000` or `$10_0000`). If you don't do much dynamic memory allocation, your code will probably coexist better with other applications if you set this value to 128K (`0x20000` or `$2_0000`). As a general rule, you should set both operands to the same value.

The `/MACHINE:IX86` option tells the linker that you're creating code for an 80x86 CPU. You should not attempt to specify a different CPU when using HLA.

`/MAP` and `/MAP:filename`. These options tell the linker to produce a map *file*. The first form, without the optional filename, causes the linker to produce a map file with the same base name as the output file and a suffix of ".map". The second form lets you specify the name of the map file. The map file is a text file that contains several bits of information about the object file. You should produce a map file something and view this information with a text editor to see the kind of information the linker produces. None of this information is usually essential, but it is handy to have now and then. By default, HLA does not produce a map file.

`/MERGE:from=to`. This option merges the segment (section) named *from* to *to*. This will cause the linker to concatenate the two segments in memory. This is roughly equivalent to using the same combine class string in the segment declaration. For example, "`/MERGE:readonly=.edata`" merges the `readonly` segment with the `CONST` segment by concatenating the two.

`/OUT:filename`. This option specifies the output (executable) filename. By default, HLA appends ".EXE" to the base name of your program and uses that as the executable name. If you would prefer a different name, then use this option to specify the executable file name that LINK produces.

`/SECTION:name,options`. This option lets you specify the ordering of segments in memory as well as apply attributes to those segments. The ".LINK" file that HLA produces contains a list of `/SECTION` commands to feed to the linker that specifies the ordering of the segments (by their appearance in the ".LINK" file) and the attributes of those segments. The *name* field is the segment name. This is a case sensitive field, so the case of *name* must exactly match the original segment declaration. The *options* field is a string of one or more characters that specifies the characteristics of that segment in memory. Here are some of the more common options:

- E Allows the execution of code in this segment
- R Allows the program to read data in this segment
- W Allows the program to write data in this segment
- S Shared. Allows multiple copies of this program to share this data.
- K Marks the page as non-cachable (generally for multiprocessing applications).
- P Marks the page as non-pageable (i.e., it must always be in real memory).

Most of the other options are either very advanced, uninteresting, or not applicable to HLA programs. Most segments will have at least one of the E, R, or W options. HLA's default segments generally use the following section options:

```
/SECTION: .text,ER      -- Note: .text = _TEXT
/SECTION: .edata,R      -- Note: .edata = CONST
/SECTION: readonly,R
/SECTION: .data,RW      -- Note: .data = _DATA
/SECTION: .bss,RW       -- Note: .bss = _BSS
```

/STACK:reserve,commit. This option is similar to the */HEAP* option except it reserves space for the program's stack segment rather than the heap segment. Like the HEAP segment, HLA defaults the stack size to 16 Mbytes (0x4000000 or \$400_0000). If you write shorter applications that don't use a lot of local variable space or heavy recursion, you may want to consider setting this value to one megabyte or less, e.g., */STACK:0x100000,0x100000*.

/SUBSYSTEM:system. You must supply a subsystem option when you create an executable program. For HLA programs you would normally use */SUBSYSTEM:CONSOLE* when writing a standard console application. You can use HLA to write GUI applications, if you do this, then you will need to use the */SUBSYSTEM:WINDOWS* linker option. By default, HLA links your code with the */SUBSYSTEM:CONSOLE* option. If you use the HLA *-w* command line option, then HLA will invoke the linker with the */SUBSYSTEM:WINDOWS* option. Of course, if you explicitly run the linker yourself, you will have to supply one of these two options.

The preceding paragraphs explain most of the command line options you'll use when linking programs written in HLA. For more information about the linker, see the Microsoft on-line documentation that accompanies the linker.

If you get tired of typing really long linker command lines every time you compile and link an HLA program, you can gather all the (non-changing) command line options into a linker command file and tell the linker to grab those options and filenames from the command file rather than from the command line. The ".LINK" file that the HLA compiler produces is a good example of a linker command file. The ".LINK" file contains the */SECTION* options for the default and user-defined segments found in an HLA program. Rather than manually supplying these options on each call to the linker, you can use a command line like the following:

```
link @filename.link  other_options file_names
```

The at-sign ("@") tells the linker to read a list of commands from the specified command file. Note that you can have several different command files, so if you're compiling and linking several different HLA source files, you can specify the ".link" file for each compilation on the command line.

The filenames you specify on the linker command line should be the names of OBJ and LIB files that you wish to link together. In addition to the OBJ files you've created with HLA, you'll probably want to specify the following library files:

- kernel32.lib Contains definitions for the base Windows API (e.g., console stuff)
- user32.lib Contains the definition of the MessageBox dialog (used for exceptions).
- hlalib.lib The HLA Standard Library

If you don't call any HLA Standard Library routines (unlikely, but possible) then you obviously don't need to specify the hlalib.lib file. Note that it doesn't hurt to specify the name of a library whose members you don't use. The linker will not include any object code from a library unless the program actually uses code or data from that library.

If you're manually linking code that you compile with HLA, you will probably want to create one linker command file containing all the static commands and include that and any appropriate HLA ".LINK" files on the linker command line. Here's a typical example of a static link file (i.e., a file that doesn't get rewritten each time you compile the HLA program):

```
/heap:0x20000, 0x20000
/stack:0x2000, 0x20000
/base:0x1000000
```

```
/machine:IX86
/entry:?HLAMain
/out:mypgm.exe
kernel32.lib
user32.lib
hlalib.lib
```

Generally, you'd use the /SECTION commands from the HLA ".LINK" file unless you wanted to explicitly set the segment ordering or change the attributes of the memory segments.

To run the linker manually, you'd normally tell HLA to perform a compile (and assemble) only operation. This is done using the HLA "-c" command line option. That is, a command like "hla -c myfile.hla" will compile "myfile.hla" to "myfile.asm" and then run MASM to assemble this to "myfile.obj". HLA will not run the linker when you specify the "-c" option. If you prefer, you can run MASM separately by using the "-s" command line option as follows:

```
hla -s myfile.hla
ml -c -Cp -COFF myfile.asm
```

However, there is very little benefit to running the assembler yourself (run "MASM /?" to see the available MASM command line options).

Once you've compiled all necessary source files, you can link them by using the Microsoft LINK.EXE program with the command line (or command file) options this section discusses. Note that this section discusses options specific to the LINK.EXE v6.0 product. These features may change in a future version of the linker. Please see the Microsoft documentation if you have any questions about how the linker operates or if you're using a different version of the linker.

6.13 Putting it All Together

CPU architects divide memory into several different types depending on cost, capacity, and speed. They call this the memory hierarchy. Many of the levels in the memory hierarchy are transparent to the programmer. That is, the system automatically moves data between levels in the memory hierarchy without intervention on the programmer's part. However, if you are aware of the effects of the memory hierarchy on program performance, you can write faster programs by organizing your data and code so that it conforms to the expectations of the caching and virtual memory subsystems in the memory hierarchy.

The I/O Subsystem

Chapter Seven

7.1 Chapter Overview

A typical program does three basic activities: input, computation, and output. In this section we will discuss the other two activities beyond computation: input and output or I/O. This chapter concentrates on low-level CPU I/O rather than high level file or character I/O. This chapter discusses how the CPU transfers bytes of data to and from the outside world. This chapter discusses the mechanisms and performance issues behind the I/O.

7.2 Connecting a CPU to the Outside World

Most I/O devices interface to the CPU in a fashion quite similar to memory. Indeed, many devices appear to the CPU as though they were memory devices. To output data to the outside world the CPU simply stores data into a "memory" location and the data magically appears on some connectors external to the computer. Similarly, to input data from some external device, the CPU simply transfers data from a "memory" location into the CPU; this "memory" location holds the value found on the pins of some external connector.

An output port is a device that looks like a memory cell to the computer but contains connections to the outside world. An I/O port typically uses a latch rather than a flip-flop to implement the memory cell. When the CPU writes to the address associated with the latch, the latch device captures the data and makes it available on a set of wires external to the CPU and memory system (see Figure 7.1). Note that output ports can be write-only, or read/write. The port in Figure 7.1, for example, is a write-only port. Since the outputs on the latch do not loop back to the CPU's data bus, the CPU cannot read the data the latch contains. Both the address decode and write control lines must be active for the latch to operate; when reading from the latch's address the decode line is active, but the write control line is not.

Figure 7.1 A Typical Output Port

Figure 7.2 shows how to create a read/write input/output port. The data written to the output port loops back to a transparent latch. Whenever the CPU reads the decoded address the read and decode lines are active and this activates the lower latch. This places the data previously written to the output port on the CPU's data bus, allowing the CPU to read that data. A read-only (input) port is simply the lower half of Figure 7.2; the system ignores any data written to an input port.

Figure 7.2 An Output Port that Supports Read/Write Access

Note that the port in Figure 7.2 is not an input port. Although the CPU can read this data, this port organization simply lets the CPU read the data it previously wrote to the port. The data appearing on an external connector is an output port (only). One could create a (read-only) input port by using the lower half of the circuit in Figure 7.2. The input to the latch would appear on the CPU's data bus whenever the CPU reads the latch data.

A perfect example of an output port is a parallel printer port. The CPU typically writes an ASCII character to a byte-wide output port that connects to the DB-25F connector on the back of the computer's case. A cable transmits this data to the printer where an input port (to the printer) receives the data. A processor inside the printer typically converts this ASCII character to a sequence of dots it prints on the paper.

Generally, a given peripheral device will use more than a single I/O port. A typical PC parallel printer interface, for example, uses three ports: a read/write port, an input port, and an output port. The read/write port is the data port (it is read/write to allow the CPU to read the last ASCII character it wrote to the printer port). The input port returns control signals from the printer; these signals indicate whether the printer is ready to accept another character, is off-line, is out of paper, etc. The output port transmits control information to the printer such as whether data is available to print.

The first thing to learn about the input/output subsystem is that I/O in a typical computer system is radically different than I/O in a typical high level programming language. In a real computer system you will rarely find machine instructions that behave like *writeln*, *cout*, *printf*, or even the HLA *stdin* and *stdout* statements. In fact, most input/output instructions behave exactly like the 80x86's MOV instruction. To send data to an output device, the CPU simply moves that data to a special memory location. To read data from an input device, the CPU simply moves data from the address of that device into the CPU. Other than there are usually more wait states associated with a typical peripheral device than actual memory, the input or output operation looks very similar to a memory read or write operation.

7.3 Read-Only, Write-Only, Read/Write, and Dual I/O Ports

We can classify input/output ports into four categories based on the CPU's ability to read and write data at a given port address. These four categories are read-only ports, write-only ports, read/write ports, and dual I/O ports.

A read-only port is (obviously) an input port. If the CPU can only read the data from the port, then that port is providing data appearing on lines external to the CPU. The system typically ignores any attempt to

write data to a read-only port¹. A good example of a read-only port is the status port on a PC's parallel printer interface. Reading data from this port lets you test the current condition of the printer. The system ignores any data written to this port.

A write-only port is always an output port. Writing data to such a port presents the data for use by an external device. Attempting to read data from a write-only port generally returns garbage (i.e., whatever values that just happen to be on the data bus at that time). You generally cannot depend on the meaning of any value read from a write-only port.

A read/write port is an output port as far as the outside world is concerned. However, the CPU can read as well as write data to such a port. Whenever the CPU reads data from a read/write port, it reads the data that was last written to the port. Reading the port does not affect the data the external peripheral device sees, reading the port is a simple convenience for the programmer so that s/he doesn't have to save the value last written to the port should they want to retrieve the value.

A dual I/O port is also a read/write port, but reading the port reads data from some external device while writing data to the port transmits data to a different external device. Figure 7.3 shows how you could interface such a device to the system. Note that the input and output ports are actually a read-only and a write-only port that share the same address. Reading the address accesses one port while writing to the address accesses the other port. Essentially, this port arrangement uses the R/W control line(s) as an extra address bit when selecting these ports.

Figure 7.3 An Input and an Output Device That Share the Same Address (a Dual I/O Port)

These examples may leave you with the impression that the CPU always reads and writes data to peripheral devices using data on the data bus (that is, whatever data the CPU places on the data bus when it writes to an output port is the data actually written to that output port). While this is generally true for input ports (that is, the CPU transfers input data across the data bus when reading data from the input port), this isn't necessarily true for output ports. In fact, a very common output mechanism is simply accessing a port. Figure 7.4 provides a very simple example. In this circuit, an address decoder decodes two separate addresses. Any access (read or write) to the first address sets the output line high; any read or write of the second address clears the output line. Note that this circuit ignores the data on the CPU's data lines. It is not important whether the CPU reads or writes data to these addresses, nor is the data written of any consequence. The only thing that matters is that the CPU access one of these two addresses.

1. Note, however, that some devices may fail if you attempt to write to their corresponding input ports, so it's never a good idea to write data to a read-only port.

Figure 7.4 **Outputting Data to a Port by Simply Accessing That Port**

Another possible way to connect an output port to the CPU is to use a D flip-flop and connect the read/write status lines to the D input on the flip-flop. Figure 7.5 shows how you could design such a device. In this diagram any read of the selected port sets the output bit to zero while a write to this output port sets the output bit to one.

Figure 7.5 **Outputting Data Using the Read/Write Control as the Data to Output**

There are a wide variety of ways you can connect external devices to the CPU. This section only provides a few examples as a sampling of what is possible. In the real world, there are an amazing number of different ways that engineers connect external devices to the CPU. Unless otherwise noted, the rest of this chapter will assume that the CPU reads and writes data to an external device using the data bus. This is not to imply that this is the only type of I/O that one could use in a given example.

7.4 I/O (Input/Output) Mechanisms

There are three basic forms of input and output that a typical computer system will use: I/O-mapped I/O, memory-mapped I/O, and direct memory access (DMA). I/O-mapped input/output uses special instructions to transfer data between the computer system and the outside world; memory-mapped I/O uses special memory locations in the normal address space of the CPU to communicate with real-world devices; DMA is a special form of memory-mapped I/O where the peripheral device reads and writes data in memory without going through the CPU. Each I/O mechanism has its own set of advantages and disadvantages, we will discuss these in this section.

7.4.1 Memory Mapped Input/Output

A memory mapped peripheral device is connected to the CPU's address and data lines exactly like memory, so whenever the CPU reads or writes the address associated with the peripheral device, the CPU transfers data to or from the device. This mechanism has several benefits and only a few disadvantages.

The principle advantage of a memory-mapped I/O subsystem is that the CPU can use any instruction that accesses memory to transfer data between the CPU and a memory-mapped I/O device. The MOV instruction is the one most commonly used to send and receive data from a memory-mapped I/O device, but any instruction that reads or writes data in memory is also legal. For example, if you have an I/O port that is read/write, you can use the ADD instruction to read the port, add data to the value read, and then write data back to the port.

Of course, this feature is only usable if the port is a read/write port (or the port is readable and you've specified the port address as the source operand of your ADD instruction). If the port is read-only or write-only, an instruction that reads memory, modifies the value, and then writes the modified value back to memory will be of little use. You should use such read/modify/write instructions only with read/write ports (or dual I/O ports if such an operation makes sense).

Nevertheless, the fact that you can use any instruction that accesses memory to manipulate port data is often a big advantage since you can operate on the data with a single instruction rather than first moving the data into the CPU, manipulating the data, and then writing the data back to the I/O port.

The big disadvantage of memory-mapped I/O devices is that they consume addresses in the memory map. Generally, the minimum amount of space you can allocate to a peripheral (or block of related peripherals) is a four kilobyte page. Therefore, a few independent peripheral peripherals can wind up consuming a fair amount of the physical address space. Fortunately, a typical PC has only a couple dozen such devices, so this isn't much of a problem. However, some devices, like video cards, consume a large chunk of the address space (e.g., some video cards have 32 megabytes of on-board memory that they map into the memory address space).

7.4.2 I/O Mapped Input/Output

I/O-mapped input/output uses special instructions to access I/O ports. Many CPUs do not provide this type of I/O, though the 80x86 does. The Intel 80x86 family uses the IN and OUT instructions to provide I/O-mapped input/output capabilities. The 80x86 IN and OUT instructions behave somewhat like the MOV instruction except they transmit their data to and from a special I/O address space that is distinct from the memory address space. The IN and OUT instructions use the following syntax:

```
in( port, al ); // ... or AX or EAX, port is a constant in the range
out( al, port ); // 0..255.

in( dx, al ); // Or AX or EAX.
out( al, dx );
```

The 80x86 family uses a separate address bus for I/O transfers². This bus is only 16-bits wide, so the 80x86 can access a maximum of 65,536 different bytes in the I/O space. The first two instructions encode the port address as an eight-bit constant, so they're actually limited to accessing only the first 256 I/O addresses in this address space. This makes the instruction shorter (two bytes instead of three). Unfortunately, most of the interesting peripheral devices are at addresses above 255, so the first pair of instructions above are only useful for accessing certain on-board peripherals in a PC system.

To access I/O ports at addresses beyond 255 you must use the latter two forms of the IN and OUT instructions above. These forms require that you load the 16-bit I/O address into the DX register and use DX as a pointer to the specified I/O address. For example, to write a byte to the I/O address \$378³ you would use an instruction sequence like the following:

```
mov( $378, dx );
out( al, dx );
```

2. Physically, the I/O address bus is the same as the memory address bus, but additional control lines determine whether the address on the bus is accessing memory or and I/O device.

3. This is typically the address of the data port on the parallel printer port.

The advantage of an I/O address space is that peripheral devices mapped to this area do not consume space in the memory address space. This allows you to fully expand the memory address space with RAM or other memory. On the other hand, you cannot use arbitrary memory instructions to access peripherals in the I/O address space, you can only use the IN and OUT instructions.

Another disadvantage to the 80x86's I/O address space is that it is quite small. Although most peripheral devices only use a couple of I/O address (and most use fewer than 16 I/O addresses), a few devices, like video display cards, can occupy millions of different I/O locations (e.g., three bytes for each pixel on the screen). As noted earlier, some video display cards have 32 megabytes of dual-ported RAM on board. Clearly we cannot easily map this many locations into the 64K I/O address space.

7.4.3 Direct Memory Access

Memory-mapped I/O subsystems and I/O-mapped subsystems both require the CPU to move data between the peripheral device and main memory. For this reason, we often call these two forms of input/output programmed I/O. For example, to input a sequence of ten bytes from an input port and store these bytes into memory the CPU must read each value and store it into memory. For very high-speed I/O devices the CPU may be too slow when processing this data a byte (or word or double word) at a time. Such devices generally have an interface to the CPU's bus so they can directly read and write memory. This is known as direct memory access since the peripheral device accesses memory directly, without using the CPU as an intermediary. This often allows the I/O operation to proceed in parallel with other CPU operations, thereby increasing the overall speed of the system. Note, however, that the CPU and DMA device cannot both use the address and data busses at the same time. Therefore, concurrent processing only occurs if the CPU has a cache and is executing code and accessing data found in the cache (so the bus is free). Nevertheless, even if the CPU must halt and wait for the DMA operation to complete, the I/O is still much faster since many of the bus operations during I/O or memory-mapped input/output consist of instruction fetches or I/O port accesses which are not present during DMA operations.

A typical DMA controller consists of a pair of counters and other circuitry that interfaces with memory and the peripheral device. One of the counters serves as an address register. This counter supplies an address on the address bus for each transfer. The second counter specifies the number of transfers to complete. Each time the peripheral device wants to transfer data to or from memory, it sends a signal to the DMA controller. The DMA controller places the value of the address counter on the address bus. At the same time, the peripheral device places data on the data bus (if this is an input operation) or reads data from the data bus (if this is an output operation). After a successful data transfer, the DMA controller increments its address register and decrements the transfer counter. This process repeats until the transfer counter decrements to zero.

7.5 I/O Speed Hierarchy

Different devices have different data transfer rates. Some devices, like keyboards, are extremely slow (comparing their speed to CPU speeds). Other devices like disk drives can actually transfer data faster than the CPU can read it. The mechanisms for data transfer differ greatly based on the transfer speed of the device. Therefore, it makes sense to create some terminology to describe the different transfer rates of peripheral devices.

Low-speed devices are those that produce or consume data at a rate much slower than the CPU is capable of processing. For the purposes of discussion, we'll claim that low-speed devices operate at speeds that are two to three orders of magnitude (or more) slower than the CPU. *Medium-speed devices* are those that transfer data at approximately the same rate (within an order of magnitude slower, but never faster) than the CPU. *High-speed devices* are those that transfer data faster than the CPU is capable of moving data between the device and the CPU. Clearly, high-speed devices must use DMA since the CPU is incapable of transferring the data between the CPU and memory.

With typical bus architectures, modern day PCs are capable of one transfer per microsecond or better. Therefore, high-speed devices are those that transfer data more rapidly than once per microsecond.

Medium-speed transfers are those that involve a data transfer every one to 100 microseconds. Low-speed devices usually transfer data less often than once every 100 microseconds. The difference between these speeds will decide the mechanism we use for the I/O operation (e.g., high-speed transfers require the use of DMA or other techniques).

Note that one transfer per microsecond is not the same thing as a one megabyte per second data transfer rate. A peripheral device can actually transfer more than one byte per data transfer operation. For example, when using the "in(dx, eax);" instruction, the peripheral device can transfer four bytes in one transfer. Therefore, if the device is reaching one transfer per microsecond, then the device can transfer four megabytes per second. Likewise, a DMA device on a Pentium processor can transfer 64 bits at a time, so if the device completes one transfer per microsecond it will achieve an eight megabyte per second data transfer rate.

7.6 System Busses and Data Transfer Rates

In Chapter One of this Volume (see "The System Bus" on page 132) you saw that the CPU communicates to memory and I/O devices using the system bus. In that chapter you saw that a typical Von Neumann Architecture machine has three different busses: the address bus, the data bus, and the control bus. If you've ever opened up a computer and looked inside or read the specifications for a system, you've probably heard terms like *PCI*, *ISA*, *EISA*, or even *NuBus* mentioned when discussing the computer's bus. If you're familiar with these terms, you may wonder what their relationship is with the CPU's bus. In this section we'll discuss this relationship and describe how these different busses affect the performance of a system.

Computer system busses like PCI (Peripheral Connection Interface) and ISA (Industry Standard Architecture) are definitions for physical connectors inside a computer system. These definitions describe a set of signals, physical dimensions (i.e., connector layouts and distances from one another), and a data transfer protocol for connecting different electronic devices. These busses are related to the CPU's bus only insofar as many of the signals on one of the peripheral busses also appear on the CPU's bus. For example, all of the aforementioned busses provide lines for address, data, and control functions.

Peripheral interconnection busses do not necessarily mirror the CPU's bus. All of these busses contain several additional lines that are not present on the CPU's bus. These additional lines let peripheral devices communicate with one other directly (without having to go through the CPU or memory). For example, most busses provide a common set of interrupt control signals that let various I/O devices communicate directly with the system's interrupt controller (which is also a peripheral device). Nor does the peripheral bus always include all the signals found on the CPU's bus. For example, the ISA bus only supports 24 address lines whereas the Pentium II supports 36 address lines. Therefore, peripherals on the ISA bus only have access to 16 megabytes of the Pentium II's 64 gigabyte address range.

A typical modern-day PC supports the PCI bus (although some older systems also provide ISA connectors). The organization of the PCI and ISA busses in a typical computer system appears in Figure 7.6.

Figure 7.6 Connection of the PCI and ISA Busses in a Typical PC

Notice how the CPU's address and data busses connect to a PCI Bus Controller device (which is, itself, a peripheral of sorts). The actual PCI bus is connected to this chip. Note that the CPU does not connect directly to the PCI bus. Instead, the PCI Bus Controller acts as an intermediary, rerouting all data transfer requests between the CPU and the PCI bus.

Another interesting thing to note is that the ISA Bus Controller is not directly connected to the CPU. Instead, it is connected to the PCI Bus Controller. There is no logical reason why the ISA Controller couldn't be connected directly to the CPU's bus, however, in most modern PCs the ISA and PCI controllers appear on the same chip and the manufacturer of this chip has chosen to interface the ISA bus through the PCI controller for cost or performance reasons.

The CPU's bus (often called the local bus) usually runs at some submultiple of the CPU's frequency. Typical local bus frequencies include 66 MHz, 100 MHz, 200 MHz, 400 MHz, and, possibly, beyond⁴. Usually, only memory and a few selected peripherals (e.g., the PCI Bus Controller) sit on the CPU's bus and operate at this high frequency. Since the CPU's bus is typically 64 bits wide (for Pentium and later processors) and it is theoretically possible to achieve one data transfer per cycle, the CPU's bus has a maximum possible data transfer rate (or maximum bandwidth) of eight times the clock frequency (e.g., 800 megabytes/second for a 100 Mhz bus). In practice, CPU's rarely achieve the maximum data transfer rate, but they do achieve some percentage of this, so the faster the bus, the more data can move in and out of the CPU (and caches) in a given amount of time.

The PCI bus comes in several configurations. The base configuration has a 32-bit wide data bus operating at 33 MHz. Like the CPU's local bus, the PCI is theoretically capable of transferring data on each clock cycle. This provides a theoretical maximum of 132 MBytes/second data transfer rate (33 MHz times four bytes). In practice, the PCI bus doesn't come anywhere near this level of performance except in short bursts. Whenever the CPU wishes to access a peripheral on the PCI bus, it must negotiate with other peripheral devices for the right to use the bus. This negotiation can take several clock cycles before the PCI controller grants the CPU the bus. If a CPU writes a sequence of values to a peripheral a double word per bus request, then the negotiation takes the majority of the time and the data transfer rate drops dramatically. The only way to achieve anywhere near the maximum theoretical bandwidth on the bus is to use a DMA controller and move blocks of data. In this block mode the DMA controller can negotiate just once for the bus and transfer a fair sized block of data without giving up the bus between each transfer. This "burst mode" allows the device to move lots of data quickly.

There are a couple of enhancements to the PCI bus that improve performance. Some PCI busses support a 64-bit wide data path. This, obviously, doubles the maximum theoretical data transfer rate. Another enhancement is to run the bus at 66 MHz, which also doubles the throughput. In theory, you could have a 64-bit wide 66 MHz bus that quadruples the data transfer rate (over the performance of the baseline configuration). Few systems or peripherals currently support anything other than the base configuration, but these optional enhancements to the PCI bus allow it to grow with the CPU as CPUs increase their performance.

The ISA bus is a carry over from the original PC/AT computer system. This bus is 16 bits wide and operates at 8 MHz. It requires four cycles for each bus cycle. This this and other reasons, the ISA bus is capable of about only one data transmission per microsecond. With a 16-bit wide bus, data transfer is limited to about two megabytes per second. This is much slower than the CPU's local bus and the PCI bus. Generally, you would only attach low-speed devices like an RS-232 communications device, a modem, or a parallel printer to the ISA bus. Most other devices (disks, scanners, network cards, etc.) are too fast for the ISA bus. The ISA bus is really only capable of supporting low-speed and medium speed devices.

Note that accessing the ISA bus on most systems involves first negotiating for the PCI bus. The PCI bus is so much faster than the ISA bus that this has very little impact on the performance of peripherals on the ISA bus. Therefore, there is very little difference to be gained by connecting the ISA controller directly to the CPU's local bus.

4. 400 MHz was the maximum CPU bus frequency as this was being written.

7.7 The AGP Bus

Video display cards are a very special peripheral that need the maximum possible amount of bus bandwidth to ensure quick screen updates and fast graphic operations. Unfortunately, if the CPU has to constantly negotiate with other peripherals for the use of the PCI bus, graphics performance can suffer. To overcome this problem, video card designers created the AGP (Advanced Graphics Port) interface between the CPU and the video display card.

The AGP is a secondary bus interface that a video card uses in addition to the PCI bus. The AGP connection lets the CPU quickly move data to and from the video display RAM. The PCI bus provides a connection to the other I/O ports on the video display card (see Figure 7.7). Since there is only one AGP port per system, only one card can use the AGP and the system never has to negotiate for access to the AGP bus.

Figure 7.7 AGP Bus Interface

7.8 Buffering

If a particular I/O device produces or consumes data faster than the system is capable of transferring data to that device, the system designer has two choices: provide a faster connection between the CPU and the device or slow down the rate of transfer between the two.

Creating a faster connection is possible if the peripheral device is already connected to a slow bus like ISA. Another possibility is going to a wider bus (e.g., to the 64-bit PCI bus) to increase bandwidth, or to use a bus with a higher frequency (e.g., a 66 MHz bus rather than a 33 MHz bus). Systems designers can sometimes create a faster interface to the bus; the AGP connection is a good example. However, once you're using the fastest bus available on the system, improving system performance by selecting a faster connection to the computer can be very expensive.

The other alternative is to slow down the transfer rate between the peripheral and the computer system. This isn't always as bad as it seems. Most high-speed devices don't transfer data at a constant rate to the system. Instead, devices typically transfer a block of data rapidly and then sit idle for some period of time. Although the burst rate is high (and faster than the CPU or system can handle), the average data transfer rate is usually lower than what the CPU/system can handle. If you could average out the peaks and transfer some of the data when the peripheral is inactive, you could easily move data between the peripheral and the computer system without resorting to an expensive, high-bandwidth, solution.

The trick is to use memory to buffer the data on the peripheral side. The peripheral can rapidly fill this buffer with data (or extract data from the buffer). Once the buffer is empty (or full) and the peripheral device is inactive, the system can refill (or empty) the buffer at a sustainable rate. As long as the average data rate of the peripheral device is below the maximum bandwidth the system will support, and the buffer is large enough to hold bursts of data to/from the peripheral, this scheme lets the peripheral communicate with the system at a lower data transfer rate than the device requires during burst operation.

7.9 Handshaking

Many I/O devices cannot accept data at an arbitrary rate. For example, a Pentium based PC is capable of sending several hundred million characters a second to a printer, but that printer is (probably) unable to print that many characters each second. Likewise, an input device like a keyboard is unable to provide several million keystrokes per second (since it operates at human speeds, not computer speeds). The CPU needs some mechanism to coordinate data transfer between the computer system and its peripheral devices.

One common way to coordinate data transfer is to provide some status bits in a secondary input port. For example, a one in a single bit in an I/O port can tell the CPU that a printer is ready to accept more data, a zero would indicate that the printer is busy and the CPU should not send new data to the printer. Likewise, a one bit in a different port could tell the CPU that a keystroke from the keyboard is available at the keyboard data port, a zero in that same bit could indicate that no keystroke is available. The CPU can test these bits prior to reading a key from the keyboard or writing a character to the printer.

Using status bits to indicate that a device is ready to accept or transmit data is known as handshaking. It gets this name because the protocol is similar to two people agreeing on some method of transfer by a hand shake.

Figure 7.8 shows the layout of the parallel printer port's status register. For the LPT1: printer interface, this port appears at I/O address \$379. As you can see from this diagram, bit seven determines if the printer is capable of receiving data from the system; this bit will contain a one when the printer is capable of receiving data.

Figure 7.8 The Parallel Port Status Port

The following short program segment will continuously loop while the H.O. bit of the printer status register contains zero and will exit once the printer is ready to accept data:

```
mov( $379, dx );
repeat

    in( dx, al );
    and( $80, al ); // Clears Z flag if bit seven is set.

until( @nz );

// Okay to write another byte to the printer data port here.
```

The code above begins by setting DX to \$379 since this is the I/O address of the printer status port. Within the loop the code reads a byte from the status port (the IN instruction) and then tests the H.O. bit of the port using the AND instruction. Note that logically ANDing the AL register with \$80 will produce zero if the H.O. bit of AL was zero (that is, if the byte read from the input port was zero). Similarly, logically anding AL with \$80 will produce \$80 (a non-zero result) if the H.O. bit of the printer status port was set. The

80x86 zero flag reflects the result of the AND instruction; therefore, the zero flag will be set if AND produces a zero result, it will be reset otherwise. The REPEAT..UNTIL loop repeats this test until the AND instruction produces a non-zero result (meaning the H.O. bit of the status port is set).

One problem with using the AND instruction to test bits as the code above is that you might want to test other bits in AL once the code leaves the loop. Unfortunately, the "and(\$80, al);" instruction destroys the values of the other bits in AL while testing the H.O. bit. To overcome this problem, the 80x86 supports another form of the AND instruction – TEST. The TEST instruction works just like AND except it only updates the flags; it does not store the result of the logical AND operation back into the destination register (AL in this case). One other advantage to TEST is that it only reads its operands, so there are less problems with data hazards when using this instruction (versus AND). Also, you can safely use the TEST instruction directly on read-only memory-mapped I/O ports since it does not write data back to the port. As an example, let's recode the previous loop using the TEST instruction:

```

mov( $379, dx );
repeat

    in( dx, al );
    test( $80, al ); // Clears Z flag if bit seven is set.

until( @nz );

// Okay to write another byte to the printer data port here.

```

Once the H.O. bit of the printer status port is set, it's okay to transmit another byte to the printer. The computer can make a byte available by storing the byte data into I/O address \$378 (for LPT1:). However, simply storing data to this port does not inform the printer that it can take the byte. The system must complete the other half of the handshake operation and send the printer a signal to indicate that a byte is available.

Figure 7.9 The Parallel Port Command Register

Bit zero (the strobe line) must be set to one and then back to zero when the CPU makes data available for the printer (the term "strobe" suggests that the system pulses this line in the command port). In order to pulse this bit without affecting the other control lines, the CPU must first read this port, OR a one into the L.O. bit, write the data to the port, then mask out the L.O. bit using an AND instruction, and write the final result back to the control port again. Therefore, it takes three accesses (a read and two writes) to send the strobe to the printer. The following code handles this transmission:

```

mov( $378, dx ); // Data port address
mov( Data2Xmit, al ); // Send the data to the printer.
out( al, dx );

mov( $37a, dx ); // Point DX at the control port.

```

```

in( dx, al );           // Get the current port setting.
or( 1, al );           // Set the L.O. bit.
out( al, dx );         // Set the strobe line high.
and( $fe, al );       // Clear the L.O. bit.
out( al, dx );         // Set the strobe line low.

```

The code above would normally follow the REPEAT..UNTIL loop in the previous example. To transmit a second byte to the printer you would jump back to the REPEAT..UNTIL loop and wait for the printer to consume the current byte.

Note that it takes a minimum of five I/O port accesses to transmit a byte to the printer use the code above (minimum one IN instruction in the REPEAT..UNTIL loop plus four instructions to send the byte and strobe). If the parallel port is connected to the ISA bus, this means it takes a minimum of five microseconds to transmit a single byte; that works out to less than 200,000 bytes per second. If you are sending ASCII characters to the printer, this is far faster than the printer can print the characters. However, if you are send a bitmap or a Postscript file to the printer, the printer port bandwidth limitation will become the bottleneck since it takes considerable data to print a page of graphics. For this reason, most graphic printers use a different technique than the above to transmit data to the printer (some parallel ports support DMA in order to get the data transfer rate up to a reasonable level).

7.10 Time-outs on an I/O Port

One problem with the REPEAT..UNTIL loop in the previous section is that it could spin indefinitely waiting for the printer to become ready to accept additional input. If someone turns the printer off or the printer cable becomes disconnected, the program could freeze up, forever waiting for the printer to become available. Usually, it's a good idea to indicate to the user that something has gone wrong rather than simply freezing up the system. A typical way to handle this problem is using a time-out period to determine that something is wrong with the peripheral device.

With most peripheral devices you can expect some sort of response within a reasonable amount of time. For example, most printers will be ready to accept additional character data within a few seconds of the last transmission (worst case). Therefore, if 30 seconds or more have passed since the printer was last willing to accept a character, this is probably an indication that something is wrong. If the program could detect this, then it could ask the user to check the printer and tell the program to resume printing once the problem is resolved.

Choosing a good time-out period is not an easy task. You must carefully balance the irritation of having the program constantly ask you what's wrong when there is nothing wrong with the printer (or other device) with the program locking up for long periods of time when there is something wrong. Both situations are equally annoying to the end user.

Any easy way to create a time-out period is to count the number of times the program loops while waiting for a handshake signal from a peripheral. Consider the following modification to the REPEAT..UNTIL loop of the previous section:

```

mov( $379, dx );
mov( 30_000_000, ecx );
repeat

    dec( ecx );           // Count down to see if the time-out has expired.
    breakif( @z );       // Leave this loop if ecx counted down to zero.

    in( dx, al );
    test( $80, al );     // Clears Z flag if bit seven is set.

until( @nz );

if( ecx = 0 ) then

    // We had a time-out error.

```

```

else

    // Okay to write another byte to the printer data port here.

endif;

```

The code above will exit once the printer is ready to accept data or when approximately 30 seconds have expired. You may question the 30 second figure. After all, a software based loop (counting down ECX to zero) should run at different speeds on different processors. However, don't miss the fact that there is an IN instruction inside this loop. The IN instruction reads a port on the ISA bus and that means this instruction will take approximately one microsecond to execute (about the fastest operation on the ISA bus). Hence, every one million times through the loop will take about a second ($\pm 50\%$, but close enough for our purposes). This is true regardless of the CPU frequency.

The 80x86 provides a couple of instructions that are quite useful for implementing time-outs in a polling loop: LOOPZ and LOOPNZ. We'll consider the LOOPZ instruction here since it's perfect for the loop above. The LOOPZ instruction decrements the ECX register by one and falls through to the next instruction if ECX contains zero. If ECX does not contain zero, then this instruction checks the zero flag setting prior to decrementing ECX; if the zero flag was set, then LOOPZ transfers control to a label specified as LOOPZ's operand. Consider the implementation of the previous REPEAT..UNTIL loop using LOOPZ:

```

mov( $379, dx );
mov( 30_000_000, ecx );
PollingLoop:

    in( dx, al );
    test( $80, al );    // Clears Z flag if bit seven is set.

loopz PollingLoop;    // Repeat while zero and ECX<>0.

if( ecx = 0 ) then

    // We had a time-out error.

else

    // Okay to write another byte to the printer data port here.

endif;

```

Notice how this code doesn't need to explicitly decrement ECX and check to see if it became zero.

Warning: the LOOPZ instruction can only transfer control to a label with ± 127 bytes of the LOOPZ instruction. Due to a design problem, HLA cannot detect this problem. If the branch range exceeds 127 bytes HLA will not report an error. Instead, MASM will report the error when it assembles HLA's output. Since it's somewhat difficult to track down these problems in the MASM listing, the best solution is to never use the LOOPZ instruction to jump more than a few instructions in your code. It's perfect for short polling loops like the one above, it's not suitable for branching large distances.

7.11 Interrupts and Polled I/O

Polling is constantly testing a port to see if data is available. That is, the CPU polls (asks) the port if it has data available or if it is capable of accepting data. The REPEAT..UNTIL loop in the previous section is a good example of polling. The CPU continually polls the port to see if the printer is ready to accept data. Polled I/O is inherently inefficient. Consider what happens in the previous section if the printer takes ten seconds to accept another byte of data – the CPU spins in a loop doing nothing (other than testing the printer status port) for those ten seconds.

In early personal computer systems, this is exactly how a program would behave; when it wanted to read a key from the keyboard it would poll the keyboard status port until a key was available. Such computers could not do other operations while waiting for the keyboard.

The solution to this problem is to provide an *interrupt mechanism*. An interrupt is an external hardware event (such as the printer becoming ready to accept another byte) that causes the CPU to interrupt the current instruction sequence and call a special interrupt service routine. (ISR). An interrupt service routine typically saves all the registers and flags (so that it doesn't disturb the computation it interrupts), does whatever operation is necessary to handle the source of the interrupt, it restores the registers and flags, and then it resumes execution of the code it interrupted. In many computer systems (e.g., the PC), many I/O devices generate an interrupt whenever they have data available or are able to accept data from the CPU. The ISR quickly processes the request in the background, allowing some other computation to proceed normally in the foreground.

An interrupt is essentially a procedure call that the hardware makes (rather than explicit call to some procedure, like a call to the *stdout.put* routine). The most important thing to remember about an interrupt is that it can pause the execution of some program at any point between two instructions when an interrupt occurs. Therefore, you typically have no guarantee that one instruction always executes immediately after another in the program because an interrupt could occur between the two instructions. If an interrupt occurs in the middle of the execution of some instruction, then the CPU finishes that instruction before transferring control to the appropriate interrupt service routine. However, the interrupt generally interrupts execution before the start of the next instruction⁵. Suppose, for example, that an interrupt occurs between the execution of the following two instructions:

```
add( i, eax );
                                <---- Interrupt occurs here.
mov( eax, j );
```

When the interrupt occurs, control transfers to the appropriate ISR that handles the hardware event. When that ISR completes and executes the IRET (interrupt return) instruction, control returns back to the point of interruption and execution of the original code continues with the instruction immediately after the point of interrupt (e.g., the MOV instruction above). Imagine an interrupt service routine that executes the following code:

```
mov( 0, eax );
iret;
```

If this ISR executes in response to the interrupt above, then the main program will not produce a correct result. Specifically, the main program should compute "j := eax +i;" Instead, it computes "j := 0;" (in this particular case) because the interrupt service routine sets EAX to zero, wiping out the sum of *i* and the previous value of EAX. This highlights a very important fact about ISRs: **ISRs must preserve all registers and flags whose values they modify**. If an ISR does not preserve some register or flag value, this will definitely affect the correctness of the programs running when an interrupt occurs. Usually, the ISR mechanism itself preserves the flags (e.g., the interrupt pushes the flags onto the stack and the IRET instruction restores those flags). However, the ISR itself is responsible for preserving any registers that it modifies.

Although the preceding discussion makes it clear that ISRs must preserve registers and the flags, your ISRs must exercise similar care when manipulating any other resources the ISR shares with other processes. This includes variables, I/O ports, etc. Note that preserving the values of such objects isn't always the correct solution. Many ISRs communicate their results to the foreground program using shared variables. However, as you will see, the ISR and the foreground program must coordinate access to shared resources or they may produce incorrect results. Writing code that correctly works with shared resources is a difficult challenge; the possibility of subtle bugs creeping into the program is very great. We'll consider some of these issues a little later in this chapter; the messy details will have to wait for a later volume of this text.

5. The situation is somewhat fuzzy if you have pipelines and superscalar operation. Exactly what instruction does an interrupt precede if there are multiple instructions executing simultaneously? The answer is somewhat irrelevant, however, since the interrupt does take place between the execution of some pair of instructions; in reality, the interrupt may occur immediately after the last instruction to enter the pipeline when the interrupt occurs. Nevertheless, the system does interrupt the execution of the foreground process after the execution of some instruction.

CPUs that support interrupts must provide some mechanism that allows the programmer to specify the address of the ISR to execute when an interrupt occurs. Typically, an interrupt vector is a special memory location that contains the address of the ISR to execute when an interrupt occurs. PCs typically support up to 16 different interrupts.

After an ISR completes its operation, it generally returns control to the foreground task with a special “return from interrupt” instruction. On the Y86 hypothetical processor, for example, the IRET (interrupt return) instruction handles this task. This same instruction does a similar task on the 80x86. An ISR should always end with this instruction so the ISR can return control to the program it interrupted.

7.12 Using a Circular Queue to Buffer Input Data from an ISR

A typical interrupt-driven input system uses the ISR to read data from an input port and buffer it up whenever data becomes available. The foreground program can read that data from the buffer at its leisure without losing any data from the port. A typical foreground/ISR arrangement appears in Figure 7.10. In this diagram the ISR reads a value from the peripheral device and then stores the data into a common buffer that the ISR shares with the foreground application. Sometime later, the foreground process removes the data from the buffer. If (during a burst of input) the device and ISR produce data faster than the foreground application reads data from the buffer, the ISR will store up multiple unread data values in the buffer. As long as the average consumption rate of the foreground process matches the average production rate of the ISR, and the buffer is large enough to hold bursts of data, there will be no lost data.

The background process produces data (by reading it from the device) and places it in the buffer. The foreground process consumes data by removing it from the buffer.

Figure 7.10 Interrupt Service Routine as a Data Produce/Application as a Data Consumer

If the foreground process in Figure 7.10 consumes data faster than the ISR produces it, sooner or later the buffer will become empty. When this happens the foreground process will have to wait for the background process to produce more data. Typically the foreground process would poll the data buffer (or, in a more advanced system, block execution) until additional data arrives. Then the foreground process can easily extract the new data from the buffer and continue execution.

There is nothing special about the data buffer. It is just a block of contiguous bytes in memory and a few additional pieces of information to maintain the list of data in the buffer. While there are lots of ways to maintain data in a buffer such as this one, probably the most popular technique is to use a *circular buffer*. A typical circular buffer implementation contains three objects: an array that holds the actual data, a pointer to the next available data object in the buffer, and a length value that specifies how many objects are currently in the buffer.

In the next volume of this series you will see how to declare and use arrays. However, in Chapter Two of this volume you saw how to allocate a block of data in the STATIC section (see “The Static Sections” on

page 161) or how to use *malloc* to allocate a block of bytes (see “Dynamic Memory Allocation and the Heap Segment” on page 180). For our purposes, declaring a block of bytes in the *STATIC* section is just fine; the following code shows one way to set aside 16 bytes for a buffer:

```
static
    buffer:    byte := 0;                // Reserves one byte.
              byte 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0 // 15 additional bytes.
```

Of course, this technique would not be useful if you wanted to set aside storage for a really large buffer, but it works fine for small buffers (like our example above). See the discussion of arrays in the next volume if you need to allocate storage for a larger buffer.

In addition to the buffer data itself, a circular buffer also needs at least two other values: an index into the buffer that specifies where the next available data object appears and a count of valid items in the buffer. Given that the 80x86’s addressing modes all use 32-bit registers, we’ll find it most convenient to use a 32-bit unsigned integer for this purpose even though the index and count values never exceed 16. The declaration for these values might be the following:

```
static
    index: uns32 := 0; // Start with first element of the array.
    count: uns32 := 0; // Initially, there is no data in the array.
```

The data producer (the ISR in our example) inserts data into the buffer by following these steps:

- Check the count. If the count is equal to the buffer size, then the buffer is full and some corrective action is necessary.
- Store the new data object at location $((\text{index} + \text{count}) \bmod \text{buffer_size})$.
- Increment the count variable.

Suppose that the producer wishes to add a character to the initially empty buffer. The *count* is zero so we don’t have to deal with a buffer overflow. The *index* value is also zero, so $((\text{index} + \text{count}) \bmod 16)$ is zero and we store our first data byte at index zero in the array. Finally, we increment *count* by one so that the producer will put the next byte at offset one in the array of bytes.

If the consumer never removes any bytes and the producer keeps producing bytes, sooner or later the buffer will fill up and *count* will hit 16. Any attempt to insert additional data into the buffer is an error condition. The producer needs to decide what to do at that point. Some simple routines may simply ignore any additional data (that is, any additional incoming data from the device will be lost). Some routines may signal an exception and leave it up to the main application to deal with the error. Some other routines may attempt to expand the buffer size to allow additional data in the buffer. The corrective action is application-specific. In our examples we’ll assume the program either ignores the extra data or immediately stops the program if a buffer overflow occurs.

You’ll notice that the producer stores the data at location $((\text{index} + \text{count}) \bmod \text{buffer_size})$ in the array. This calculation, as you’ll soon see, is how the circular buffer obtains its name. HLA does provide a *MOD* instruction that will compute the remainder after the division of two values, however, most buffer routines don’t compute remainder using the *MOD* instruction. Instead, most buffer routines rely on a cute little trick to compute this value much more efficiently than with the *MOD* instruction. The trick is this: if a buffer’s size is a power of two (16 in our case), you can compute $(x \bmod \text{buffer_size})$ by logically ANDing *x* with *buffer_size* - 1. In our case, this means that the following instruction sequence computes $((\text{index} + \text{count}) \bmod 16)$ in the EBX register:

```
mov( index, ebx );
add( count, ebx );
and( 15, ebx );
```

Remember, this trick only works if the buffer size is an integral power of two. If you look at most programs that use a circular buffer for their data, you’ll discover that they commonly use a buffer size that is an integral power of two. The value is not arbitrary; they do this so they can use the AND trick to efficiently compute the remainder.

To remove data from the buffer, the consumer half of the program follows these steps:

- The consumer first checks to the count to see if there is any data in the buffer. If not, the consumer waits until data is available.
- If (or when) data is available, the consumer fetches the value at the location *index* specifies within the buffer.
- The consumer then decrements the *count* and computes $index := (index + 1) \text{ MOD } buffer_size$.

To remove a byte from the circular buffer in our current example, you'd use code like the following:

```
// wait for data to appear in the buffer.

repeat
until( count <> 0 );

// Remove the character from the buffer.

mov( index, ebx );
mov( buffer[ ebx ], al ); // Fetch the byte from the buffer.
dec( count );           // Note that we've removed a character.
inc( ebx );             // Index := Index + 1;
and( 15, ebx );        // Index := (index + 1) mod 16;
mov( ebx, index );     // Save away the new index value.
```

As the consumer removes data from the circular queue, it advances the index into the array. If you're wondering what happens at the end of the array, well that's the purpose of the MOD calculation. If *index* starts at zero and increments with each character, you'd expect the sequence 0, 1, 2, ... At some point or another the *index* will exceed the bounds of the buffer (i.e., when *index* increments to 16). However, the MOD operation resets this value back to zero (since 16 MOD 16 is zero). Therefore, the consumer, after that point, will begin removing data from the beginning of the buffer.

Take a close look at the REPEAT..UNTIL loop in the previous code. At first blush you may be tempted to think that this is an infinite loop if *count* initially contains zero. After all, there is no code in the body of the loop that modifies *count*'s value. So if *count* contains zero upon initial entry, how does it ever change? Well, that's the job of the ISR. When an interrupt comes along the ISR suspends the execution of this loop at some arbitrary point. Then the ISR reads a byte from the device, puts the byte into the buffer, and updates the *count* variable (from zero to one). Then the ISR returns and the consumer code above resumes where it left off. On the next loop iteration, however, *count*'s value is no longer zero, so the loop falls through to the following code. This is a classic example of how an ISR communicates with a foreground process – by writing a value to some shared variable.

There is a subtle problem with the producer/consumer code in this section. It will fail if the producer is attempting to insert data into the buffer at exactly the same time the consumer is removing data. Consider the following sequence of instructions:

```
// wait for data to appear in the buffer.

repeat
until( count <> 0 );

// Remove the character from the buffer.

mov( index, ebx );
mov( buffer[ ebx ], al ); // Fetch the byte from the buffer.
dec( count );           // Note that we've removed a character.

*** Assume the interrupt occurs here, so we begin executing
*** the data insertion sequence:

mov( index, ebx );
add( count, ebx );
and( 15, ebx );
mov( al, buffer[ebx] );
inc( count );
```

*** now the ISR returns to the consumer code (assume we've preserved EBX):

```
inc( ebx );           // Index := Index + 1;
and( 15, ebx );      // Index := (index + 1) mod 16;
mov( ebx, index );   // Save away the new index value.
```

The problem with this code, which is very subtle, is that the consumer has decremented the count variable and an interrupt occurs before the consumer can update the index variable as well. Therefore, upon arrival into the ISR, the *count* value and the *index* value are inconsistent. That is, *index+count* now points at the last value placed in the buffer rather than the next available location. Therefore, the ISR will overwrite the last byte in the buffer rather than properly placing this byte after the (current) last byte. Worse, once the ISR returns to the consumer code, the consumer will update the *index* value and effectively add a byte of garbage to the end of the circular buffer. The end result is that we wipe out the next to last value in the buffer and add a garbage byte to the end of the buffer.

Note that this problem doesn't occur all the time, or even frequently for that matter. In fact, it only occurs in the very special case where the interrupt occurs between the "dec(count);" and "mov(ebx, index);" instructions in this code. If this code executes a very tiny percentage of the time, the likelihood of encountering this error is quite small. This may seem good, but this is actually worse than having the problem occur all the time; the fact that the problem rarely occurs just means that it's going to be really hard to find and correct this problem when you finally do detect that something has gone wrong. ISRs and concurrent programs are among the most difficult programs in the world to test and debug. The best solution is to carefully consider the interaction between foreground and background tasks when writing ISRs and other concurrent programs. In a later volume, this text will consider the issues in concurrent programming, for now, be very careful about using shared objects in an ISR.

There are two ways to correct the problem that occurs in this example. One way is to use a pair of (somewhat) independent variables to manipulate the queue. The original PC's type ahead keyboard buffer, for example, used two index variables rather than an index and a count to maintain the queue. The ISR would use one index to insert data and the foreground process would use the second index to remove data from the buffer. The only sharing of the two pointers was a comparison for equality, which worked okay even in an interrupt environment. Here's how the code worked:

```
// Declarations

static
buffer: byte := 0; byte 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0;
Ins: uns32 := 0; // Insert bytes starting here.
Rmv: uns32 := 0; // Remove bytes starting here.

// Insert a byte into the queue (the ISR ):

mov( Ins, ebx );
inc( ebx );
and( 15, ebx );
if( ebx <> Rmv ) then

    mov( al, buffer[ ebx ] );
    mov( ebx, Ins );

else

    // Buffer overflow error.
    // Note that we don't update INS in this case.

endif;

// Remove a byte from the queue (the consumer process).
```

```

mov( Rmv, ebx );
repeat

    // Wait for data to arrive

until( ebx <> Ins );
mov( buffer[ ebx ], al );
inc( ebx );
and( 15, ebx );
mov( ebx, Rmv );

```

If you study this code (very) carefully, you'll discover that the two code sequences don't interfere with one another. The difference between this code and the previous code is that the foreground and background processes don't write to a (control) variable that the other routine uses. The ISR only writes to *Ins* while the foreground process only writes to *Rmv*. In general, this is not a sufficient guarantee that the two code sequences won't interfere with one another, but it does work in this instance.

One drawback to this code is that it doesn't fully utilize the buffer. Specifically, this code sequence can only hold 15 characters in the buffer; one byte must go unused because this code determines that the buffer is full when the value of *Ins* is one less than *Rmv* (MOD 16). When the two indices are equal, the buffer is empty. Since we need to test for both these conditions, we can't use one of the bytes in the buffer.

A second solution, that many people prefer, is to protect that section of code in the foreground process that could fail if an interrupt comes along. There are lots of ways to protect this *critical section*⁶ of code. Alas, most of the mechanisms are beyond the scope of this chapter and will have to wait for a later volume in this text. However, one simple way to protect a critical section is to simply disable interrupts during the execution of that code. The 80x86 family provides two instructions, CLI and STI that let you enable and disable interrupts. The CLI instruction (clear interrupt enable flag) disables interrupts by clearing the "I" bit in the flags register (this is the interrupt enable flag). Similarly, the STI instruction enables interrupts by setting this flag. These two instructions use the following syntax:

```

cli(); // Disables interrupts from this point forward...
.
.
.
sti(); // Enables interrupts from this point forward...

```

You can surround a critical section in your program with these two instructions to protect that section from interrupts. The original consumer code could be safely written as follows:

```

// wait for data to appear in the buffer.

repeat
until( count <> 0 );

// Remove the character from the buffer.

cli(); // Protect the following critical section.
mov( index, ebx );
mov( buffer[ ebx ], al ); // Fetch the byte from the buffer.
dec( count ); // Note that we've removed a character.
inc( ebx ); // Index := Index + 1;
and( 15, ebx ); // Index := (index + 1) mod 16;
mov( ebx, index ); // Save away the new index value.
sti(); // Critical section is done, restore interrupts.

```

6. A critical section is a region of code during which certain resources have to be protected from other processes. For example, the consumer code that fetches data from the buffer needs to be protected from the ISR.

Perhaps a better sequence to use is to push the EFLAGS register (that contains the I flag) and turn off the interrupts. Then, rather than blindly turning interrupts back on, you can restore the original I flag setting using a POPFD instruction:

```
// Remove the character from the buffer.

pushfd();           // Preserve current I flag value.
cli();              // Protect the following critical section.
mov( index, ebx );
mov( buffer[ ebx ], al ); // Fetch the byte from the buffer.
dec( count );      // Note that we've removed a character.
inc( ebx );        // Index := Index + 1;
and( 15, ebx );    // Index := (index + 1) mod 16;
mov( ebx, index ); // Save away the new index value.
popfd();           // Restore original I flag value
```

This mechanism is arguably safer since it doesn't turn the interrupts on even if they were already off before executing this sequence.

In our simple example (with a single producer and a single consumer) there is no need to protect the code in the ISR. However, if it were possible for two different ISRs to insert data into the buffer, and one ISR could interrupt another, then you would have to protect the code inside the ISR as well.

You must be very careful about turning the interrupts on and off. If you turn the interrupts off and forget to turn them back on, the next time you enter a loop like one of the REPEAT..UNTIL loops in this section the program will lock up because the loop control variable (*count*) will never change if an ISR cannot execute and update its value. This situation is called *deadlock* and you must take special care to avoid it.

Note that applications under Win32 cannot change the state of the interrupt disable flag. This technique is useful mainly in embedded system or under simpler operating systems like DOS. Fortunately, advanced 32-bit operating systems like Windows provide other mechanisms for protecting critical sections. A later chapter will discuss these facilities.

7.13 Using a Circular Queue to Buffer Output Data for an ISR

You can also use a circular buffer to hold data waiting for transmission. For example, a program can buffer up data in bursts while an output device is busy and then the output device can empty the buffer at a steady state. The queuing and dequeuing routines are very similar to those found in the previous section with one major difference: output devices don't automatically initiate the transfer like input devices. This problem is a source of many bugs in output buffering routines and one that we'll pay careful attention to in this section.

As noted above, one advantage of an input device is that it automatically interrupts the system whenever data is available. This activates the corresponding ISR that reads the data from the device and places the data in the buffer. No special processing is necessary to prepare the interrupt system for the next input value.

There is a subtle difference between the interrupts an input device generates and the interrupts an output device generates. An input device generates an interrupt when data is available, output devices generate an interrupt when they are ready to accept more data. For example, a keyboard device generates an interrupt when the user presses a key and the system has to read the character from the keyboard. A printer device, on the other hand, generates an interrupt once it is done with the last character transmitted to it and it's ready to accept another character. Whenever the user presses a keyboard for the very first time, the system will generate an interrupt in response to that event. However, the printer does not generate an interrupt when the system first powers up to tell the system that it's ready to accept a character. Even if it did, the system would ignore the interrupt since it (probably) doesn't have any data to transmit to the printer at that point. Later, when the system puts data in the printer's buffer for transmission, there is no interrupt that activates the ISR to remove a character from the buffer and send it to the printer. The printer device only sends interrupts when it is done processing a character; if it isn't processing any characters, it won't generate any interrupts.

This creates a bit of a problem. If the foreground process places characters in the queue and the background process (the ISR, which is the consumer in this case) only removes those characters when an inter-

rupt occurs, the system will never activate the ISR since the device isn't currently processing anything. To correct this problem, the producer code (the foreground process) must maintain a flag that indicates whether the output device is currently processing a character; if so, then the producer can simply queue up the character in the buffer. If the device is not currently processing any data, then the producer should send the data directly to the device rather than queue up the data in the buffer⁷. Old time programmers refer to this as "priming the pump" since we have to put data in the transmission pipeline in order to get the process working properly.

Once the producer "primes the pump" the process continues automatically as long as there is data in the buffer. After the output device processes the current byte it generates an interrupt. The ISR removes a byte from the buffer and transmits this data to the device. When that byte completes transmission the device generates another interrupt and the process repeats. This process repeats automatically as long as there is data in the buffer to transmit to the output device.

When the ISR transmits the last character from the buffer, the output device still generates an interrupt at the end of the transmission. The ISR, upon noting that the buffer is empty, returns without sending any new data to the output device. Since there is no pending data transmission to the output device, there will be no new interrupts to activate the ISR when new data appears in the buffer. Once again the foreground process (producer) will have to prime the pump to get the process going when it attempts to put data in the buffer.

Perhaps the easiest way to handle this process is to use a boolean variable to indicate whether the output device is currently transmitting data (and will generate an interrupt to process the next byte). If the flag is set, the foreground process can simply enqueue the data; if the flag is clear, the foreground process must transmit the data directly to the device (or call the code that does this). In this latter case, the foreground process must also set the flag to denote a transmission in progress.

Here is some code that can implement this functionality:

```
static
OutBuf: byte := 0; byte 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0;
Index: uns32 := 0;
Count: uns32 := 0;
Xmitting: boolean := false; // Flag to denote transmission in progress.
.
.
.
// Code to enqueue a byte (foreground process executes this)

if( Count = 16 ) then

    // Error, buffer is full. Do whatever processing is necessary to
    // deal with this problem.
    .
    .
    .

elseif( Xmitting ) then

    // If we're currently transmitting data, just add the byte to the queue.

    pushfd(); // Critical region! Turn off the interrupts.
    cli();
    mov( Index, ebx ); // Store the new byte at address (Index+Count) mod 16
    add( Count, ebx );
    and( 15, ebx );
    mov( al, OutBuf[ ebx ] );
    inc( Count );
    popfd(); // Restore the interrupt flag's value.
```

7. Another possibility is to go ahead and queue up the data and then manually activate the code that dequeues the data and sends it to the output device.

```

else

    // The buffer is empty and there is no character in transmission.
    // Do whatever is necessary to transmit the character to the output
    // device.
    .
    .
    .

    // Be sure to set the Xmitting flag since a character is now being
    // transmitted to the output device.

    mov( true, Xmitting );

endif;
.
.
.
// Here's the code that would appear inside the ISR to remove a character
// from the buffer and send it to the output device. The system calls this
// ISR whenever the device finishes processing some character.
// (Presumably, the ISR preserves all registers this code sequence modifies)

if( Count > 0 ) then

    // Okay, there are characters in the buffer. Remove the first one
    // and transmit it to the device:

    mov( Index, ebx );
    mov( OutBuf[ ebx ], al ); // Get the next character to output
    inc( ebx ); // Point Index at the next byte in the
    and( 15, ebx ); // circular buffer.
    mov( ebx, Index );
    dec( Count ); // Decrement count since we removed a char.

    << At this point, do whatever needs to be done in order to
        transmit a character to the output device >>
    .
    .
    .

else

    // At this point, the ISR was called but the buffer is empty.
    // Simply clear the Xmitting flag and return. (this will force the
    // next buffer insertion operation to transmit the data directly to the
    // device.)

    mov( true, Xmitting );

endif;

```

7.14 I/O and the Cache

It goes without saying that the CPU cannot cache values for memory-mapped I/O ports. If a port is an input port, caching the data from that port would always return the first value read; subsequent reads would read the value in the cache rather than the possible (volatile) data at the input port. Similarly, with a write-back cache mechanism, writes to an output port may never reach that port (i.e., the CPU may save up

several writes in the cache and send the last such write to the actual I/O port). Therefore, there must be some mechanism to tell the CPU not to cache up accesses to certain memory locations.

The solution is in the virtual memory subsystem of the 80x86. The 80x86's page table entries contain information that the CPU can use to determine whether it is okay to map data from a page in memory to cache. If this flag is set one way, then the cache operates normally; if the flag is set the other way, then the CPU does not cache up accesses to that page.

Unfortunately, the granularity (that is, the minimum size) of this access is the 4K page. So if you need to map 16 device registers into memory somewhere and cannot cache them, you must actually consume 4K of the address space to hold these 16 locations. Fortunately, there is a lot of room in the 4 GByte virtual address space and there aren't that many peripheral devices that need to be mapped into the memory address space. So assigning these device addresses sparsely in the memory map will not present too many problems.

7.15 Windows and Protected Mode Operation

Windows employs the 80x86's protected mode of operation. In this mode of operation, direct access to devices is restricted to the operating system and certain privileged programs. Standard applications, even those written in assembly language, are not so privileged. If you write a simple program that attempts to send data to an I/O port via an IN or an OUT instruction, the system will generate an illegal access exception and halt your program. Unless you're willing to write a device driver for Windows, you'll probably not be able to access the I/O devices directly.

Not all versions of Windows deny access to the peripherals. Windows 95 and 98, for example, don't prevent I/O access. So if you're using one of these operating systems, you can write assembly code that accesses the ports directly. However, the days of being able to access I/O devices directly from an application are clearly over. Future versions of Windows will restrict this activity.

This chapter has provided an introduction to I/O in a very general, architectural sense. It hasn't spent too much time discussing the particular peripheral devices present in a typical PC. This is an intended omission; there is no need to confuse readers with information they can't use. Furthermore, as manufacturers introduce new PCs they are removing many of the common peripherals like parallel and serial ports that are relatively easy to program in assembly language. They are replacing these devices with complex peripherals like USB and Firewire. Unfortunately, programming these newer peripheral devices is well beyond the scope of this text (Microsoft's USB code, for example, is well over 100 pages of C++ code).

Those who are interested in additional information about programming standard PC peripherals may want to consult one of the many excellent hardware references available for the PC or take a look at the DOS/16-bit version of this text.

IN and OUT aren't the only instructions that you cannot execute in an application running under protected mode. The system considers many instructions to be "privileged" and will abort your program if you attempt to use these instructions. The CLI and STI instructions are good examples. If you attempt to execute either of these instructions, the system will stop your program.

Some instructions will execute in an application, but behave differently than they do when the operating system executes them. The PUSHFD and POPFD instructions are good examples. These instruction push and pop the interrupt enable flag (among others). Therefore, you could use PUSHFD to push the flags on the stack, pop this double word off the stack and clear the bit associated with the interrupt flag, push the value back onto the stack and then use POPFD to restore the flags (and, in the process, clear the interrupt flag). This would seem like a sneaky way around clearing the interrupt flag. The CPU must allow applications to push and pop the flags for other reasons. However, for various security reasons the CPU cannot allow applications to manipulate the interrupt disable flag. Therefore, the POPFD instruction behaves a little differently in an application than it does when the operating system executes it. In an application, the CPU ignores the interrupt flag bit it pops off the stack. In operating system ("kernel") mode, popping the flags register does restore the interrupt flag.

7.16 Device Drivers

If Win32 doesn't allow direct access to peripheral devices, how does a program communicate with these devices? Clearly this can be done since applications interact with real-world devices all the time. If you reread the previous section carefully, you'll note that it doesn't claim that programs can't access the devices, it only states that application programs are denied such access. Specially written modules, known as device drivers, are able to access I/O ports by special permission from the operating system. Writing device drivers is well beyond the scope of this chapter (though it will make an excellent subject for a later volume in this text). Nevertheless, an understanding of how device drivers work may help you understand the possibilities and limitations of I/O under a Win32 operating system.

A device driver is a special type of program that connects to the Windows operating system. The device driver must follow some special protocols and it must make some special calls to Windows that are not available to standard applications. Further, in order to install a device driver in your system you must have administrator privileges (device drivers create all kinds of security and resource allocation problems; you can't have every hacker in the world taking advantage of rogue device drivers running on your system). Therefore, "whipping out a device driver" is not a trivial process and application programs cannot load and unload arbitrary drivers at will.

Fortunately, there are only a limited number of devices you'd typically find on a PC, therefore you only need a limited number of device drivers. You would typically install a device driver in the operating system the same time you install the device (or when you install the operating system if the device is built into the PC). About the only time you'd really need to write your own device driver is when you build your own device or in some special instance when you need to take advantage of some devices capabilities that the standard device drivers don't allow for.

One big advantage to the device driver mechanism is that the operating system (or device vendors) must provide a reasonable set of device drivers or the system will never become popular (one of the reasons Microsoft and IBM's OS/2 operating system was never successful was the dearth of device drivers). This means that applications can easily manipulate lots of devices without the application programmer having to know much about the device itself; the real work has been taken care of by the operating system.

The device driver model does have a few drawbacks, however. The device driver model is great for low-speed devices, where the OS and device driver can respond to the device much more quickly than the device requires. The device driver model is also great for medium and high-speed devices where the system transmits large blocks of data in one direction at a time; in such a situation the application can pass a large block of data to the operating system and the OS can transmit this data to the device (or conversely, read a large block of data from the device and place it in an application-supplied buffer). One problem with the device driver model is that it does not support medium and high-speed data transfers that require a high degree of interaction between the device and the application.

The problem is that calling the operating system is an expensive process. Whenever an application makes a call to the OS to transmit data to the device it could actually take hundreds of microseconds, if not milliseconds, before the device driver actually sees the data. If the interaction between the device and the application requires a constant flurry of bytes moving back and forth, there will be a big delay if each transfer has to go through the operating system. For such applications you will need to write a special device driver to handle the transactions directly in the driver rather than continually returning to the application.

7.17 Putting It All Together

Although the CPU is where all the computation takes place in a computer system, that computation would be for naught if there was no way to get information into and out of the computer system. This is the responsibility of the I/O subsystem. I/O at the machine level is considerably different than the interface high level languages and I/O subroutine libraries (like *stdout.put*) provide. At the machine level, I/O transfers consist of moving bytes (or other data units) between the CPU and device registers or memory.

The 80x86 family supports two types of *programmed I/O*: memory-mapped input/output and I/O-mapped I/O. PCs also provide a third form of I/O that is mostly independent of the CPU: direct memory

access or DMA. Memory-mapped input/output uses standard instructions that access memory to move data between the system and the peripheral devices. I/O-mapped input/output uses special instructions, IN and OUT, to move data between the CPU and peripheral devices. I/O-mapped devices have the advantage that they do not consume memory addresses normally intended for system memory. However, the only access to devices using this scheme is through the IN and OUT instructions; you cannot use arbitrary instructions that manipulate memory to control such peripherals. Devices that use DMA have special hardware that let them transmit data to and from system memory without going through the CPU. Devices that use DMA tend to be very high performance, but this I/O mechanism is really only useful for devices that transmit large blocks of data at high speeds.

I/O devices have many different operating speeds. Some devices are far slower than the CPU while other devices can actually produce or consume data faster than the CPU. For devices that are slower than the CPU, some sort of handshaking mechanism is necessary in order to coordinate the data transfer between the CPU and the device. High-speed devices require a DMA controller or buffering since the CPU cannot handle the data rates of these devices. In all cases, some mechanism is necessary to tell the CPU that the I/O operation is complete so the CPU can go about other business.

In modern 32-bit operating systems like Win32, applications programs do not have direct access to the peripheral devices. The operating system coordinates all I/O via the use of device drivers. The good thing about device drivers is that you (usually) don't have to write them – the operating system provides them for you. The bad thing about writing device drivers is if you have to write one, they are very complex. A later volume in this text will discuss how to do this.

Because HLA programs usually run as applications under Win32, you will not be able to use most of the coding techniques this chapter discusses within your HLA applications. Nevertheless, understanding how device I/O works can help you write better applications. Of course, if you ever have to write a device driver for some device, then the basic knowledge this chapter presents is a good foundation for learning how to write such code.

Questions, Projects, and Labs

Chapter Eight

8.1 Questions

1. What three components make up Von Neumann Machines?
2. What is the purpose of
 - a) The system bus
 - b) The address bus
 - c) The data bus
 - d) The control bus
3. Which bus defines the “size” of the processor?
4. Which bus controls how much memory you can have?
5. Does the size of the data bus control the maximum value the CPU can process? Explain.
6. What are the data bus sizes of:

| | | | |
|----------|----------|------------|---------------|
| a) 8088 | b) 8086 | c) 80286 | d) 80386sx |
| e) 80386 | f) 80486 | g) Pentium | h) Pentium II |
7. What are the address bus sizes of the above processors?
8. How many “banks” of memory do each of the above processors have?
9. Explain how to store a word in byte addressable memory (that is, at what addresses). Explain how to store a double word.
10. How many memory operations will it take to read a word from the following addresses on the following processors?

Table 32: Memory Cycles for Word Accesses

| | \$100 | \$101 | \$102 | \$103 | \$104 | \$105 |
|-------|-------|-------|-------|-------|-------|-------|
| 8088 | | | | | | |
| 80286 | | | | | | |
| 80386 | | | | | | |

11. Repeat the above for double words

Table 33: Memory Cycles for Doubleword Accesses

| | \$100 | \$101 | \$102 | \$103 | \$104 | \$105 |
|------|-------|-------|-------|-------|-------|-------|
| 8088 | | | | | | |

Table 33: Memory Cycles for Doubleword Accesses

| | \$100 | \$101 | \$102 | \$103 | \$104 | \$105 |
|-------|-------|-------|-------|-------|-------|-------|
| 80286 | | | | | | |
| 80386 | | | | | | |

12. Explain which addresses are best for byte, word, and doubleword variables on an 8088, 80286, and 80386 processor.
13. Given the system bus size, what address boundary is best for a *real64* object in memory?
14. What is the purpose of the system clock?
15. What is a clock cycle?
16. What is the relationship between clock frequency and the clock period?
17. Explain why 10ns memory should not work on a 500 MHz Pentium III processor? Explain why it does.
18. What does the term “memory access time” mean?
19. What is a *wait state*?
20. If you are running an 80486 at the following clock speeds, how many wait states are required if you are using 80ns RAM (assuming no other delays)?
 - a) 20 MHz
 - b) 25 MHz
 - c) 33 MHz
 - d) 50 MHz
 - e) 100 MHz
21. If your CPU runs at 50 MHz, 20ns RAM probably won’t be fast enough to operate at zero wait states. Explain why.
22. Since sub-10ns RAM is available, why aren’t most systems zero wait state systems?
23. Explain how the cache operates to save some wait states.
24. What is the difference between spatial and temporal locality of reference?
25. Explain where temporal and spatial locality of reference occur in the following Pascal code:

```
while i < 10 do begin
    x := x * i;
    i := i + 1;
end;
```
26. How does cache memory improve the performance of a section of code exhibiting spatial locality of reference?
27. Under what circumstances is a cache not going to save you any wait states?
28. What is the effective (average) number of wait states the following systems will operate under?
 - a) 80% cache hit ratio, 10 wait states (WS) for memory, 0 WS for cache.
 - b) 90% cache hit ratio; 7 WS for memory; 0 WS for cache.
 - c) 95% cache hit ratio; 10 WS memory; 1 WS cache.
 - d) 50% cache hit ratio; 2 WS memory; 0 WS cache.
29. What is the purpose of a two level caching system? What does it save?
30. What is the effective number of wait states for the following systems?
 - a) 80% primary cache hit ratio (HR) zero WS; 95% secondary cache HR with 2 WS; 10 WS for main memory access.

- b) 50% primary cache HR, zero WS; 98% secondary cache HR, one WS; five WS for main memory access.
- c) 95% primary cache HR, one WS; 98% secondary cache HR, 4 WS; 10 WS for main memory access.

32. In what HLA declaration section would you declare initialized values that must not be changed during program execution?
33. In what HLA declaration section would you declare uninitialized variables?
34. In what HLA declaration section would you declare automatic variables?
35. Explain how you allocate and deallocate dynamic memory using the HLA Standard Library.
36. Provide two ways to take the address of a variable you declare in the STATIC section of your program.
37. What is the difference between the DATA and STATIC sections of your program?
38. Suppose you have a word variable, “w”, and you wish to load the L.O. byte of “w” into the AH register. What MOV instruction could you use to achieve this?
39. Suppose you have a word variable, “w”, and you wish to load the H.O. byte of “w” into the AL register. What MOV instruction could you use to achieve this?
40. What is the difference between “add(1, [eax]);” and “add(0, [eax+1]);”?
41. By default, the “stdout.put(eax);” statement will print EAX as an eight-digit hexadecimal value. Explain how to tell *stdout.put* to print EAX as an unsigned 32-bit integer; as a signed 32-bit integer. Provide the actual instructions to accomplish this.
42. Explain, step by step, what the “PUSH(EAX);” instruction does.
43. Explain, step by step, what the “POP(EAX);” instruction does.
44. What is the purpose of the PUSHW and PUSHHD instructions? What kind of data do they push? Why are there no POPW and POPD instructions?
45. What is the purpose of the “PUSHAD();” instruction? In what order does it push its data onto the stack?
46. Suppose you execute the following three instructions:

```

push( eax );
pop( bx );
pop( cx );
            
```

What value will be left in BX after this sequence? What value will be left in CX?
47. Suppose you needed to save the value of the carry flag across the execution of several instructions. Explain how you could do this (and provide the code).
48. Suppose you’ve executed the following two instructions to push EAX and EBX onto the stack:

```

push( eax );
push( ebx );
            
```

Without popping any data off the stack, explain how you can reload EAX’s value that was pushed on the stack. Provide a single instruction that will do this.
49. What is the difference between the “DEC(EAX);” instruction and the “SUB(1, EAX);” instruction?
50. How can you check for unsigned arithmetic overflow immediately after an “INC(EAX);” instruction?
51. What is the identity element with respect to
 - a) AND b) OR c) XOR d) NOT e) NAND f) NOR
52. Provide truth tables for the following functions of two input variables:
 - a) AND b) OR c) XOR d) NAND e) NOR
 - f) Equivalence g) A < B h) A > B i) A implies B
53. Provide the truth tables for the following functions of three input variables:

- a) ABC (and) b) $A+B+C$ (OR) c) $(ABC)'$ (NAND) d) $(A+B+C)'$ (NOR)
 e) Equivalence $(ABC) + (A'B'C')$ f) XOR $(ABC + A'B'C)'$

54. Provide schematics (electrical circuit diagrams) showing how to implement each of the functions in question three using only two-input gates and inverters. E.g.,

A) $ABC =$

55. Provide implementations of an AND gate, OR gate, and inverter gate using one or more NOR gates.
56. What is the principle of duality? What does it do for us?
57. Build a single truth table that provides the outputs for the following three boolean functions of three variables:
- $$F_x = A + BC$$
- $$F_y = AB + C'B$$
- $$F_z = A'B'C' + ABC + C'B'A$$
58. Provide the function numbers for the three functions in question seven above.
59. How many possible (unique) boolean functions are there if the function has
 a) one input b) two inputs c) three inputs d) four inputs e) five inputs
60. Simplify the following boolean functions using algebraic transformations. Show your work.
- a) $F = AB + AB'$ b) $F = ABC + BC' + AC + ABC'$
 c) $F = A'B'C'D' + A'B'C'D + A'B'CD + A'B'CD'$
 d) $F = A'BC + ABC' + A'BC' + AB'C' + ABC + AB'C$
61. Simplify the boolean functions in question 60 using the mapping method.
62. Provide the logic equations in canonical form for the boolean functions $S_0..S_6$ for the seven segment display (see "Combinatorial Circuits" on page 215).
63. Provide the truth tables for each of the functions in question 62
64. Minimize each of the functions in question 62 using the map method.
65. The logic equation for a half-adder (in canonical form) is
 $Sum = AB' + A'B$ $Carry = AB$
- a) Provide an electronic circuit diagram for a half-adder using AND, OR, and Inverter gates
 b) Provide the circuit using only NAND gates
66. The canonical equations for a full adder take the form:
 $Sum = A'B'C + A'BC' + AB'C' + ABC$
 $Carry = ABC + ABC' + AB'C + A'BC$
- a) Provide the schematic for these circuits using AND, OR, and inverter gates.
 b) Optimize these equations using the map method.
 c) Provide the electronic circuit for the optimized version (using AND, OR, and inverter gates).
67. Assume you have a D flip-flop (use this definition in this text) whose outputs currently are $Q=1$ and $Q'=0$. Describe, in minute detail, exactly what happens when the clock line goes
 a) from low to high with $D=0$

- b) from high to low with $D=0$
68. Rewrite the following Pascal statements to make them more efficient:
 - a) if (x or (not x and y)) then write('1');
 - b) while(not x and not y) do somefunc(x,y);
 - c) if not((x <> y) and (a = b)) then Something;
 69. Provide canonical forms (sum of minterms) for each of the following:
 - a) $F(A,B,C) = A'BC + AB + BCb$ $F(A,B,C,D) = A + B + CD' + D$
 - c) $F(A,B,C) = A'B + B'Ad$ $F(A,B,C,D) = A + BD'$
 - e) $F(A,B,C,D) = A'B'C'D + AB'C'D' + CD + A'BCD'$
 70. Convert the sum of minterms forms in question 69 to the product of maxterms forms.
 71. What is the difference between the Harvard and the Von Neumann Architectures?
 72. Explain how encoding instructions in binary saves space in an opcode (see “Basic CPU Design” on page 235).
 73. What is the difference between Random Logic and Microcode?
 74. What do the following acronyms stand for? CISC, RISC, VLIW.
 75. Is the LOOP instruction a “RISC Core” or a “Complex” instruction? Explain.
 76. What is the difference between an 80x86 “RISC Core” and a “Complex” instruction?
 77. What sequence of instructions is the LOOP instruction equivalent to?
 78. Explain, step-by-step, how a MOV instruction might work.
 79. Explain how CPU designers use parallelism to increase the CPU’s throughput (# of instrs/second).
 80. What is a prefetch queue?
 81. What is pipelining?
 82. What is a pipeline stall?
 83. How can creating separate instruction and data caches improve performance?
 84. Why do separate instruction and data caches often operate at a greater miss rate than a unified cache?
 85. What is a data hazard?
 86. What is a superscalar CPU?
 87. Explain how “out of order” execution works. Under what circumstances can “out of order” execution improve performance?
 88. What is “register renaming?” How can it improve performance?
 89. Explain the following terms: SISD, SIMD, MIMD.
 90. Are MMX instructions SISD, SIMD, or MIMD?
 91. Provide four reasons why we can’t/shouldn’t design a CPU with as many instructions as possible.
 92. Explain why, when decoding an instruction, it is better to use several smaller decoders rather than one big decoder.
 93. Explain how to use an opcode prefix byte to extend an instruction set.
 94. What is the value of the opcode prefix byte on the 80x86 CPU?
 95. What is the maximum length of an 80x86 instruction?
 96. What is the purpose of the MOD-REG-R/M byte on the 80x86?
 97. What is the purpose of the SIB byte on the 80x86?
 98. How long (in bytes) is the 80x86 opcode?

99. When encoding an instruction with a memory addressing mode that has a displacement, where does the 80x86 expect the displacement value to appear?
100. On the 80x86, how do you encode immediate constant within the instruction?
101. What are the displacement sizes that the 80x86 supports for memory operands (under Win32)? Hint: this one is a little tricky.
102. How do you select the displacement size in the instruction encoding?
103. Based on the values in the MOD-REG-R/M byte, explain why the 80x86 instructions don't allow memory to memory operations.
104. Explain why there is no "[EBP]" addressing mode on the 80x86.
105. The "[ESP]" address mode requires an SIB byte even though this instruction doesn't have an index register associated with it. Explain.
106. 80x86 opcodes only have one bit to specify the operand size. Explain how the 80x86 encodes three different operand sizes.
107. Under Win32, what are the two default operand sizes?
108. What is an *alternate instruction encoding*?
109. What is the *memory hierarchy*?
110. What is the difference between a direct-mapped cache and a fully associative cache?
111. What is the difference between a two-way set associative cache and a four-way set associative cache?
112. Why would a direct-mapped cache offer better performance than a fully associative cache? Why would a fully associative cache offer better performance than a direct-mapped cache? Give the circumstances for both.
113. What is the difference between the write-through and the write-back cache policies? Which is higher performance? Which is best in a multiprocessor system?
114. What is paging?
115. What is virtual memory?
116. What is thrashing?
117. What does NUMA stand for? How can it affect the performance of your programs?
118. What is the difference between the read-only, write-only, read/write, and dual I/O ports?
119. If the CPU sees a port as read/write, how does the external world see that port (input, output, both)?
120. What is the difference between I/O-mapped input/output and memory-mapped input/output?
121. What is DMA? Explain, don't just spell out the acronym.
122. What is polling?
123. What are the relative speed differences between low, medium, and high speed I/O devices?
124. How are busses like PCI and ISA different than the CPU's address and data busses?
125. Which bus is higher performance, PCI or ISA? Give performance numbers to back up your claim.
126. What is the AGP bus and what advantage does it have over the PCI bus?
127. What is I/O buffering? How can it keep a system from losing data?
128. What is the purpose of handshaking?
129. What is a time-out? What are some convenient instructions for checking for a time-out while waiting on a bit in an I/O port?
130. What is the difference between interrupt driven I/O and polled I/O?

8.2 Programming Projects

1. Write a program that requests a number from the user and then allows the user to enter the specified number of characters. Display the characters in the reverse order the user enters them. If the user enters fewer than the specified number of characters, fill the remainder of your buffer with spaces. Repeat until the user enters an empty line of text. (Idea: Use the HLA Standard Library `stdin.eoln()` function, that returns true (1) or false (0) depending on whether the character just read by `stdin.getc()` was the last character on the line). Be sure to free up any dynamically allocated storage you use after displaying the user output.
2. Write a program that requests a count from the user and allocates storage for that many 32-bit integers (don't forget to multiply the count by four since *int32* objects are four bytes long; use `SHL` to multiply by four). The program should then read the specified number of integers from the user and store them away in the allocated buffer. Finally, the program should sum up each value in the buffer, display the sum, and then free the allocated storage and quit.
3. Modify program (2) above so that it reports the largest (maximum) and smallest (minimum) integer values in the buffer.
4. Write a program that allocates a buffer containing 32 bytes of storage, reads an integer value from the user, and then copies each bit from the integer into successive bytes of memory; that is, bit zero winds up in the first byte, bit 1 winds up in the second byte, etc. When your program is done copying the bits, the 32 bytes should all contain a zero or a one depending upon the setting of the corresponding bit in the input integer. Write each of these bits to the display. Sum the 32 bits up and print the sum (which tells you how many one-bits were in the number). Be sure to free the storage before your program quits.
5. Write a program that allocates storage for two buffers. A single user input should determine the size of these two buffers: the first buffer will contain the number of bytes specified by the user and the second buffer will contain four times this many bytes. Read a sequence of *int8* values from the user and store them into the first buffer. Then copy the values from first buffer to consecutive dwords in the second buffer, using sign extension to convert the values. Display both buffers using hexadecimal notation once the conversion is complete.
6. Using HLA Standard Library `console.fillRect` procedure, write a program that generates a checkerboard pattern on the screen. The user should be able to specify the number of squares on each side of the checkerboard as well as the two colors to use for the checkerboard display. Your program should verify that the checkerboard will fit on the display before drawing it and report an error if it does not fit.
7. Write a two-player tic-tac-toe game. Use the HLA Standard Library `console` module to clear the screen and draw the board between each move. Let the users alternate moves until one of them decides to quit (don't bother trying to have your program determine if the game is over, just use a special input value to end the game). Be sure to draw a second game board listing numbers or characters by which each player can choose the square into which they want to move. Use different colors for each player's symbols. If you want to get real fancy, you can draw the X's and O's by printing blocks of spaces on the screen. If you really want to be impressive, read the HLA console documentation and learn how to use the mouse. Then use mouse clicks to make the moves (this is optional!).
8. Write a program that inputs an (x,y) coordinate from the user and a single unsigned integer value. Your program should draw a rectangle on the screen using the PC's line drawing graphic characters (see Appendix B). The upper left hand corner of the rectangle should be at the coordinate specified by the user. The integer value specifies the width and height of the rectangle on the screen. Before drawing the rectangle, verify that it will fit on the screen and print an error message if it won't. Use the `console.gotoxy` procedure to position the cursor before drawing each character; do not disturb any other characters on the screen except those character positions where you actually draw one of the line drawing characters.
9. The HLA "`console.getRect(top, left, bottom, right, buffer)`" function copies the data in the specified rectangle on the screen to the buffer passed as the last parameter. E.g., "`console.getRect(10, 10, 20, 20, (type byte [eax]);`" copies the 10x10 matrix of characters into the block of memory pointed at by `EAX`. Similarly, the "`console.putRect(top, left, bottom, right, buffer);`" call will copy the data from the specified buffer to the screen at the specified coordinates. The buffer must contain twice the number of bytes as there are characters in the rectangular region. Allocate a sufficient amount of storage using `malloc` and

then use these two routines to temporarily save a portion of the screen while you write something else to it. Then, upon prompt from the program's user, restore the original rectangle.

- 10) Write a program that reads four values from the user, I, J, K, and L, and plugs these values into a truth table with $B'A' = I$, $B'A = J$, $BA' = K$, and $BA = L$. Ensure that these input values are only zero or one. Then input a series of pairs of zeros or ones from the user and plug them into the truth table. Display the result for each computation.
- 11) Write a program that, given a 4-bit logic function number, displays the truth table for that function of two variables.
- 12) Write a program that, given an 8-bit logic function number, displays the truth table for that function of three variables.
- 13) Write a program that, given a 16-bit logic function number, displays the truth table for that function of four variables.
- 14) Write a program that, given a 16-bit logic function number, displays the canonical equation for that function (hint: build the truth table).

8.3 Chapters One and Two Laboratory Exercises

Accompanying this text is a significant amount of software. This software can be found in the AOA_Software directory. Inside this directory are a set of subdirectories with names like *Volume2* and *Volume3*. Inside those directories are files with names like *Ch02* and *Ch03* with the names obviously corresponding to chapters in this text. The code for these laboratory exercises appears in the Volume2\Ch08 sub-directory. Please see this directory for more details.

8.3.1 Memory Organization Exercises

The following program (Program 8.1) demonstrates the memory layout of an HLA program. It does this by declaring variables or other symbols in each of the various run-time memory segments. This program uses the LEA instruction to take the address of each memory object and then displays the address using hexadecimal notation. Run this program and compare the addresses of each of the objects.

For your lab report, compare the output addresses against the memory layout presented in this chapter. Since each memory segment begins on a 4096 byte (\$1000) boundary, what clues do the output addresses give us concerning the grouping of variables in the memory segments? Given the output of this program, and the address of some other variable declared in this program, describe how you could determine which segment that other variable is in given no other information than the variable's location.

```
// Sample program for Memory Organization Laboratory Exercise
// in "The Art of Assembly Language Programming"
// (HLA Edition).

program MemOrg;
#include( "stdlib.hhf" );

// Declare a set of variables in each of the
// different memory sections so we can compare
// their addresses in memory.

var
    AutoVar:int32;

static
    StaticVar:int32;

data
    DataVar:int32;
        dword 0;

readonly
    ROVar: int32 := 0;

storage
    StorageVar:int32;

begin MemOrg;

    // Take the address of each of the variables (plus allocate
    // storage for a dynamic variable) and display the addresses.

    lea( eax, AutoVar );
    stdout.put( "AutoVar address in memory is: $", eax, nl );
```

```

lea( eax, StaticVar );
stdout.put( "StaticVar address in memory is: $", eax, nl );

lea( eax, DataVar );
stdout.put( "DataVar address in memory is: $", eax, nl );

lea( eax, ROVar );
stdout.put( "ROVar address in memory is: $", eax, nl );

lea( eax, StorageVar );
stdout.put( "StorageVar address in memory is: $", eax, nl );

// Dynamically allocate a variable on the heap.

malloc( 4 );
stdout.put( "Dynamic variable address in memory is: $", eax, nl );
free( eax );

// The following code computes the address of this instruction
// in memory:

CodeAdrs: lea( eax, CodeAdrs );
stdout.put( "CodeAdrs label's address in memory is: $", eax, nl );

// Just to put things into perspective, display the value of the
// stack pointer as well:

stdout.put( "Stack Pointer contains the address: $", esp, nl );

end MemOrg;

```

Program 8.1 Demonstration of Memory Sections

8.3.2 Data Alignment Exercises

The following program lets you test the effect of data alignment on your program. It allocates a block of 1,000,000 dword values and then runs through two loops that access these values on an address that is an even multiple of four and at an address that is not an even multiple of four. By measuring the time these two code fragments take to execute, you can compare the difference between aligned and non-aligned memory access.

Note: keep in mind that Windows is a multi-tasking operating system. Therefore, the difference in execution time will not be as great as you might expect because a large percentage of the execution time you measure with this program will be spent in another process. You can assume that approximately the same amount of time is spent outside this process in both halves of the program.

To avoid optimizations by the cache hardware, this program accesses data at over four million different addresses. The fact that most memory accesses will experience a cache miss will also skew the timings (and make them more similar). Finally, different processors (e.g., Pentium vs. Pentium II vs. K6 vs. Athlon) have different penalties for misaligned data. Hence, you should expect to see only a small percentage difference between the two halves of the following program.

This program also demonstrates the use of the align directive in the code segment. If used immediately before a loop that executes a large number of times (as it is in this code), the align directive can improve the performance of the loop slightly.

Run this program and time the two halves using a watch. Record the difference in your lab report and provide an explanation for the different running times.

```
// Sample program for Data Alignment Laboratory Exercise
// in "The Art of Assembly Language Programming"
// (HLA Edition).

program DataAlign;
#include( "stdlib.hhf" );

begin DataAlign;

    console.cls();
    stdout.put
    (
        "Memory Alignment Exercise",nl,
        nl,
        "Using a watch (preferably a stopwatch), time the execution of", nl
        "the following code to determine how many seconds it takes to", nl
        "execute.", nl
        nl
        "Press Enter to begin timing the code:"
    );

    // Allocate enough dynamic memory to ensure that it does not
    // all fit inside the cache. Note: the machine had better have
    // at least four megabytes free or virtual memory will kick in
    // and invalidate the timing.

    malloc( 4_000_000 );

    // Zero out the memory (this loop really exists just to
    // ensure that all memory is mapped in by the OS).

    mov( 1_000_000, ecx );
    repeat

        dec( ecx );
        mov( 0, (type dword [eax+ecx*4]));

    until( !ecx );// Repeat until ECX = 0.

    // Okay, wait for the user to press the Enter key.

    stdin.readLn();

    // Note: as processors get faster and faster, you may
    // want to increase the size of the following constant.
    // Execution time for this loop should be approximately
    // 10-30 seconds.

    mov( 1000, edx );
    add( 30, eax );// Force misalignment of data.
```

```

repeat

    mov( 999_992, ecx );
    align( 16 );
    repeat

        sub( 4, ecx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );

    until( !ecx );
    dec( edx );

until( !edx ); // Repeat until EAX is zero.

stdout.put( stdio.bell, "Stop timing and record time spent", nl, nl );

// Okay, time the aligned access.

stdout.put
(
    "Press Enter again to begin timing access to aligned variable:"
);
stdin.readLn();

// Note: if you change the constant above, be sure to change
// this one, too!

mov( 1000, edx );
add( 30, eax );// Realign the data.
repeat

    mov( 999_992, ecx );
    align( 16 );
    repeat

        sub( 4, ecx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );

    until( !ecx );
    dec( edx );

until( !edx ); // Repeat until EAX is zero.

stdout.put( stdio.bell, "Stop timing and record time spent", nl, nl );
free( eax );

end DataAlign;

8.3.3 Readonly Segment Exercises

The following exercise demonstrates that you cannot write data to a readonly variable. The variable *i*, appearing in the READONLY section, generates an *ex.AccessViolation* exception if you attempt to write to it. Run this program and document what happens in your lab report. Explain how you might use READONLY variables in your program to protect against errors in your code.

```
// Sample program for Read Only Data Laboratory Exercise
// in "The Art of Assembly Language Programming"
// (HLA Edition).

program ReadOnlyDemo;
#include( "stdlib.hhf" );

readonly
    i:int32 := 10;

begin ReadOnlyDemo;

    stdout.put( "i = ", i, nl );
    try

        mov( 0, i );
        stdout.put( "Now i contains ", i, nl );

        exception( ex.AccessViolation )

            stdout.put( "Error attempting to write to variable 'i'", nl );

    endtry;

end ReadOnlyDemo;
```

Program 8.3 READONLY Variable Demonstration

8.3.4 Type Coercion Exercises

The HLA type coercion operators are actually useful for many things besides letting you load a portion of a variable into a smaller register (the primary example this chapter has given thus far). Many HLA instructions and Standard Library routines use the type information associated with a variable to determine how to use that variable. For example, the *stdout.put* routine in the Standard Library determines how to display a value based on its type. For example, if you have an *int32* variable, *i32*, and you decide to print it with *stdout.put*, it will use the type information to determine that it must print this value as a signed 32-bit integer. This laboratory exercise demonstrates that you can use the type coercion operators to display a value as a different type.

Compile and run the following program that demonstrates how to display an *int32* variable (*testVar*) using hexadecimal notation:

```
// Sample program for Coercion Laboratory Exercise
// in "The Art of Assembly Language Programming"
```

```
// (HLA Edition).

program Coercion;
#include( "stdlib.hhf" );

static
    testVar:int32;

begin Coercion;

    stdout.put( "Enter a 32-bit signed integer value: " );
    stdin.get( testVar );
    stdout.put
    (
        nl,
        "In decimal: ", testVar, nl
        "In hexadecimal: $", (type dword testVar), nl
    );

end Coercion;
```

Program 8.4 Type Coercion Exercise

After running this program and noting the results, modify the type of *testVar* so that it is a *real32* variable. Rerun the program. Based on what you've learned from Chapter Two, explain the output when you enter 1.0 as the real value. Note that you can also use type coercion in the *stdin.get* routine. Type cast the *testVar* parameter in *stdin.get* so that it is a *real32* object. Rerun the program and explain the results in your lab report.

8.3.5 Dynamic Memory Allocation Exercises

The following short program demonstrates how to use the *malloc* procedure to allocate storage for 10 integer values. Note that this program doesn't declare any variables at all. All memory accesses occur in the dynamically allocated block of memory. Compile and run this program. Describe the results in your lab report.

```
// Sample program for dynamic allocation Laboratory Exercise
// in "The Art of Assembly Language Programming"
// (HLA Edition).

program DynAlloc;
#include( "stdlib.hhf" );

begin DynAlloc;

    stdout.put( "Allocating storage for 10 integers", nl );

    // Note: we must allocate storage for 40 bytes since
    // each integer consumes four bytes. This function
    // returns a pointer to the data in EAX.

    malloc( 40 );

    // Move pointer to storage to the ESI register so we
```

```

// can use EAX for other purposes.

mov( eax, esi );

// Prompt the user to enter a value:

stdout.put( "Enter a integer to initialize the data with: " );
stdin.geti32();

// Use the input value as a starting value with which to
// initialize the storage we've just created:

stdout.newln();
for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

    mov( eax, [esi+ebx*4] );
    inc( eax );

endfor;

// Okay, display these values from the allocated storage:

for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

    mov( [esi+ebx*4], eax );
    stdout.put
    (
        "Value[",
        (type uns32 ebx),
        "] = ",
        (type int32 eax),
        nl
    );

endfor;

// Free up the storage allocated above.

stdout.put( nl, "Freeing storage:", nl );
free( esi );

end DynAlloc;

```

Program 8.5 MALLOC and FREE Exercise

Modify this program to read and display 20 characters rather than 10 integers. Describe the necessary changes in your lab report and include a copy of the new program with your lab report.

8.4 Chapter Three Laboratory Exercises

This laboratory uses several Windows programs to manipulate truth tables and logic expressions, optimize logic equations, and simulate logic equations. These programs will help you understand the relationship between logic equations and truth tables as well as gain a fuller understanding of logic systems.

$$\begin{aligned}
 E &= D'C'B'A' + D'C'BA' + D'C'BA + D'CB'A + D'CBA' + D'CBA + DC'B'A' + DC'B'A \\
 F &= D'C'B'A' + D'CB'A' + D'CB'A + D'CBA' + DC'B'A' + DC'B'A \\
 G &= D'C'B'A' + D'C'B'A + D'C'BA' + D'C'BA + D'CB'A' + D'CBA + DC'B'A' + DC'B'A \\
 H &= D'C'BA' + D'C'BA + D'CB'A' + D'CB'A + D'CBA' + DC'B'A' + DC'B'A \\
 I &= D'C'B'A' + D'C'BA' + D'CBA' + DC'B'A' \\
 J &= D'C'B'A' + D'C'B'A + D'C'BA + D'CB'A' + D'CB'A + D'CBA' + D'CBA + DC'B'A' + DC'B'A \\
 K &= D'C'B'A' + D'C'BA' + D'C'BA + D'CB'A + D'CBA' + DC'B'A'
 \end{aligned}$$

Convert each of these logic equations to a truth table by setting all entries in the table to zero and then clicking on each square corresponding to each minterm in the equation. Verify by observing the equation that TRUTHTBL produces that you've successfully converted each equation to a truth table. Describe the results and provide the truth tables in your lab report.

For Additional Credit: Modify the equations above to include the following hexadecimal characters. Determine the new truth tables and use the TRUTHTBL program to verify that your truth tables and logic equations are correct.

8.4.2 Canonical Logic Equations Exercises

In this laboratory you will enter several different logic equations and compute their canonical forms as well as generate their truth table. In a sense, this exercise is the opposite of the previous exercise where you generated a canonical logic equation from a truth table.

This exercise uses the CANON.EXE program found in the Volume2\Ch08 subdirectory. Run this program from Windows by double clicking on its icon. This program displays a text box, a truth table, and several buttons. Unlike the TRUTHTBL.EXE program from the previous exercise, you cannot modify the truth table in the CANON.EXE program; it is a display-only table. In this program you will enter logic equations in the text entry box and then press the "Compute" button to see the resulting truth table. This program also produces the sum of minterms canonical form for the logic equation you enter (hence this program's name).

Valid logic equations take the following form:

- A *term* is either a variable (A, B, C, or D) or a logic expression surrounded by parentheses.
- A *factor* is either a term, or a factor followed by the prime symbol (an apostrophe, i.e., "'"). The prime symbol logically negates the factor immediately preceding it.
- A *product* is either a factor, or a factor concatenated with a product. The concatenation denotes logical AND operation.
- An expression is either a product or a product followed by a "+" (denoting logical OR) and followed by another expression.

Note that logical OR has the lowest precedence, logical AND has an intermediate precedence, and logical NOT has the highest precedence of these three operators. You can use parentheses to override operator

precedence. The logical NOT operator, since its precedence is so high, applies only to a variable or a parenthesized expression. The following are all examples of legal expressions:

$$\begin{aligned} & AB'C + D(B'+C') \\ & AB(C+D)' + A'B'(C+D) \\ & A'B'C'D' + ABCD + A(B+C) \\ & (A+B)' + A'B' \end{aligned}$$

For this set of exercises, you should create several logic expression and feed them through CANON.EXE. Include the truth tables and canonical logic forms in your lab report. Also verify that the theorems appearing in this chapter (See “Boolean Algebra” on page 195.) are valid by entering each side of the theorem and verifying that they both produce the same truth table (e.g., $(AB)' = A' + B'$). For additional credit, create several complex logic equations and generate their truth tables and canonical forms by hand. Then input them into the CANON.EXE program to verify your work.

8.4.3 Optimization Exercises

In this set of laboratory exercises, the OPTIMZP.EXE program (found in the Volume2\Ch08 subdirectory) will guide you through the steps of logic function optimization. The OPTIMZP.EXE program uses the Karnaugh Map technique to produce an equation with the minimal number of terms.

Run the OPTIMZP.EXE program by clicking on its icon or running the OPTIMZP.EXE program using the program manager’s File>Run menu option. This program lets you enter an arbitrary logic equation using the same syntax as the CANON.EXE program in the previous exercise.

After entering an equation press the “Optimize” button in the OPTIMZP.EXE window. This will construct the truth table, canonical equation, and an optimized form of the logic equation you enter. Once you have optimized the equation, OPTIMZP.EXE enables the “Step” button. Pressing this button walks you through the optimization process step-by-step.

For this exercise you should enter the seven equations for the seven-segment display. Generate and record the optimize versions of these equations for your lab report and the next set of exercises. Single step through each of the equations to make sure you understand how OPTIMZP.EXE produces the optimal expressions.

For additional credit: OPTIMZP.EXE generates a single optimal expression for any given logic function. Other optimal functions may exist. Using the Karnaugh mapping technique, see if you can determine if other, equivalent, optimal expressions exist. Feed the optimal equations OPTIMZP.EXE produces and your optimal expressions into the CANON.EXE program to verify that their canonical forms are identical (and, hence, the functions are equivalent).

8.4.4 Logic Evaluation Exercises

In this set of laboratory exercises you will use the LOGIC.EXE program to enter, edit, initialize, and evaluation logic expressions. This program lets you enter up to 22 distinct logic equations involving as many as 26 variables plus a clock value. LOGIC.EXE provides four input variables and 11 output variables (four simulated LEDs and a simulated seven-segment display).

Execute the LOGIC.EXE program by double-clicking on its icon. This program consists of three main parts: an equation editor, an initialization screen, and an execution module. LOGIC.EXE uses a set of *tabbed notebook screens* to switch between these three modules. By clicking on the “Create”, *Initialize*, and *Execute* tabs at the top of the screen with your mouse, you can select the specific module you want to use. Typically, you would first create a set of equations on the *Create* page and then execute those functions on the *Execute* page. Optionally, you can initialize any necessary logic variables (D-Z) on the *Initialize* page. At any time you can easily switch between modules by pressing on the appropriate notebook tab. For example, you could create a set of equations, execute them, and then go back and modify the equations (e.g., to correct any mistakes) by pressing on the *Create* tab.

The Create page lets you add, edit, and delete logic equations. Logic equations may use the variables A-Z plus the “#” symbol (“#” denotes the clock). The equations use a syntax that is very similar to the logic

expressions you've used in previous exercises in this chapter. In fact, there are only two major differences between the functions LOGIC.EXE allows and the functions that the other programs allow. First, LOGIC.EXE lets you use the variables A-Z and “#” (the other programs only let you enter functions of four variables using A-D). The second difference is that LOGIC.EXE functions must take the form:

$$variable = expression$$

where *variable* is a single alphabetic character E-Z² and *expression* is a logic expression using the variables A-Z and #. An expression may use a maximum of four different variables (A-Z) plus the clock value (#). During the expression evaluation, the LOGIC.EXE program will evaluate the expression and store the result into the specified destination variable.

If you enter more than four variables, LOGIC.EXE will complain about your expression. LOGIC.EXE can only evaluation expressions that contain a maximum of four alphabetic characters (not counting the variable to the left of the equals sign). Note that the destination variable may appear within the expression; the following is perfectly legal:

$$F = FA+FB$$

This expression would use the *current* value of F, along with the current values of A and B to compute the new value for F.

Unlike a programming language like “C++”, LOGIC.EXE does not evaluate this expression only once and store the result into F. *It will evaluate the expression several times until the value for F stabilizes.* That is, it will evaluate the expression several times until the evaluation produces the same result twice in a row. Certain expressions will produce an *infinite loop* since they will never produce the same value twice in a row. For example, the following function is unstable:

$$F = F'$$

Note that instabilities can cross function boundaries. Consider the following pair of equations:

$$\begin{aligned} F &= G \\ G &= F' \end{aligned}$$

LOGIC.EXE will attempt to execute this set of equations until the values for the variables stop changing. However, the system above will produce an infinite loop.

Sometimes a system of logic equations will only produce an infinite loop given certain data values. For example, consider the following of logic equation:

$$F = GF' + G'F \quad (F = G \text{ xor } F)$$

If G's value is one, this system is unstable. If G's value is zero, this equation is stable. Unstable equations like this one are somewhat harder to discover.

LOGIC.EXE will detect and warn you about logic system instabilities when you attempt to execute the logic functions. Unfortunately, it will not pinpoint the problem for you; it will simply tell you that the problem exists and expect you to fix it.

The A-D, E-K, and W-Z variables are special. A-D are read-only input variables. E-K correspond to the seven segments of a simulated seven-segment display on the *Execute* page:

2. A-D are read-only values that you read from a set of switches. Therefore, you cannot store a value into these variables.

W-Z correspond to four output LEDs on the *Execute* page. If the variables E-K or W-Z contain a one, then the corresponding LED (or segment) turns red (on). If the variable contains zero, the corresponding LED is off.

The *Create* page contains three important buttons: *Add*, *Edit*, and *Delete*. When you press the *Add* button LOGIC.EXE opens a dialog box that lets you enter an equation. Type your equation (or edit the default equation) and press the *Okay* button. If there is a problem with the equation you enter, LOGIC.EXE will report the error and make you fix the problem, otherwise, LOGIC.EXE will attempt to add this equation to the system you are building. If a function already exists that has the same destination variable as the equation you've just added, LOGIC.EXE will ask you if you really want to replace that function before proceeding with the replacement. Once LOGIC.EXE adds your equation to its list, it also displays the truth table for that equation. You can add up to 22 equations to the system (since there are 22 possible destination variables, E-Z). LOGIC.EXE displays those functions in the list box on the right hand side of the window.

Once you've entered two or more logic functions, you can view the truth table for a given logic function by simply clicking on that function with the mouse in the function list box.

If you make a mistake in a logic function you can delete that function by selecting with the mouse and pressing the *delete* button, or you can edit it by selecting it with the mouse and pressing the *edit* button. You can also edit a function by double-clicking on the function in the expression list.

The *Initialize* page displays boxes for each of the 26 possible variables. It lets you view the current values for these 26 variables and change the values of the E-Z variables (remember, A-D are read-only). As a general rule, you will not need to initialize any of the variables, so you can skip this page if you don't need to initialize any variables.

The *Execute* page contains five buttons of importance: *A-D* and *Pulse*. The *A-D* toggle switches let you set the input values for the A-D variables. The *Pulse* switch toggles the clock value from zero to one and then back to zero, evaluating the system of logic functions while the clock is in each state.

In addition to the input buttons, there are several outputs on the *Execute* page. First, of course, are the four LEDs (W, X, Y, and Z) as well as the seven-segment display (output variables E-K as noted above). In addition to the LEDs, there is an *Instability* annunciator that turns red if LOGIC.EXE detects an instability in the system. There is also a small panel that displays the current values of all the system variables at the bottom of the window.

To execute the system of equations simply change one of the input values (A-D) or press the *Pulse* button. LOGIC.EXE will automatically reevaluate the system of equations whenever A-D or # changes.

To familiarize yourself with the LOGIC.EXE program, enter the following equations into the equation editor:

| | |
|-----------------|--------------------|
| $W = AB$ | $A \text{ and } B$ |
| $X = A + B$ | $A \text{ or } B$ |
| $Y = A'B + AB'$ | $A \text{ xor } B$ |
| $Z = A'$ | $\text{not } A$ |

After entering these equations, go to the execute page and enter the four values 00, 01, 10, and 11 for BA. Note the values for W, X, Y, and Z for your lab report.

The LOGIC.EXE program simulates a seven segment display. Variables E-K light the individual segments as follows:

Here are the segments to light for the binary values DCBA = 0000 - 1001:

Enter the seven equations for these segments into LOGIC.EXE and try out each of the patterns (0000 through 1111). **Hint:** use the optimized equations you developed earlier. **Optional, for additional credit:** enter the equations for the 16 hexadecimal values and cycle through those 16 values. Include the results in your lab manual.

A simple sequential circuit. For this exercise you will enter the logic equations for a simple set / reset flip-flop. The circuit diagram is

Since there are two outputs, this circuit has two corresponding logic equations. They are

$$\begin{aligned} X &= (AY)' \\ Y &= (BX)' \end{aligned}$$

These two equations form a *sequential circuit* since they both use variables that are function outputs. In particular, Y uses the previous value for X and X uses the previous value for Y when computing new values for X and Y.

Enter these two equations into LOGIC.EXE. Set the A and B inputs to one (the normal or *quiescent* state) and run the logic simulation. Try setting the A switch to zero and determine what happens. Press the *Pulse* button several times with A still at zero to see what happens. Then switch A back to one and repeat this process. Now try this experiment again, this time setting B to zero. Finally, try setting *both* A and B to zero and then press the *Pulse* key several times while they are zero. Then set A back to one. Try setting both to zero and then set B back to one. **For your lab report:** provide diagrams for the switch settings and resultant LED values for each time you toggle one of the buttons.

A true D flip-flop only latches the data on the D input during a clock transition from low to high. In this exercise you will simulate a D flip-flop. The circuit diagram for a true D flip-flop is

A True D flip-flop

$$\begin{aligned}
 F &= (IG)' \\
 G &= (\#F)' \\
 H &= (G\#I)' \\
 I &= (DH)' \\
 X &= (GY)' \\
 Y &= (HX)'
 \end{aligned}$$

Enter this set of equations and then test your flip-flop by entering different values on the D input switch and pressing the clock pulse button. Explain your results in your lab report.

In this exercise you will build a three-bit shift register using the logic equations for a true D flip-flop. To construct a shift register, you connect the outputs from each flip-flop to the input of the next flip-flop. The data input line provides the input to the first flip-flop, the last output line is the “carry out” of the circuit. Using a simple rectangle to represent a flip-flop and ignoring the Q’ output (since we don’t use it), the schematic for a four-bit shift register looks something like the following:

A Three-bit Shift Register Built from D Flip-flops

In the previous exercise you used six boolean expressions to define the D flip-flop. Therefore, we will need a total of 18 boolean expressions to implement a three-bit flip-flop. These expressions are

Flip-Flop #1:

$$\begin{aligned}
 W &= (GR)' \\
 F &= (IG)'
 \end{aligned}$$

$$\begin{aligned} G &= (F\#)' \\ H &= (G\#I)' \\ I &= (DH)' \\ R &= (HW)' \end{aligned}$$

Flip-Flop #2:

$$\begin{aligned} X &= (KS)' \\ J &= (MK)' \\ K &= (J\#)' \\ L &= (K\#M)' \\ M &= (WL)' \\ S &= (LX)' \end{aligned}$$

Flip-Flop #3:

$$\begin{aligned} Y &= (OT)' \\ N &= (QO)' \\ O &= (N\#)' \\ P &= (O\#Q)' \\ Q &= (XP)' \\ T &= (PY)' \end{aligned}$$

Enter these equations into LOGIC.EXE. Initialize W, X, and Y to zero. Set D to one and press the *Pulse* button once to shift a one into W. Now set D to zero and press the pulse button several times to shift that single bit through each of the output bits. **For your lab report:** try shifting several bit patterns through the shift register. Describe the step-by-step operation in your lab report.

For additional credit: Describe how to create a *recirculating shift register*. One whose output from bit four feeds back into bit zero. What would be the logic equations for such a shift register? How could you initialize it (since you cannot use the D input) when using LOGIC.EXE?

Post-lab, for additional credit: Design a two-bit full adder that computes the sum of BA and DC and stores the binary result to the WXY LEDs. Include the equations and sample results in your lab report.

8.5 Laboratory Exercises for Chapters Four, Five, Six, and Seven

In this laboratory you will use the “SIMY86.EXE” program found in the Volume\Ch08 subdirectory. This program contains a built-in assembler (compiler), debugger, and interrupter for the Y86 hypothetical CPUs. You will learn how to write basic Y86 assembly language programs, assemble (compile) them, modify the contents of memory, and execute your Y86 programs. You will also experiment with memory-mapped I/O, I/O-mapped input/output, DMA, and polled as well as interrupt-driven I/O systems.

8.5.1 The SIMY86 Program – Some Simple Y86 Programs

To run the SIMY86 program double click on its icon or enter the pathname for SIMY86 at a command line prompt. The SIMY86 program consists of three main screen that you can select by clicking on the *Editor*, *Memory*, or *Emulator* notebook tabs in the window. By default, SIMY86 opens the Editor screen. From the Editor screen you can edit and assemble Y86 programs; from Memory screen you can view and modify the contents of memory; from the Emulator screen you execute Y86 programs and view Y86 programs in memory.

The SIMY86 program contains two menu items: File and Edit. These are standard Windows menus so there is little need to describe their operation except for two points. First, the New, Open, Save, and Save As items under the file menu manipulate the data in the text editor box on the Editor screen, they do not affect anything on the other screens. Second, the Print menu item in the File menu prints the source code appearing in the text editor if the Editor screen is active, it prints the entire form if the Memory or Emulator screens are active.

To see how the SIMY86 program operates, switch to the Editor screen (if you are not already there). Select “Open” from the File menu and choose “EX1.Y86” from the Volume2\Ch08 subdirectory. That file should look like the following:

```

mov( [1000], ax );
mov( [1002], bx );
add( bx, ax );
sub( 1, ax );
mov( ax, bx );
add( ax, bx );
add( bx, ax );
halt;

```

This short code sequence adds the two values at location 1000 and 1002, subtracts one from their sum, and multiplies the result by three $((ax + ax) + ax) = ax*3$, leaving the result in AX and then it halts.

On the Editor screen you will see three objects: the editor window itself, a box that holds the “Starting Address,” and an “Assemble” button. The “Starting Address” box holds a hexadecimal number that specifies where the assembler will store the machine code for the Y86 program you write with the editor. By default, this address is zero. About the only time you should change this is when writing interrupt service routines since the default reset address is zero. The “Assemble” button directs the SIMY86 program to convert your assembly language source code into Y86 machine code and store the result beginning at the Starting Address in memory. Go ahead and press the “Assemble” button at this time to assemble this program to memory.

Now press the “Memory” tab to select the memory screen. On this screen you will see a set of 64 boxes arranged as eight rows of eight boxes. To the left of these eight rows you will see a set of eight (hexadecimal) memory addresses (by default, these are 0000, 0008, 0010, 0018, 0020, 0028, 0030, and 0038). This tells you that the first eight boxes at the top of the screen correspond to memory locations 0, 1, 2, 3, 4, 5, 6, and 7; the second row of eight boxes correspond to locations 8, 9, A, B, C, D, E, and F; and so on. At this point you should be able to see the machine codes for the program you just assembled in memory locations 0000 through 000D. The rest of memory will contain zeros.

The memory screen lets you look at and possibly modify 64 bytes of the total 64K memory provided for the Y86 processors. If you want to look at some memory locations other than 0000 through 003F, all you need do is edit the first address (the one that currently contains zero). At this time you should change the starting address of the memory display to 1000 so you can modify the values at addresses 1000 and 1002 (remember, the program adds these two values together). Type the following values into the corresponding cells: at address 1000 enter the value 34, at location 1001 the value 12, at location 1002 the value 01, and at location 1003 the value 02. Note that if you type an illegal hexadecimal value, the system will turn that cell red and beep at you.

By typing an address in the memory display starting address cell, you can look at or modify locations almost anywhere in memory. Note that if you enter a hexadecimal address that is not an even multiple of eight, the SIMY86 program disable up to seven cells on the first row. For example, if you enter the starting address 1002, SIMY86 will disable the first two cells since they correspond to addresses 1000 and 1001. The first active cell is 1002. Note the SIMY86 reserves memory locations FFF0 through FFFF for memory-mapped I/O. Therefore, it will not allow you to edit these locations. Addresses FFF0 through FFF7 correspond to read-only input ports (and you will be able to see the input values even though SIMY86 disables these cells). Locations FFF8 through FFFF are write-only output ports, SIMY86 displays garbage values if you look at these locations.

On the Memory page along with the memory value display/edit cells, there are two other entry cells and a button. The “Clear Memory” button clears memory by writing zeros throughout. Since your program’s object code and initial values are currently in memory, you should not press this button. If you do, you will need to reassemble your code and reenter the values for locations 1000 through 1003.

The other two items on the Memory screen let you set the interrupt vector address and the reset vector address. By default, the reset vector address contains zero. This means that the SIMY86 begins program execution at address zero whenever you reset the emulator. Since your program is currently sitting at location zero in memory, you should not change the default reset address.

The “Interrupt Vector” value is FFFF by default. FFFF is a special value that tells SIMY86 “there is no interrupt service routine present in the system, so ignore all interrupts.” Any other value must be the address of an ISR that SIMY86 will call whenever an interrupt occurs. Since the program you assembled does not have an interrupt service routine, you should leave the interrupt vector cell containing the value FFFF.

Finally, press the “Emulator” tab to look at the emulator screen. This screen is much busier than the other two. In the upper left hand corner of the screen is a data entry box with the label IP. This box holds the current value of the Y86 *instruction pointer* register. Whenever SIMY86 runs a program, it begins execution with the instruction at this address. Whenever you press the reset button (or enter SIMY86 for the first time), the IP register contains the value found in the reset vector. If this register does not contain zero at this point, press the reset button on the Emulator screen to reset the system.

Immediately below the IP value, the Emulator page *disassembles* the instruction found at the address in the IP register. This is the very next instruction that SIMY86 will execute when you press the “Run” or “Step” buttons. Note that SIMY86 does not obtain this instruction from the source code window on the Editor screen. Instead, it decodes the opcode in memory (at the address found in IP) and generates this string itself. Therefore, there may be minor differences between the instruction you wrote and the instruction SIMY86 displays on this page. Note that a disassembled instruction contains several numeric values in front of the actual instruction. The first (four-digit) value is the memory address of that instruction. The next pair of digits (or the next three pairs of digits) are the opcodes and possible instruction operand values. For example, the “mov([1000], ax);” instruction’s machine code is C6 00 10 since these are the three sets of digits appearing at this point.

Below the current disassembled instruction, SIMY86 displays 15 instructions it disassembles. The starting address for this disassembly is *not* the value in the IP register. Instead, the value in the lower right hand corner of the screen specifies the starting disassembly address. The two little arrows next to the disassembly starting address let you quickly increment or decrement the disassembly starting address. Assuming the starting address is zero (change it to zero if it is not), press the down arrow. Note that this increments the starting address by one. Now look back at the disassembled listing. As you can see, pressing the down arrow has produced an interesting result. The first instruction (at address 0001) is “*****”. The four asterisks indicate that this particular opcode is an illegal instruction opcode. The second instruction, at address 0002, is “not(ax);”. Since the program you assembled did not contain an illegal opcode or a “not(ax);” instruction, you may be wondering where these instructions came from. However, note the starting address of the first instruction: 0001. This is the second byte of the first instruction in your program. In fact, the illegal instruction (opcode=00) and the “not(ax);” instruction (opcode=10) are actually a disassembly of the “mov([1000], ax);” instruction’s two-byte operand. This should clearly demonstrate a problem with disassembly – it is possible to get “out of phase” by specify a starting address that is in the middle of a multi-byte instruction. You will need to consider this when disassembling code.

In the middle of the Emulator screen there are several buttons: Run, Step, Halt, Interrupt, and Reset (the “Running” box is an annunciator, not a button). Pressing the Run button will cause the SIMY86 program to run the program (starting at the address in the IP register) at “full” speed. Pressing the Step button instructs SIMY86 to execute only the instruction that IP points at and then stop. The Halt button, which is only active while a program is running, will stop execution. Pressing the Interrupt button generates an interrupt and pressing the Reset button resets the system (and halts execution if a program is currently running). Note that pressing the Reset button clears the Y86 registers to zero and loads the ip register with the value in the reset vector.

The “Running” annunciator is gray if SIMY86 is not currently running a program. It turns red when a program is actually running. You can use this annunciator as an easy way to tell if a program is running if the program is busy computing something (or is in an infinite loop) and there is no I/O to indicate program execution.

The boxes with the AX, BX, CX, and DX labels let you modify the values of these registers while a program is not running (the entry cells are not enabled while a program is actually running). These cells also display the current values of the registers whenever a program stops or between instructions when you are stepping through a program. Note that while a program is running the values in these cells are static and do not reflect their current values.

The “Less” and “Equal” check boxes denote the values of the less than and equal flags. The Y86 CMP instruction sets these flags depending on the result of the comparison. You can view these values while the program is not running. You can also initialize them to true or false by clicking on the appropriate box with the mouse (while the program is not running).

In the middle section of the Emulator screen there are four “LEDs” and four “toggle switches.” Above each of these objects is a hexadecimal address denoting their memory-mapped I/O addresses. Writing a zero

to a corresponding LED address turns that LED “off” (turns it white). Writing a one to a corresponding LED address turns that LED “on” (turns it red). Note that the LEDs only respond to bit zero of their port addresses. These output devices ignore all other bits in the value written to these addresses.

The toggle switches provide four memory-mapped input devices. If you read the address above each switch SIMY86 will return a zero if the switch is off. SIMY86 will return a one if the switch is in the on position. You can toggle a switch by clicking on it with the mouse. Note that a little rectangle representing the switch turns red if the switch is in the “on” position.

The two columns on the right side of the Emulate screen (“Input” and “Output”) display input values read with the GET instruction and output values the PUT instruction prints.

For this first exercise, you will use the Step button to single step through each of the instructions in the EX1.Y86 program. First, begin by pressing the Reset button³. Next, press the Step button once. Note that the values in the IP and AX registers change. The IP register value changes to 0003 since that is the address of the next instruction in memory, AX’S value changed to 1234 since that’s the value you placed at location 1000 when operating on the Memory screen. Single step through the remaining instructions (by repeatedly pressing Step) until you get the “Halt Encountered” dialog box.

For your lab report: explain the results obtained after the execution of each instruction. Note that single-stepping through a program as you’ve done here is an excellent way to ensure that you fully understand how the program operates. As a general rule, you should always single-step through every program you write when testing it.

8.5.2 Simple I/O-Mapped Input/Output Operations

Go to the Editor screen and load the EX2.Y86 file into the editor. This program introduces some new concepts, so take a moment to study this code:

```

    mov( 1000, bx );
a:   get;
    mov( ax, [bx] );
    add( 2, bx );
    cmp( ax, 0 );
    jne a;

    mov( bx, cx );
    mov( 1000, bx )
    mov( 0, ax );
b:   add( [bx], ax );
    add( 2, bx );
    cmp( bx, cx );
    jb b;

    put;
    halt;

```

The first thing to note are the two strings “a:” and “b:” appearing in column one of the listing. The SIMY86 assembler lets you specify up to 26 statement *labels* by specifying a single alphabetic character followed by a colon. Labels are generally the operand of a jump instruction of some sort. Therefore, the “jne a;” instruction above really says “jump if not equal to the statement prefaced with the ‘a:’ label” rather than saying “jump if not equal to location ten (0Ah) in memory.”

Using labels is much more convenient than figuring out the address of a target instruction manually, especially if the target instruction appears later in the code. The SIMY86 assembler computes the address of these labels and substitutes the correct address for the operands of the jump instructions. Note that you *can* specify a numeric address in the operand field of a jump instruction. However, all numeric addresses must begin with a decimal digit (even though they are hexadecimal values). If your target address would normally

3. It is a good idea to get in the habit of pressing the Reset button before running or stepping through any program.

begin with a value in the range A through F, simply prepend a zero to the number. For example, if “jne a;” was supposed to mean “jump if not equal to location 0Ah” you would write the instruction as “jne 0a;”.

This program contains two loops. In the first loop, the program reads a sequence of values from the user until the user enters the value zero. This loop stores each word into successive memory locations starting at address 1000h. Remember, each word read by the user requires two bytes; this is why the loop adds two to bx on each iteration.

The second loop in this program scans through the input values and computes their sum. At the end of the loop, the code prints the sum to the output window using the PUT instruction.

For your lab report: single-step through this program and describe how each instruction works. Reset the Y86 and run this program at full speed. Enter several values and describe the result. Discuss the GET and PUT instructions. Describe why they do the equivalent of I/O-mapped input/output operations rather than memory-mapped input/output operations.

8.5.3 Memory Mapped I/O

From the Editor screen, load the EX3.Y86 program file. That program takes the following form (the comments were added here to make the operation of this program clearer):

```
a:    mov( [fff0], ax );
      mov( [fff2], bx );

      mov( ax, cx );    // Compute Sw0 and Sw1
      and( bx, cx );
      mov( cx, [fff8] );

      mov( ax, cx );    // Computes Sw0 OR Sw1
      or( bx, cx );
      mov( cx, [fffa] );

      mov( ax, cx );    // Computes Sw0 xor Sw1
      mov( bx, dx );    // XOR = AB' + A'B
      not( cx );
      not( dx );
      and( bx, cx );
      and( ax, dx );
      or( dx, cx );
      mov( cx, [fffc] );

      not( cx );        // Computes Sw0 = Sw1
      mov( cx, [ffffe] ); // Note: equals is not xor

      mov( [fff4], ax ); // Read the third switch.
      cmp( ax, 0 );      // See if it's on.
      je a;              // Repeat this program while it's on.
      halt;
```

Locations \$FFF0, \$FFF2, and \$FFF4 correspond to the first three toggle switches on the Execution page. These are memory-mapped I/O devices that put a zero or one into the corresponding memory locations depending upon whether the toggle switch is in the on or off state. Locations \$FFF8, \$FFFA, \$FFFC, and \$FFFFE correspond to the four LEDs. Writing a zero to these locations turns the corresponding LED off, writing a one turns it on.

This program computes the logical AND, OR, XOR, and XNOR (not XOR) functions for the values read from the first two toggle switches. This program displays the results of these functions on the four output LEDs. This program reads the value of the third toggle switch to determine when to quit. When the third toggle switch is in the on position, the program will stop.

For your lab report: run this program and cycle through the four possible combinations of on and off for the first two switches. Include the results in your lab report.

8.5.4 DMA Exercises

In this exercise you will start a program running (EX4.Y86) that examines and operates on values found in memory. Then you will switch to the Memory screen and modify values in memory (that is, you will directly access memory while the program continues to run), thus simulating a peripheral device that uses DMA.

The EX4.Y86 program begins by setting memory location \$1000 to zero. Then it loops until one of two conditions is met – either the user toggles the FFF0 switch or the user changes the value in memory location \$1000. Toggling the FFF0 switch terminates the program. Changing the value in memory location \$1000 transfers control to a section of the program that adds together n words, where n is the new value in memory location \$1000. The program sums the words appearing in contiguous memory locations starting at address \$1002. The actual program looks like the following:

```
d:    mov( 0, cx );          // Clear location $1000 before we begin testing it.
      mov( cx, [1000] );

// The following loop checks to see if memory location $1000 changes or if
// the FFF0 switch is in the on position.

a:    mov( [1000], cx );    // Check to see if location $1000
      cmp( cx, 0 );        // Changes. Jump to the section that
      jne c;              // sums the values if it does.

      mov( [fff0], ax );    // If location $1000 still contains zero,
      cmp( ax, 0 );        // read the FFF0 switch and see if it is
      je a;              // of. If so, loop back. If the switch
      halt;              // is on, quit the program.

// The following code sums up the "cx" contiguous words of memory starting at
// memory location $1002. After it sums up these values, it prints their sum.

c:    mov( 1002, bx );     // Initialize BX to point at data array.
      mov( 0, ax );       // Initialize the sum.
b:    add( [bx], ax );     // Sum in the next array value.
      add( 2, bx );       // Point BX at the next item in the array.
      sub( 1, cx );       // Decrement the element count.
      cmp( cx, 0 );       // Test to see if we've added up all the
      jne b;              // values in the array.

      put;                // Print the sum and start over.
      jmp d;
```

Load this program into SIMY86 and assemble it. Switch to the Emulate screen, press the Reset button, make sure the FFF0 switch is in the off position, and then run the program. Once the program is running switch to the memory screen by pressing the Memory tab. Change the starting display address to \$1000. Change the value at location \$1000 to 5. Switch back to the emulator screen. Assuming memory locations \$1002 through \$100B all contain zero, the program should display a zero in the output column.

Switch back to the memory page. What does location \$1000 now contain? Change the L.O. bytes of the words at address \$1002, \$1004, and \$1006 to 1, 2, and 3, respectively. Change the value in location \$1000 to three. Switch to the Emulator page. Describe the output in your lab report. Try entering other values into memory. Toggle the FFF0 switch when you want to quit running this program.

For your lab report: explain how this program uses DMA to provide program input. Run several tests with different values in location \$1000 and different values in the data array starting at location \$1002. Include the results in your report.

For additional credit: Store the value \$12 into memory location \$1000. Explain why the program prints *two* values instead of just one value.

8.5.5 Interrupt Driven I/O Exercises

In this exercise you will load *two* programs into memory: a main program and an interrupt service routine. This exercise demonstrates the use of interrupts and an interrupt service routine.

The main program (EX5a.Y86) will constantly compare memory locations \$1000 and \$1002. If they are not equal, the main program will print the value of location \$1000 and then copy this value to location \$1002 and repeat this process. The main program repeats this loop until the user toggles switch FFF0 to the on position. The code for the main program is the following:

```
a:   mov( [1000], ax );      // Fetch the data at location $1000 and
      cmp( ax, [1002] );    // see if it is the same as location
      je b;                 // $1002. If so, check the FFF0 switch.
      put;                  // If the two values are different, print
      mov( ax, [1002] );    // $1000's value and make them the same.

b:   mov( [fff0], ax );    // Test the FFF0 switch to see if we
      cmp( ax, 0 );        // should quit this program.
      je a;
      halt;
```

The interrupt service routine (EX5b.Y86) sits at location \$100 in memory. Whenever an interrupt occurs, this ISR simply increments the value at location \$1000 by loading this value into AX, adding one to the value in AX, and then storing this value back to location \$1000. After these instructions, the ISR returns to the main program. The interrupt service routine contains the following code:

```
mov( ax, [1004] );        // The ISR must preserve any register it uses!
mov( [1000], ax );        // Increment the value at location $1000 by one
add( 1, ax );             // and return to the interrupted code.
mov( ax, [1000] );
mov( [1004], ax );        // Restore AX's original value.
iret;                     // Return from the interrupt.
```

You must load and assemble both files before attempting to run the main program. Begin by loading the main program (EX5a.Y86) into memory and assemble it at address zero. Then load the ISR (EX5b.Y86) into memory, set the Starting Address to 100, and then assemble your code. **Warning:** *if you forget to change the starting address you will wipe out your main program when you assemble the ISR. If this happens, you will need to repeat this procedure from the beginning.*

After assembling the code, the next step is to set the interrupt vector so that it contains the address of the ISR. To do this, switch to the Memory screen. The interrupt vector cell should currently contain \$FFFF (this value indicates that interrupts are disabled). Change this to \$100 so that it contains the address of the interrupt service routine. This also enables the interrupt system.

Finally, switch to the Emulator screen, make sure the FFF0 toggle switch is in the off position, reset the program, and start it running. Normally, nothing will happen. Now press the interrupt button and observe the results.

For your lab report: describe the output of the program whenever you press the interrupt button. Explain all the steps you would need to follow to place the interrupt service routine at address \$2000 rather than \$100.

For additional credit: write your own interrupt service routine that does something simple. Run the main program and press the interrupt button to test your code. Verify that your ISR works properly.

8.5.6 Machine Language Programming & Instruction Encoding Exercises

To this point you have been creating machine language programs with SIMY86's built-in assembler. An assembler is a program that translates an ASCII source file containing textual representations of a program into the actual machine code. The assembler program saves you a considerable amount of work by translat-

ing human readable instructions into machine code. Although tedious, you can perform this translation yourself. In this exercise you will create some very short *machine language* programs by encoding the instructions and entering their hexadecimal opcodes into memory on the memory screen.

Using the instruction encodings found in Figure 5.3, Figure 5.4, Figure 5.5, and Figure 5.6, write the hexadecimal values for the opcodes beside each of the following instructions:

| | Binary Opcode | Hex Operand | |
|----------------|----------------------|----------------------|----------------------|
| mov(0, cx); | <input type="text"/> | <input type="text"/> | <input type="text"/> |
| a: get; | <input type="text"/> | | |
| put; | <input type="text"/> | | |
| add(ax, ax); | <input type="text"/> | | |
| put; | <input type="text"/> | | |
| add(ax, ax); | <input type="text"/> | | |
| put; | <input type="text"/> | | |
| add(ax, ax); | <input type="text"/> | | |
| put; | <input type="text"/> | | |
| add(1, cx); | <input type="text"/> | <input type="text"/> | <input type="text"/> |
| cmp(cx, 4); | <input type="text"/> | <input type="text"/> | <input type="text"/> |
| jb a; | <input type="text"/> | <input type="text"/> | <input type="text"/> |
| halt; | <input type="text"/> | | |

Figure 8.1 A Simple Program to Convert to Machine Code

You can assume that the program starts at address zero and, therefore, label *a* will be at address \$0003 since the “mov(0, cx);” instruction is three bytes long.

For your lab report: enter the hexadecimal opcodes and operands into memory starting at location zero using the Memory editor screen. Dump these values and include them in your lab report. Switch to the Emulator screen and disassemble the code starting at address zero. Verify that this code is the same as the assembly code above. Print a copy of the disassembled code and include it in your lab report. Run the program and verify that it works properly.

8.5.7 Self Modifying Code Exercises

In the previous laboratory exercise, you discovered that the system doesn't really differentiate data and instructions in memory. You were able to enter hexadecimal data and the Y86 processor treats it as a sequence of executable instructions. It is also possible for a program to store data into memory and then execute it. A program is *self-modifying* if it creates or modifies some of the instructions it executes.

Consider the following Y86 program (EX6.Y86):

```

    sub( ax, ax );      // Trick:  sets AX to zero.
    mov( ax, [100] );

a:   mov( [100], ax );
     cmp( ax, 0 );
     je b;
     halt;

b:   mov( c6, ax );
     mov( ax, [100] );
     mov( 710, ax );
     mov( ax, [102] );
     mov( a6a0, ax );
     mov( ax, [104] );
     mov( 1000, ax );
     mov( ax, [106] );
     mov( 8007, ax );
     mov( ax, [108] );
     mov( e6, ax );
     mov( ax, [10a] );
     mov( e10, ax );
     mov( ax, [10c] );
     mov( 4, ax );
     mov( ax, [10e] );
     jmp 100;

```

This program writes the following code to location \$100 and then executes it:

```

mov( [1000], ax );
put;
add( ax, ax );
add( [1000], ax );
put;
sub( ax, ax );
mov( ax, [1000] );
put;
sub( ax, ax );
mov( ax, [1000] );
jmp 0004;           // $0004 is the address of the a: label.

```

For your lab report: execute the EX7.Y86 program and verify that it generates the above code at location 100.

Although this program demonstrates the principle of self-modifying code, it hardly does anything useful. As a general rule, one would not use self-modifying code in the manner above, where one segment writes some sequence of instructions and then executes them. Instead, most programs that use self-modifying code only modify existing instructions and often only the operands of those instructions.

Self-modifying code is rarely found in modern assembly language programs. Programs that are self-modifying are hard to read and understand, difficult to debug, and often unstable. Programmers often resort to self-modifying code when the CPU's architecture lacks sufficient power to achieve a desired goal. The later Intel 80x86 processors do not lack for instructions or addressing modes, so it is very rare to find

80x86 programs that use self-modifying code⁴. The Y86 processors, however, have a very weak instruction set, so there are actually a couple of instances where self-modifying code may prove useful.

A good example of an architectural deficiency where the Y86 is lacking is with respect to subroutines. The Y86 instruction set does not provide any (direct) way to call and return from a subroutine. However, you can easily simulate a call and return using the JMP instruction and self-modifying code. Consider the following Y86 “subroutine” that sits at location \$100 in memory:

```
// Integer to Binary converter.
// Expects an unsigned integer value in AX.
// Converts this to a string of zeros and ones storing this string of
// values into memory starting at location $1000.

        mov( 1000, ax );    // Starting address of string.
        mov( 10, cx );    // 16 ($10) digits in a word.
a:      mov( 0, dx );      // Assume current bit is zero.
        cmp( ax, 8000 );  // See if AX's H.O. bit is zero or one.
        jnb b;           // Branch if AX's H.O. bit is zero.
        mov( 1, dx );    // AX's H.O. bit is one, set that here.
b:      mov( dx, [bx] );  // Store zero or one to next location.
        add( 1, bx );    // Bump BX to point at next byte in memory.
        add( ax, ax );   // AX = AX *2 (shift left operation).
        sub( 1, cx );    // Count off 16 bits.
        cmp( cx, 0 );    // Repeat 16 times.
        ja a;
        jmp 0;          // Return to caller via self-modifying code.
```

The only instruction that a program will modify in this subroutine is the very last JMP instruction. This jump instruction must transfer control to the first instruction beyond the JMP in the calling code that transfers control to this subroutine; that is, the caller must store the return address into the operand of the JMP instruction in the code above. As it turns out, the JMP instruction is at address \$120 (assuming the code above starts at location \$100). Therefore, the caller must store the return address into location \$121 (the operand of the JMP instruction). The following sample “main” program makes three calls to the “subroutine” above:

```
mov( c, ax );    // Address of the BRK instruction below.
mov( ax, [121] ); // Store into JMP as return address.
mov( 1234, ax ); // Convert $1234 to binary.
jmp 100;         // "Call" the subroutine above.
brk;            // Pause to let the user example bytes at $1000.

mov( 19, ax );  // Address of the BRK instruction below.
mov( ax, [121] ); // Store into JMP as return address.
mov( fdeb, ax ); // Convert $FDEB to binary.
jmp 100;        // "Call" the subroutine above.
brk;           // Pause to let the user example bytes at $1000.

mov( 16, ax );  // Address of the BRK instruction below.
mov( ax, [121] ); // Store into JMP as return address.
mov( 2345, ax ); // Convert $2345 to binary.
jmp 100;        // "Call" the subroutine above.
brk;           // Pause to let the user example bytes at $1000.

halt;
```

Load the subroutine (EX7s.Y86) into SIMY86 and assemble it starting at location \$100. Next, load the main program (EX7m.Y86) into memory and assemble it starting at location zero. Switch to the Emulator screen and verify that all the return addresses (\$c, \$19, and \$26) are correct. Also verify that the return

4. Many viruses and copy protection programs use self modifying code to make it difficult to detect or bypass them.

address needs to be written to location \$121. Next, run the program. The program will execute a BRK instruction after each of the first two calls. The BRK instruction pauses the program. At this point you can switch to the memory screen and look at locations \$1000..100F in memory. They should contain the pseudo-binary conversion of the value passed to the subroutine. Once you verify that the conversion is correct, switch back to the Emulator screen and press the Run button to continue program execution after the BRK.

For your lab report: describe how self-modifying code works and explain in detail how this code uses self-modifying code to simulate call and return instructions. Explain the modifications you would need to make to move the main program to address \$800 and the subroutine to location \$900.

For additional credit: Actually change the program and subroutine so that they work properly at the addresses above (\$800 and \$900).

8.5.8 Virtual Memory Exercise

The SIMY86 emulator treats the two 4K blocks of memory starting at addresses \$D000 and \$E000 specially. These blocks use virtual memory for their actual implementation. Only one block at a time can be in memory. If you access an address in the range \$D000..\$DFFF and that block is not currently in memory, the SIMY86 program will read the data for this block from the disk. Ditto for \$E000..\$EFFF. However, since only one of the two blocks can be in memory at a time, any attempt to access a block that is not in memory replaces other other block. If the block is “dirty” when the system needs to replace it (i.e., you’ve written data to the block) then the system first writes the data to the “paging file” before reading the other block from memory. In this laboratory exercise you will experiment with the performance of virtual memory on the Y86 hypothetical processor.

In the first exercise you will measure the amount of time a program takes to execute that exhibits spatial locality of reference. The first version of this program (EX8a.Y86) reads and writes data to locations \$B000..\$CFFF. This is our control case; we’ll run this program and time its execution to obtain a baseline to compare with our other experiments. Here’s the code for the control case:

```

        mov( 80, dx );           // Repeat the outer loop this many times (128).
a:      mov( 0, bx );           // Starting index for block one.
        mov( 0, ax );           // Write zeros to page $b000.
b:      mov( ax, [b000+bx] );
        mov( ax, [c000+bx] ); // Write zeros to page $c000 too.
        add( 2, bx );           // Move on to the next word in these pages.
        cmp( bx, 1000 );        // See if we’re done yet.
        jb b;
        sub( 1, dx );           // Repeat this whole process DX times.
        cmp( dx, 0 );
        ja a;
        halt;

```

This program will repeatedly clear locations \$D000..\$EFFF in a sequential fashion, starting at location \$D000. Note that this code writes two adjacent words in memory and bumps the index by four on each iteration of the loop. This ensures that we access all the locations in page \$D000 in a sequential fashion and then access all the locations in page \$E000 in a sequential fashion. This keeps these two pages in (physical) memory for the greatest length of time. Here’s the program (EX8b.Y86) that does the job:

```

        mov( 80, dx );           // Repeat the outer loop this many times (128).
a:      mov( 0, bx );           // Starting index for block one.
        mov( 0, ax );
b:      mov( ax, [d000+bx] ); // Write zeros to pages $d000-$e000
        mov( ax, [d002+bx] ); // Write alternate words.
        add( 4, bx );           // Move on to the next word in these pages.
        cmp( bx, 2000 );        // See if we’re done yet.
        jb b;

```

```

sub( 1, dx );          // Repeat this whole process DX times.
cmp( dx, 0 );
ja a;
halt;

```

Now load the following program into memory (EX8c.Y86) and repeat the timing of this code. This code also accesses pages \$D000 and \$E000 but the access pattern is different. Rather than accessing all the locations in page \$D000 and then accessing all the locations in \$E000, this code “ping-pongs” between the two pages, accessing a word in one page and then accessing a word in the second page. This forces the virtual memory subsystem to continuously reload the two pages on each access (i.e., thrashing occurs). Measure the amount of time it takes to execute. Record the time for your lab report. Note a major difference between this program and the previous two: the previous programs executed the outer loop 128 times while the following program only executes eight times. Be sure to multiply the running time of the following program by 16 to obtain a fair comparison of the running time of this program.

```

mov( 8, dx );          // Repeat the outer loop this many times (8).
a:  mov( 0, bx );        // Starting index for block one.
    mov( 0, ax );        // Write zeros to page $d000.
b:  mov( ax, [d000+bx] );
    mov( ax, [e000++bx] ); // Write zeros to page $e000 too.
    add( 2, bx );        // Move on to the next word in these pages.
    cmp( bx, 1000 );     // See if we're done yet.
    jb b;
    sub( 1, dx );        // Repeat this whole process DX times.
    cmp( dx, 0 );
    ja a;
    halt;

```

For your lab report: Measure the execution time of these three programs. Present the results in your lab report. In light of this experiment, describe how you might restructure a real program running in virtual memory to obtain the best performance.

For additional credit: Explain, based on your knowledge of the hardware needed to implement paging, why there is a difference in execution time between the first and second programs in this experiment.

Volume Three: Basic Assembly Language

- Chapter One: Constants, Variables, and Data Types
How to declare objects in HLA.
- Chapter Two: Character Strings
A discussion of HLA's character string representation and an introduction to string routines in the HLA Standard Library.
- Chapter Three: Characters and Character Sets
A discussion of characters and the operations on them plus character sets and HLA's representation of character sets.
- Chapter Four: Arrays
How to declare and access elements of arrays.
- Chapter Five: Records, Unions, and Namespaces
How to declare records (structures) and how to access the fields within those records.
- Chapter Six: Dates and Times
Dates and Times are two important data types whose importance was underscored by the Y2K problem. This chapter discusses how to properly implement these data types.
- Chapter Seven: File I/O
Maintaining persistent information (across executions) within your programs.
- Chapter Eight: Introduction to Procedures
The ability to create your own procedures is of great importance in any program. This chapter discusses HLA's high level procedure declaration syntax and how to call procedures you've written.
- Chapter Nine: Managing Large Programs
This chapter discusses how to break up a program into modules and separately compile them.

Volume Three:

Basic Assembly Language

Chapter Ten: Integer Arithmetic

This chapter discusses how to compute the values of integer expressions. In particular, it describes how to convert arithmetic expressions into assembly language.

Chapter Eleven: Real Arithmetic

This chapter discusses how to compute the values of floating point expressions. In particular, it describes how to convert arithmetic expressions into assembly language.

Chapter Twelve: Calculation Via Table Lookups

This chapter discusses how to quickly compute some value using a table lookup.

Chapter Thirteen: Questions, Projects, and Laboratory Exercises

Test your knowledge.

This Volume provides a basic introduction to assembly language programming. By the end of this volume you should be able to write meaningful programs using HLA. This Volume plus Volume Four present all the basic skills a typical assembly language programmer needs to write real-world applications in assembly language.

Chapters One through Seven provide information about important data types and data structures found in typical assembly language programs. For courses that have a limited amount of time available, Chapters One, Four, and Five from this set are the most important, closely followed by Chapters Two and Seven. Chapters Three and Six are optional though students should read these on their own.

Chapters Eight and Ten are also essential. Chapters Nine and Eleven are important and the course should cover them if time permits. Chapter Twelve discusses an optimization that is becoming less and less important as CPU speeds vastly outstrip memory access times. Those interested in programming embedded systems should read this chapter, other instructors may elect to skip this material.

Constants, Variables, and Data Types Chapter One

Volume One discussed the basic format for data in memory. Volume Two covered how a computer system physically organizes that data. This chapter finishes this discussion by connecting the concept of *data representation* to its actual physical representation. As the title implies, this chapter concerns itself with three main topics: constants, variables and data structures. This chapter does not assume that you've had a formal course in data structures, though such experience would be useful.

1.1 Chapter Overview

This chapter discusses how to declare and use constants, scalar variables, integers, reals, data types, pointers, arrays, and structures. You must master these subjects before going on to the next chapter. Declaring and accessing arrays, in particular, seems to present a multitude of problems to beginning assembly language programmers. However, the rest of this text depends on your understanding of these data structures and their memory representation. Do not try to skim over this material with the expectation that you will pick it up as you need it later. You will need it right away and trying to learn this material along with later material will only confuse you more.

1.2 Some Additional Instructions: INTMUL, BOUND, INTO

This chapter introduces arrays and other concepts that will require the expansion of your 80x86 instruction set knowledge. In particular, you will need to learn how to multiply two values; hence the first instruction we will look at is the INTMUL (integer multiply) instruction. Another common task when accessing arrays is to check to see if an array index is within bounds. The 80x86 BOUNDS instruction provides a convenient way to check a register's value to see if it is within some range. Finally, the INTO (interrupt on overflow) instruction provides a quick check for signed arithmetic overflow. Although INTO isn't really necessary for array (or other data type access), its function is very similar to BOUND, hence the presentation at this point.

The INTMUL instruction takes one of the following forms:

```
// The following compute destreg = destreg * constant

intmul( constant, destreg16 );
intmul( constant, destreg32 );

// The following compute dest = src * constant

intmul( constant, srcreg16, destreg16 );
intmul( constant, srcmem16, destreg16 );

intmul( constant, srcreg32, destreg32 );
intmul( constant, srcmem32, destreg32 );

// The following compute dest = dest * src

intmul( srcreg16, destreg16 );
intmul( srcmem16, destreg16 );
intmul( srcreg32, destreg32 );
intmul( srcmem32, destreg32 );
```

Note that the syntax of the INTMUL instruction is different than the ADD and SUB instructions. In particular, note that the destination operand must be a register (ADD and SUB both allow a memory operand as a

destination). Also note that INTMUL allows three operands when the first operand is a constant. Another important difference is that the INTMUL instruction only allows 16-bit and 32-bit operands; it does not allow eight-bit operands.

INTMUL computes the product of its specified operands and stores the result into the destination register. If an overflow occurs (which is always a signed overflow, since INTMUL only multiplies signed integer values), then this instruction sets both the carry and overflow flags. INTMUL leaves the other condition code flags undefined (so, for example, you cannot check the sign flag or the zero flag after INTMUL and expect them to tell you anything about the INTMUL operation).

The BOUND instruction checks a 16-bit or 32-bit register to see if it is between one of two values. If the value is outside this range, the program raises an exception and aborts operation. This instruction is particularly useful for checking to see if an array index is within a given range. The BOUND instruction takes one of the following forms:

```
bound( reg16, LBconstant, UBconstant );
bound( reg32, LBconstant, UBconstant );
```

```
bound( reg16, Mem16[2] );1
bound( reg32, Mem32[2] );2
```

The BOUND instruction compares its register operand against an unsigned lower bound value and an unsigned upper bound value to ensure that the register is in the range:

```
lower_bound <= register <= upper_bound
```

The form of the BOUND instruction with three operands compares the register against the second and third parameters (the lower bound and upper bound, respectively)³. The BOUND instruction with two operands checks the register against one of the following ranges:

```
Mem16[0] <= register <= Mem16[2]
Mem32[0] <= register <= Mem32[4]
```

If the specified register is not within the given range, then the 80x86 raises an exception. You can trap this exception using the HLA TRY..ENDTRY exception handling statement. The `excepts.hhf` header file defines an exception, `ex.BoundsInstr`, specifically for this purpose. The following code fragment demonstrates how to use the BOUND instruction to check some user input:

```
program BoundDemo;
#include( "stdlib.hhf" );

static
    InputValue:int32;
    GoodInput:boolean;

begin BoundDemo;

    // Repeat until the user enters a good value:
    repeat

        // Assume the user enters a bad value.

        mov( false, GoodInput );
```

-
1. The “[2]” suggests that this variable must be an array of two consecutive word values in memory.
 2. Likewise, this memory operand must be two consecutive dwords in memory.
 3. This form isn’t a true 80x86 instruction. HLA converts this form of the bound instruction to the two operand form by creating two readonly memory variables initialized with the specified constant.

```

// Catch bad numeric input via the try..endtry statement.

try

    stdout.put( "Enter an integer between 1 and 10: " );
    stdin.flushInput();
    stdin.geti32();

    mov( eax, InputValue );

    // Use the BOUND instruction to verify that the
    // value is in the range 1..10.

    bound( eax, 1, 10 );

    // If we get to this point, the value was in the
    // range 1..10, so set the boolean "GoodInput"
    // flag to true so we can exit the loop.

    mov( true, GoodInput );

    // Handle inputs that are not legal integers.
exception( ex.ConversionError )

    stdout.put( "Illegal numeric format, reenter", nl );

    // Handle integer inputs that don't fit into an int32.
exception( ex.ValueOutOfRange )

    stdout.put( "Value is *way* too big, reenter", nl );

    // Handle values outside the range 1..10 (BOUND instruction)
exception( ex.BoundInstr )

    stdout.put
    (
        "Value was ",
        InputValue,
        ", it must be between 1 and 10, reenter",
        nl
    );

endtry;

until( GoodInput );
stdout.put( "The value you entered, ", InputValue, " is valid.", nl );

end BoundDemo;

```

Program 1.1 Demonstration of the BOUND Instruction

The INTO instruction, like BOUND, also generates an exception under certain conditions. Specifically, INTO generates an exception if the overflow flag is set. Normally, you would use INTO immediately after a signed arithmetic operation (e.g., INTMUL) to see if an overflow occurs. If the overflow flag is not set, the system ignores the INTO instruction; however, if the overflow flag is set, then the INTO instruction raises the HLA *ex.IntoInstr* exception. The following code sample demonstrates the use of the INTO instruction:

```
program INTOdemo;
#include( "stdlib.hhf" );

static
    LOperand:int8;
    ResultOp:int8;

begin INTOdemo;

    // The following try..endtry checks for bad numeric
    // input and handles the integer overflow check:

    try

        // Get the first of two operands:

        stdout.put( "Enter a small integer value (-128..+127):" );
        stdin.geti8();
        mov( al, LOperand );

        // Get the second operand:

        stdout.put( "Enter a second small integer value (-128..+127):" );
        stdin.geti8();

        // Produce their sum and check for overflow:

        add( LOperand, al );
        into();

        // Display the sum:

        stdout.put( "The eight-bit sum is ", (type int8 al), nl );

        // Handle bad input here:

    exception( ex.ConversionError )

        stdout.put( "You entered illegal characters in the number", nl );

        // Handle values that don't fit in a byte here:

    exception( ex.ValueOutOfRange )

        stdout.put( "The value must be in the range -128..+127", nl );

        // Handle integer overflow here:

    exception( ex.IntoInstr )
```

```

        stdout.put
        (
            "The sum of the two values is outside the range -128..+127",
            nl
        );
    endtry;

end INTOdemo;

```

1.3 The QWORD and TBYTE Data Types

HLA lets you declare eight-byte and ten-byte variables using the *qword*, and *tbyte* data types, respectively. Since HLA does not allow the use of 64-bit or 80-bit non-floating point constants, you may not associate an initializer with these two data types. However, if you wish to reserve storage for a 64-bit or 80-bit variable, you may use these two data types to do so.

The *qword* type lets you declare *quadword* (eight byte) variables. Generally, *qword* variables will hold 64-bit integer or unsigned integer values, although HLA and the 80x86 certainly don't enforce this. The HLA Standard Library contains several routines to let you input and display 64-bit signed and unsigned integer values. The chapter on advanced arithmetic will discuss how to calculate 64-bit results on the 80x86 if you need integers of this size.

The *tbyte* directive allocates ten bytes of storage. There are two data types indigenous to the 80x87 (math coprocessor) family that use a ten byte data type: ten byte BCD values and extended precision (80 bit) floating point values. Since you would normally use the *real80* data type for floating point values, about the only purpose of *tbyte* in HLA is to reserve storage for a 10-byte BCD value (or other data type that needs 80 bits). Once again, the chapter on advanced arithmetic may provide some insight into the use of this data type. However, except for very advanced applications, you could probably ignore this data type and not suffer.

1.4 HLA Constant and Value Declarations

HLA's CONST and VAL sections let you declare symbolic constants. The CONST section lets you declare identifiers whose value is constant throughout compilation and run-time; the VAL section lets you declare symbolic constants whose value can change at compile time, but whose values are constant at run-time (that is, the same name can have a different value at several points in the source code, but the value of a VAL symbol at a given point in the program cannot change while the program is running).

The CONST section appears in the same declaration section of your program that contains the STATIC, READONLY, STORAGE, VAR, and DATA sections. It begins with the CONST reserved word and has a syntax that is nearly identical to the READONLY section, that is, the CONST section contains a list of identifiers followed by a type and a constant expression. The following example will give you an idea of what the CONST section looks like:

```

const
    pi:          real32 := 3.14159;
    MaxIndex:   uns32  := 15;
    Delimiter:  char   := '/';
    BitMask:    byte   := $F0;
    DebugActive: boolean:= true;

```

Once you declare these constants in this manner, you may use the symbolic identifiers anywhere the corresponding literal constant is legal. These constants are known as *manifest constants*. A manifest con-

stant is a symbolic representation of a constant that allows you to substitute the literal value for the symbol anywhere in the program. Contrast this with READONLY variables; a READONLY variable is certainly a constant value since you cannot change such a variable at run time. However, there is a memory location associated with READONLY variables and the operating system, not the HLA compiler, enforces the read-only attribute at run-time. Although it will certainly crash your program when it runs, it is perfectly legal to write an instruction like “MOV(EAX, ReadOnlyVar);” On the other hand, it is no more legal to write “MOV(EAX, MaxIndex);” (using the declaration above) than it is to write “MOV(EAX, 15);” In fact, both of these statements are equivalent since the compiler substitutes “15” for *MaxIndex* whenever it encounters this manifest constant.

If there is absolutely no ambiguity about a constant’s type, then you may declare a constant by specifying only the name and the constant’s value, omitting the type specification. In the example earlier, the *pi*, *Delimiter*, *MaxIndex*, and *DebugActive* constants could use the following declarations:

```
const
  pi          := 3.14159;
  MaxIndex    := 15;
  Delimiter:  := '/' ;
  DebugActive := true;
```

Symbol constants that have an integer literal constant are always given the type *uns32* if the constant is zero or positive, or *int32* if the value is negative. This is why *MaxIndex* was okay in this CONST declaration but *BitMask* was not. Had we included the statement “BitMask := \$F0;” in this latter CONST section, the declaration would have been legal but *BitMask* would be of type *uns32* rather than *byte*.

Constant declarations are great for defining “magic” numbers that might possibly change during program modification. The following is a modification of the data alignment exercise in the previous Volume.

```
program ConstDemo;
#include( "stdlib.hhf" );

const
  MemToAllocate:= 4_000_000;
  NumDWords:= MemToAllocate div 4;
  MisalignBy:= 62;

  MainRepetitions:= 1000;
  DataRepetitions := 999_900;

  CacheLineSize:= 16;

begin ConstDemo;

  console.cls();
  stdout.put
  (
    "Memory Alignment Exercise",nl,
    nl,
    "Using a watch (preferably a stopwatch), time the execution of", nl
    "the following code to determine how many seconds it takes to", nl
    "execute.", nl
    nl
    "Press Enter to begin timing the code:"
  );

  // Allocate enough dynamic memory to ensure that it does not
  // all fit inside the cache. Note: the machine had better have
  // at least four megabytes free or virtual memory will kick in
  // and invalidate the timing.
```

```

malloc( MemToAllocate );

// Zero out the memory (this loop really exists just to
// ensure that all memory is mapped in by the OS).

mov( NumDWords, ecx );
repeat

    dec( ecx );
    mov( 0, (type dword [eax+ecx*4]));

until( !ecx );// Repeat until ECX = 0.

// Okay, wait for the user to press the Enter key.

stdin.readLine();

// Note: as processors get faster and faster, you may
// want to increase the size of the following constant.
// Execution time for this loop should be approximately
// 10-30 seconds.

mov( MainRepetitions, edx );
add( MisalignBy, eax );// Force misalignment of data.

repeat

    mov( DataRepetitions, ecx );
    align( CacheLineSize );
    repeat

        sub( 4, ecx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );
        mov( [eax+ecx*4], ebx );

    until( !ecx );
    dec( edx );

until( !edx ); // Repeat until EAX is zero.

stdout.put( stdio.bell, "Stop timing and record time spent", nl, nl );

// Okay, time the aligned access.

stdout.put
(
    "Press Enter again to begin timing access to aligned variable:"
);
stdin.readLine();

// Note: if you change the constant above, be sure to change
// this one, too!

mov( MainRepetitions, edx );
sub( MisalignBy, eax );// Realign the data.
repeat

```

```

mov( DataRepetitions, ecx );
align( CacheLineSize );
repeat

    sub( 4, ecx );
    mov( [eax+ecx*4], ebx );
    mov( [eax+ecx*4], ebx );
    mov( [eax+ecx*4], ebx );
    mov( [eax+ecx*4], ebx );

until( !ecx );
dec( edx );

until( !edx ); // Repeat until EAX is zero.

stdout.put( stdio.bell, "Stop timing and record time spent", nl, nl );
free( eax );

end ConstDemo;

```

Program 1.3 Data Alignment Program Rewritten Using CONST Definitions

1.4.1 Constant Types

Manifest constants can be any of the HLA primitive types plus a few of the composite types this chapter discusses. Volumes One and Two discussed most of the primitive types; these primitive types include the following:

- Boolean constants (true or false)
- Uns8 constants (0..255)
- Uns16 constants (0..65535)
- Uns32 constants (0..4,294,967,295)
- Int8 constants (-128..+127)
- Int16 constants (-32768..+32767)
- Int32 constants (-2,147,483,648..+2,147,483,647)
- Char constants (any ASCII character with a character code in the range 0..255)
- Byte constants (any eight-bit value including integers, booleans, and characters)
- Word constants (any 16-bit value)
- DWord constants (any 32-bit value)
- Real32 constants (floating point values)
- Real64 constants (floating point values)
- Real80 constants (floating point values)

In addition to the constant types appearing above, the CONST section supports six additional constant types:

- String constants
- Text constants
- Enumerated constant values
- Array constants
- Record/Union constants
- Character set constants

These data types are the subject of this Volume and the discussion of most of them appears in later chapters. However, the string and text constants are sufficiently important to warrant an early discussion of these constant types.

1.4.2 String and Character Literal Constants

HLA, like most programming languages, draws a distinction between a sequence of characters, a *string*, and a single character. This distinction is present both in the type declarations and in the syntax for literal character and string constants. Until now, this text has not drawn a fine distinction between character and string literal constants; now it is time to do so.

String literal constants consist of a sequence of zero or more characters surrounded by the ASCII quote characters. The following are all examples of legal literal string constants:

```
"This is a string"      // String with 16 characters.
""                     // Zero length string.
"a"                   // String with a single character.
"123"                 // String of length three.
```

A string of length one is not the same thing as a character constant. HLA uses two completely different internal representations for character and string values. Hence, "a" is not a character value, it is a string value that just happens to contain a single character.

Character literal constants take a couple forms, but the most common consist of a single character surrounded by ASCII apostrophe characters:

```
'2'                   // Character constant equivalent to ASCII code $32.
'a'                   // Character constant for lower case 'A'.
```

As noted above, "a" and 'a' are not equivalent.

Those who are familiar with C/C++/Java probably recognize these literal constant forms, since they are similar to the character and string constants in C/C++/Java. In fact, this text has made a tacit assumption to this point that you are somewhat familiar with C/C++ insofar as examples appearing up to this point use character and string constants without an explicit definition of them⁴.

Another similarity between C/C++ strings and HLA's is the automatic concatenation of adjacent literal string constants within your program. For example, HLA concatenates the two string constants

```
"First part of string, " "second part of string"
```

to form the single string constant

```
"First part of string, second part of string"
```

Beyond these few similarities, however, HLA strings and C/C++ strings are different. For example, C/C++ strings let you specify special character values using the escape character sequence consisting of a backslash character followed by one or more special characters; HLA does not use this escape character mechanism. HLA does provide, however, several other ways to achieve this same goal.

Since HLA does not allow escape character sequences in literal string and character constants, the first question you might ask is "How does one embed quote characters in string constants and apostrophe characters in character constants?" To solve this problem, HLA uses the same technique as Pascal and many other languages: you insert two quotes in a string constant to represent a single quote or you place two apostrophes in a character constant to represent a single apostrophe character, e.g.,

```
"He wrote a ""Hello World"" program as an example."
```

The above is equivalent to:

```
He wrote a "Hello World" program as an example.
```

```
''''
```

The above is equivalent to a single apostrophe character.

4. Apologies are due to those of you who do not know C/C++/Java or a language that shares these string and constant definitions.

HLA provides a couple of other features that eliminate the need for escape characters. In addition to concatenating two adjacent string constants to form a longer string constant, HLA will also concatenate any combination of adjacent character and string constants to form a single string constant:

```
'1' '2' '3'           // Equivalent to "123"
"He wrote a " '"" "Hello World" '"" " program as an example."
```

Note that the two “He wrote...” strings in the above examples are identical to HLA.

HLA provides a second way to specify character constants that handles all the other C/C++ escape character sequences: the ASCII code literal character constant. This literal character constant form uses the syntax:

```
#integer_constant
```

This form creates a character constant whose value is the ASCII code specified by *numeric_constant*. The numeric constant can be a decimal, hexadecimal, or binary value, e.g.,

```
#13    #$d    %#1101    // All three are the same character, a
                        // carriage return.
```

Since you may concatenate character literals with strings, and the *#constant* form is a character literal, the following are all legal strings:

```
"Hello World" #13 #10    // #13 #10 is the newline sequence (carriage
                        // return followed by line feed).

"Error: Bad Value" #7    // #7 is the bell character.
"He wrote a " # $22 "Hello World" # $22 " program as an example."
```

Since \$22 is the ASCII code for the quote character, this last example is yet a third form of the “He wrote...” string literal.

1.4.3 String and Text Constants in the CONST Section

String and text constants in the CONST section use the following declaration syntax:

```
const
AStringConst:    string := "123";
ATextConst:      text   := "123";
```

Other than the data type of these two constants, their declarations are identical. However, their behavior in an HLA program is quite different.

Whenever HLA encounters a symbolic string constant within your program, it substitutes the string literal constant in place of the string name. So a statement like “`stdout.put(AStringConst);`” prints the string “123” (without quotes, of course) to the display. No real surprise here.

Whenever HLA encounters a symbolic text constant within your program, it substitutes the text of that string (rather than the string literal constant) for the identifier. That is, HLA substitutes the characters between the delimiting quotes in place of the symbolic text constant. Therefore, the following statement is perfectly legal given the declarations above:

```
mov( ATextConst, al );    // equivalent to mov( 123, al );
```

Note that substituting *AStringConst* for *ATextConst* in this example is illegal:

```
mov( AStringConst, al ); // equivalent to mov( "123", al );
```

This latter example is illegal because you cannot move a string literal constant into the AL register.

Whenever HLA encounters a symbol text constant in your program, it immediately substitutes the value of the text constant’s string for that text constant and continues the compilation as though you had written the text constant’s value rather than the symbolic identifier in your program. This can save some typing and

help make your programs a little more readable if you often enter some sequence of text in your program. For example, consider the *nl* (newline) text constant declaration found in the HLA `stdio.hhf` library header file:

```
const
  nl: text := "#$d #$a";
```

Whenever HLA encounters the symbol *nl*, it immediately substitutes the value of the string “#\$d #\$a” for the *nl* identifier. When HLA sees the `#$d` (carriage return) character constant followed by the `#$a` (line feed) character constants, it concatenates the two to form the string containing the newline sequence (a carriage return followed by a line feed). Consider the following two statements:

```
stdout.put( "Hello World", nl );
stdout.put( "Hello World" nl );
```

(Notice that the second statement above does not separate the string literal and the *nl* symbol with a comma.) In the first example, HLA emits code that prints the string “Hello World” and then emits some additional code that prints a newline sequence. In the second example, HLA expands the *nl* symbol as follows:

```
stdout.put( "Hello World" #$d #$a );
```

Now HLA sees a string literal constant (“Hello World”) followed by two character constants. It concatenates the three of them together to form a single string and then prints this string with a single call. Therefore, leaving off the comma between the string literal and the *nl* symbol produces slightly more efficient code. Keep in mind that this only works with string literal constants. You cannot concatenate string variables, or a string variable with a string literal, by using this technique.

In the constant section, if you specify only a constant identifier and a string constant (i.e., you do not supply a type), HLA defaults to type *string*. If you want to declare a *text* constant you must explicitly supply the type.

```
const
  AStrConst := "String Constant";
  ATextConst: text := "mov( 0, eax );";
```

1.4.4 Constant Expressions

Thus far, this chapter has given the impression that a symbolic constant definition consists of an identifier, an optional type, and a literal constant. Actually, HLA constant declarations can be a lot more sophisticated than this because HLA allows the assignment of a constant expression, not just a literal constant, to a symbolic constant. The generic constant declaration takes one of the following two forms:

```
Identifier : typeName := constant_expression ;
Identifier := constant_expression ;
```

Constant expressions take the familiar form you’re used to in high level languages like C/C++ and Pascal. They may contain literal constant values, previously declared symbolic constants, and various arithmetic operators. The following lists some of the operations possible in a constant expression:

Arithmetic Operators

- (unary negation) Negates the expression immediately following the “-”.
- * Multiplies the integer or real values around the asterisk.
- div Divides the left integer operand by the right integer operand producing an integer (truncated) result.
- mod Divides the left integer operand by the right integer operand producing an integer remainder.
- / Divides the left numeric operand by the second numeric operand producing a floating point result.
- + Adds the left and right numeric operands.
- Subtracts the right numeric operand from the left numeric operand.

Comparison Operators

```

=, ==  Compares left operand with right operand. Returns TRUE if equal.
<>, != Compares left operand with right operand. Returns TRUE if not equal.
<      Returns true if left operand is less than right operand.
<=     Returns true if left operand is <= right operand.
>      Returns true if left operand is greater than right operand.
>=     Returns true if left operand is >= right operand.

```

Logical Operators⁵:

```

&, &&  For boolean operands, returns the logical AND of the two operands.
|, ||  For boolean operands, returns the logical OR of the two operands.
^      For boolean operands, returns the logical exclusive-OR.
!      Returns the logical NOT of the single operand following "!".

```

Bitwise Logical Operators:

```

&, &&  For integer numeric operands, returns bitwise AND of the operands.
|, ||  For integer numeric operands, returns bitwise OR of the operands.
^      For integer numeric operands, returns bitwise XOR of the operands.
!      For an integer numeric operand, returns bitwise NOT of the operand.

```

String Operators:

```

`+'    Returns the concatenation of the left and right string operands.

```

The constant expression operators follow standard precedence rules; you may use the parentheses to override the precedence if necessary. See the HLA reference in the appendix for the exact precedence relationships between the operators. In general, if the precedence isn't obvious, use parentheses to exactly state the order of evaluation.

If an identifier appears in a constant expression, that identifier must be a constant identifier that you have previously defined in your program. You may not use variable identifiers in a constant expression; their values are not defined at compile-time when HLA evaluates the constant expression. Also, don't confuse the following two types of operations:

```

// Constant expression, computed while HLA is compiling your program:

const
    x      := 5;
    y      := 6;
    Sum    := x + y;

// Run-time calculation, computed while your program is running, long after
// HLA has compiled it:

mov( x, al );
add( y, al );

```

HLA directly interprets the value of a constant expression during compilation. It does not emit any machine instructions to compute "x+y" in the constant expression above. Instead, it directly computes the sum of these two constant values. From that point forward in the program, HLA associates the value 11 with the constant *Sum* just as if the program had contained the statement "Sum := 11;" rather than "Sum := x+y;" On the other hand, HLA does not precompute the value 11 in AL for the MOV and ADD instructions above⁶,

5. Note to C/C++ and Java users. HLA's constant expressions use complete boolean evaluation rather than short-circuit boolean evaluation. Hence, HLA constant expressions do not behave identically to C/C++/Java expressions.

it faithfully emits the object code for these two instructions and the 80x86 computes their sum when the program is run (sometime after the compilation is complete).

In general, constant expressions don't get very sophisticated. Usually, you're adding, subtracting, or multiplying two integer values. For example, the following CONST section defines a set of constants that have consecutive values:

```
const
  TapeDAT      := 1;
  Tape8mm      := TapeDAT + 1;
  TapeQIC80    := Tape8mm + 1;
  TapeTravan   := TapeQIC80 + 1;
  TapeDLT      := TapeTravan + 1;
```

The constants above have the following values: TapeDAT = 1, Tape8mm = 2, TapeQIC80 = 3, TapeTravan = 4, and TapeDLT = 5.

1.4.5 Multiple CONST Sections and Their Order in an HLA Program

Although CONST sections must appear in the declaration section of an HLA program (e.g., between the "PROGRAM *pgmname*;" header and the corresponding "BEGIN *pgmname*;" statement), they do not have to appear before or after any other items in the declaration section. In fact, like the variable declaration sections, you can place multiple CONST sections in the declaration section. The only restriction on HLA constant declarations is that you must declare any constant symbol before it appears in some other constant expression.

The CONST section begins with the CONST keyword and ends with the next declaration keyword or BEGIN (e.g., VAR, STATIC, or READONLY). In fact, you could have multiple CONST sections adjacent to one another. Some C/C++ programmers, for example, are more comfortable writing their constant declarations as follows (since this is closer to C/C++'s syntax for declaring constants):

```
const  TapeDAT      := 1;
const  Tape8mm      := TapeDAT + 1;
const  TapeQIC80    := Tape8mm + 1;
const  TapeTravan   := TapeQIC80 + 1;
const  TapeDLT      := TapeTravan + 1;
```

The placement of the CONST section in a program seems to be a personal issue among programmers. Other than the requirements of defining all constants before you use them, you may feel free to insert the constant declaration section anywhere in the declaration section. Some programmers prefer to put all their CONST declarations at the beginning of their declaration section, some programmers prefer to spread them throughout declaration section, defining the constants just before they need them for some other purpose. Putting all your constants at the beginning of an HLA declaration section is probably the wisest choice right now. Later in this text you'll see reasons why you might want to define your constants later in a declaration section.

1.4.6 The HLA VAL Section

You cannot change the value of a constant you define in the CONST section. While this seems perfectly reasonable (constants after all, are supposed to be, well, constant), there are different ways we can define the term *constant* and CONST objects only follow the rules of one specific definition. HLA's VAL section lets you define constant objects that follow slightly different rules. This section will discuss the VAL section and the difference between VAL constants and CONST constants.

6. Technically, if HLA had an optimizer it could replace these two instructions with a single "MOV(11, al);" instruction. HLA, however, does not do this.

The concept of “*const-ness*” can exist at two different times: while HLA is compiling your program and later when your program executes (and HLA is no longer running). All reasonable definitions of a constant require that a value not change while the program is running. Whether or not the value of a “constant” can change during compilation is a separate issue. The difference between HLA CONST objects and HLA VAL objects is whether the value of the constant can change during compilation.

Once you define a constant in the CONST section, the value of that constant is immutable from that point forward *both at run-time and while HLA is compiling your program*. Therefore, an instruction like “`mov(SymbolicCONST, EAX);`” always moves the same value into EAX, regardless of where this instruction appears in the HLA main program. Once you define the symbol *SymbolicCONST* in the CONST section, this symbol has the same value from that point forward.

The HLA VAL section lets you declare symbolic constants, just like the CONST section. However, HLA VAL constants can change their value throughout the source code in your program. The following HLA declarations are perfectly legal:

```
val    InitialValue    := 0;
const  SomeVal         := InitialValue + 1;    // = 1
const  AnotherVal      := InitialValue + 2;    // = 2

val    InitialValue    := 100;
const  ALargerVal      := InitialValue;        // = 100
const  LargeValTwo     := InitialValue*2;      // = 200
```

All of the symbols appearing in the CONST sections use the symbolic value *InitialValue* as part of the definition. Note, however, that *InitialValue* has different values at different points in this code sequence; at the beginning of the code sequence *InitialValue* has the value zero, while later it has the value 100.

Remember, at run-time a VAL object is not a variable; it is still a manifest constant and HLA will substitute the current value of a VAL identifier for that identifier⁷. Statements like “`MOV(25, InitialValue);`” are no more legal than “`MOV(25, 0);`” or “`MOV(25, 100);`”

1.4.7 Modifying VAL Objects at Arbitrary Points in Your Programs

If you declare all your VAL objects in the declaration section, it would seem that you would not be able to change the value of a VAL object between the BEGIN and END statements of your program. After all, the VAL section must appear in the declaration section of the program and the declaration section ends before the BEGIN statement. Later, you will learn that most VAL object modifications occur between the BEGIN and END statements; hence, HLA must provide some way to change the value of a VAL object outside the declaration section. The mechanism to do this is the “?” operator.

Not only does HLA allow you to change the value of a VAL object outside the declaration section, it allows you to change the value of a VAL object almost *anywhere* in the program. Anywhere a space is allowed inside an HLA program, you can insert a statement of the form:

```
? ValIdentifier := constant_expression ;
```

This means that you could write a short program like the following:

```
program VALdemo;
#include( "stdlib.hhf" );

val
    NotSoConstant := 0;
```

7. In this context, *current* means the value last assigned to a VAL object looking backward in the source code.

```

begin VALdemo;

    mov( NotSoConstant, eax );
    stdout.put( "EAX = ", (type uns32 eax ), nl );

    ?NotSoConstant := 10;
    mov( NotSoConstant, eax );
    stdout.put( "EAX = ", (type uns32 eax ), nl );

    ?NotSoConstant := 20;
    mov( NotSoConstant, eax );
    stdout.put( "EAX = ", (type uns32 eax ), nl );

    ?NotSoConstant := 30;
    mov( NotSoConstant, eax );
    stdout.put( "EAX = ", (type uns32 eax ), nl );

end VALdemo;

```

Program 1.4 Demonstration of VAL Redefinition Using “?” Operator

You probably won't have much use for VAL objects at this time. However, you'll see (in the chapter on the HLA compile-time language) how useful VAL objects can be to you.

1.5 The HLA TYPE Section

Let's say that you simply do not like the names that HLA uses for declaring byte, word, double word, real, and other variables. Let's say that you prefer Pascal's naming convention or, perhaps, C's naming convention. You want to use terms like *integer*, *float*, *double*, or whatever. If this were Pascal you could redefine the names in the **type** section of the program. With C you could use a **#define** or a **typedef** statement to accomplish the task. Well, HLA, like Pascal, has it's own **TYPE** statement that also lets you create aliases of these names. The following example demonstrates how to set up some C/C++/Pascal compatible names in your HLA programs:

```

type
    integer:    int32;
    float:      real32;
    double:     real64;
    colors:     byte;

```

Now you can declare your variables with more meaningful statements like:

```

static
    i:          integer;
    x:          float;
    HouseColor: colors;

```

If you are an Ada, C/C++, or FORTRAN programmer (or any other language, for that matter), you can pick type names you're more comfortable with. Of course, this doesn't change how the 80x86 or HLA reacts to these variables one iota, but it does let you create programs that are easier to read and understand since the type names are more indicative of the actual underlying types. One warning for C/C++ programmers: don't get too excited and go off and define an *int* data type. Unfortunately, INT is an 80x86 machine instruction (interrupt) and therefore, this is a reserved word in HLA.

The **TYPE** section is useful for much more than creating type isomorphism (that is, giving a new name to an existing type). The following sections will demonstrate many of the possible things you can do in the **TYPE** section.

1.6 ENUM and HLA Enumerated Data Types

In a previous section discussing constants and constant expressions, you saw the following example:

```
const  TapeDAT      := 1;
const  Tape8mm     := TapeDAT + 1;
const  TapeQIC80   := Tape8mm + 1;
const  TapeTravan  := TapeQIC80 + 1;
const  TapeDLT     := TapeTravan + 1;
```

This example demonstrates how to use constant expressions to develop a set of constants that contain unique, consecutive, values. There are, however, a couple of problems with this approach. First, it involves a lot of typing (and extra reading when reviewing this program). Second, it's very easy to make a mistake when creating long lists of unique constants and reuse or skip some values. The HLA ENUM type provides a better way to create a list of constants with unique values.

ENUM is an HLA type declaration that lets you associate a list of names with a new type. HLA associates a unique value with each name (that is, it *enumerates* the list). The ENUM keyword typically appears in the TYPE section and you use it as follows:

```
type
  enumTypeID:  enum { comma_separated_list_of_names };
```

The symbol *enumTypeID* becomes a new type whose values are specified by the specified list of names. As a concrete example, consider the data type *TapeDrives* and a corresponding variable declaration of type *TypeDrives*:

```
type
  TapeDrives: enum{ TapeDAT, Tape8mm, TapeQIC80, TapeTravan, TapeDLT};

static
  BackupUnit:  TapeDrives := TapeDAT;

  .
  .
  .

  mov( BackupUnit, al );
  if( al = Tape8mm ) then

      ...

  endif;

  // etc.
```

By default, HLA reserves one byte of storage for enumerated data types. So the *BackupUnit* variable will consume one byte of memory and you would typically use an eight-bit register to access it⁸. As for the constants, HLA associates consecutive *uns8* constant values starting at zero with each of the enumerated identifiers. In the *TapeDrives* example, the tape drive identifiers would have the values *TapeDAT*=0, *Tape8mm*=1, *TapeQIC80*=2, *TapeTravan*=3, and *TapeDLT*=4. You may use these constants exactly as though you had defined them with these values in a CONST section.

8. HLA provides a mechanism by which you can specify that enumerated data types consume two or four bytes of memory. See the HLA documentation for more details.

1.7 Pointer Data Types

Some people refer to pointers as scalar data types, others refer to them as composite data types. This text will treat them as scalar data types even though they exhibit some tendencies of both scalar and composite data types.

Of course, the place to start is with the question “What is a pointer?” Now you’ve probably experienced pointers first hand in the Pascal, C, or Ada programming languages and you’re probably getting worried right now. Almost everyone has a real bad experience when they first encounter pointers in a high level language. Well, fear not! Pointers are actually *easier* to deal with in assembly language. Besides, most of the problems you had with pointers probably had nothing to do with pointers, but rather with the linked list and tree data structures you were trying to implement with them. Pointers, on the other hand, have lots of uses in assembly language that have nothing to do with linked lists, trees, and other scary data structures. Indeed, simple data structures like arrays and records often involve the use of pointers. So if you’ve got some deep-rooted fear about pointers, well forget everything you know about them. You’re going to learn how *great* pointers really are.

Probably the best place to start is with the definition of a pointer. Just exactly what is a pointer, anyway? Unfortunately, high level languages like Pascal tend to hide the simplicity of pointers behind a wall of abstraction. This added complexity (which exists for good reason, by the way) tends to frighten programmers because *they don’t understand what’s going on*.

Now if you’re afraid of pointers, well, let’s just ignore them for the time being and work with an array. Consider the following array declaration in Pascal:

```
M: array [0..1023] of integer;
```

Even if you don’t know Pascal, the concept here is pretty easy to understand. *M* is an array with 1024 integers in it, indexed from *M*[0] to *M*[1023]. Each one of these array elements can hold an integer value that is independent of all the others. In other words, this array gives you 1024 different integer variables each of which you refer to by number (the array index) rather than by name.

If you encountered a program that had the statement “*M*[0]:=100;” you probably wouldn’t have to think at all about what is happening with this statement. It is storing the value 100 into the first element of the array *M*. Now consider the following two statements:

```
i := 0; (* Assume "i" is an integer variable *)
M [i] := 100;
```

You should agree, without too much hesitation, that these two statements perform the same exact operation as “*M*[0]:=100;”. Indeed, you’re probably willing to agree that you can use any integer expression in the range 0...1023 as an index into this array. The following statements *still* perform the same operation as our single assignment to index zero:

```
i := 5;      (* assume all variables are integers*)
j := 10;
k := 50;
m [i*j-k] := 100;
```

“Okay, so what’s the point?” you’re probably thinking. “Anything that produces an integer in the range 0...1023 is legal. So what?” Okay, how about the following:

```
M [1] := 0;
M [ M [1] ] := 100;
```

Whoa! Now that takes a few moments to digest. However, if you take it slowly, it makes sense and you’ll discover that these two instructions perform the exact same operation you’ve been doing all along. The first statement stores zero into array element *M*[1]. The second statement fetches the value of *M*[1], which is an integer so you can use it as an array index into *M*, and uses that value (zero) to control where it stores the value 100.

If you're willing to accept the above as reasonable, perhaps bizarre, but usable nonetheless, then you'll have no problems with pointers. *Because $m[1]$ is a pointer!* Well, not really, but if you were to change "M" to "memory" and treat this array as all of memory, this is the exact definition of a pointer.

1.7.1 Using Pointers in Assembly Language

A pointer is simply a memory location whose value is the address (or index, if you prefer) of some other memory location. Pointers are very easy to declare and use in an assembly language program. You don't even have to worry about array indices or anything like that.

An HLA pointer is a 32 bit value that may contain the address of some other variable. If you have a word variable p that contains \$1000_0000, then p "points" at memory location \$1000_0000. To access the word that p points at, you could use code like the following:

```
mov( p, ebx );          // Load EBX with the value of pointer p.
mov( [ebx], eax );     // Fetch the data that p points at.
```

By loading the value of p into EBX this code loads the value \$1000_0000 into EBX (assuming p contains \$1000_0000 and, therefore, points at memory location \$1000_0000). The second instruction above loads the EAX register with the word starting at the location whose offset appears in EBX. Since EBX now contains \$1000_0000, this will load EAX from locations \$1000_0000 through \$1000_0003.

Why not just load EAX directly from location \$1000_0000 using an instruction like "MOV(mem, EAX);" (assuming mem is at address \$1000_0000)? Well, there are lots of reasons. But the primary reason is that this single instruction always loads EAX from location mem . You cannot change the location from which it loads EAX. The former instructions, however, always load EAX from the location where p is pointing. This is very easy to change under program control. In fact, the simple instruction "MOV(&mem2, p);" will cause those same two instructions above to load EAX from $mem2$ the next time they execute. Consider the following instructions:

```
mov( &i, p );          // Assume all variables are STATIC variables.
.
.
.
if( some_expression ) then

    mov( &j, p );      // Assume the code above skips this instruction and
.                      // you get to the next instruction by jumping
.                      // to this point from somewhere else.
.

endif;
mov( p, ebx );        // Assume both of the above code paths wind up
mov( [ebx], eax );    // down here.
```

This short example demonstrates two execution paths through the program. The first path loads the variable p with the address of the variable i . The second path through the code loads p with the address of the variable j . Both execution paths converge on the last two MOV instructions that load EAX with i or j depending upon which execution path was taken. In many respects, this is like a *parameter* to a procedure in a high level language like Pascal. Executing the same instructions accesses different variables depending on whose address (i or j) winds up in p .

1.7.2 Declaring Pointers in HLA

Since pointers are 32 bits long, you could simply use the `dword` directive to allocate storage for your pointers. However, there is a much better way to do this: HLA provides the `POINTER TO` phrase specifically for declaring pointer variables. Consider the following example:

```
static
  b:          byte;
  d:          dword;
  pByteVar:   pointer to byte := &b;
  pDWordVar:  pointer to dword := &d;
```

This example demonstrates that it is possible to initialize as well as declare pointer variables in HLA. Note that you may only take addresses of static variables (`STATIC`, `READONLY`, `DATA`, and `STORAGE` objects) with the address-of operator, so you can only initialize pointer variables with the addresses of static objects.

You can also define your own pointer types in the `TYPE` section of an HLA program. For example, if you often use pointers to characters, you'll probably want to use a `TYPE` declaration like the one in the following example:

```
type
  ptrChar:   pointer to char;

static
  cString:   ptrChar;
```

1.7.3 Pointer Constants and Pointer Constant Expressions

HLA allows two literal constant forms: the address-of operator followed by the name of a static variable or the constant zero. In addition to these two literal pointer constants, HLA also supports simple pointer constant expressions.

The constant zero represents the `NULL` or `NIL` pointer, that is, an illegal address that does not exist⁹. Programs typically initialize pointers with `NULL` to indicate that a pointer has explicitly *not* been initialized. The HLA Standard Library predefines both the “`NULL`” and “`nil`” constants in the `memory.hhf` header file¹⁰.

In addition to simple address literals and the value zero, HLA allows very simple constant expressions wherever a pointer constant is legal. Pointer constant expressions take one of the two following forms:

$$\begin{aligned} & \&StaticVarName + PureConstantExpression \\ & \&StaticVarName - PureConstantExpression \end{aligned}$$

The *PureConstantExpression* term is a numeric constant expression that does not involve any pointer constants. This type of expression produces a memory address that is the specified number of bytes before or after (“-” or “+”, respectively) the *StaticVarName* variable in memory.

Since you can create pointer constant expressions, it should come as no surprise to discover that HLA lets you define manifest pointer constants in the `CONST` section. The following program demonstrates how you can do this.

```
program PtrConstDemo;
#include( "stdlib.hhf" );
```

9. Actually, address zero does exist, but if you try to access it under Win32 you will get a general protection fault.

10. `NULL` is for C/C++ programmers and `nil` is familiar to Pascal/Delphi programmers.

```

static
  b: byte := 0;
    byte1, 2, 3, 4, 5, 6, 7;

const
  pb:= &b + 1;

begin PtrConstDemo;

  mov( pb, ebx );
  mov( [ebx], al );
  stdout.put( "Value at address pb = $", al, nl );

end PtrConstDemo;

```

Program 1.5 Pointer Constant Expressions in an HLA Program

Upon execution, this program prints the value of the byte just beyond *b* in memory (which contains the value \$01).

1.7.4 Pointer Variables and Dynamic Memory Allocation

Pointer variables are the perfect place to store the return result from the HLA Standard Library *malloc* function. The *malloc* function returns the address of the storage it allocates in the EAX register; therefore, you can store the address directly into a pointer variable with a single MOV instruction immediately after a call to *malloc*:

```

type
  bytePtr:  pointer to byte;

var
  bPtr: bytePtr;
  .
  .
  .
  malloc( 1024 );           // Allocate a block of 1,024 bytes.
  mov( eax, bPtr );        // Store address of block in bPtr.
  .
  .
  .
  free( bPtr );           // Free the allocated block when done using it.
  .
  .
  .

```

In addition to *malloc* and *free*, that the last volume introduced, the HLA Standard Library provides a *realloc* procedure. The *realloc* routine takes two parameters, a pointer to a block of storage that *malloc* (or *realloc*) previously created, and a new size. If the new size is less than the old size, *realloc* releases the storage at the end of the allocated block back to the system. If the new size is larger than the current block, then *realloc* will allocate a new block and move the old data to the start of the new block, then free the old block.

Typically, you would use *realloc* to correct a bad guess about a memory size you'd made earlier. For example, suppose you want to read a set of values from the user but you won't know how many memory locations you'll need to hold the values until after the user has entered the last value. You could make a wild guess and then allocate some storage using *malloc* based on your estimate. If, during the input, you discover that your estimate was too low, simply call *realloc* with a larger value. Repeat this as often as required until

all the input is read. Once input is complete, you can make a call to *realloc* to release any unused storage at the end of the memory block.

The *realloc* procedure uses the following calling sequence:

```
realloc( ExistingPointer, NewSize );
```

Realloc returns a pointer to the newly allocated block in the EAX register.

One danger exists when using *realloc*. If you've made multiple copies of pointers into a block of storage on the heap and then call *realloc* to resize that block, all the existing pointers are now invalid. Effectively *realloc* frees the existing storage and then allocates a new block. That new block may not be in the same memory location as the old block, so any existing pointers (into the block) that you have will be invalid after the *realloc* call.

1.7.5 Common Pointer Problems

There are five common problems programmers encounter when using pointers. Some of these errors will cause your programs to immediately stop with a diagnostic message; other problems are more subtle, yielding incorrect results without otherwise reporting an error or simply affecting the performance of your program without displaying an error. These five problems are

- Using an uninitialized pointer
- Using a pointer that contains an illegal value (e.g., NULL)
- Continuing to use malloc'd storage after that storage has been free'd
- Failing to free storage once the program is done using it
- Accessing indirect data using the wrong data type.

The first problem above is using a pointer variable before you have assigned a valid memory address to the pointer. Beginning programmers often don't realize that declaring a pointer variable only reserves storage for the pointer itself, it does not reserve storage for the data that the pointer references. The following short program demonstrates this problem:

```
// Program to demonstrate use of
// an uninitialized pointer. Note
// that this program should terminate
// with a Memory Access Violation exception.

program UninitPtrDemo;
#include( "stdlib.hhf" );

static

    // Note: by default, variables in the
    // static section are initialized with
    // zero (NULL) hence the following
    // is actually initialized with NULL,
    // but that will still cause our program
    // to fail because we haven't initialized
    // the pointer with a valid memory address.

    Uninitialized: pointer to byte;

begin UninitPtrDemo;

    mov( Uninitialized, ebx );
    mov( [ebx], al );
    stdout.put( "Value at address Uninitialized: = $", al, nl );
```

```
end UninitPtrDemo;
```

Program 1.6 Uninitialized Pointer Demonstration

Although variables you declare in the `STATIC` section are, technically, initialized; static initialization still doesn't initialize the pointer in this program with a valid address.

Of course, there is no such thing as a truly uninitialized variable on the 80x86. What you really have are variables that you've explicitly given an initial value and variables that just happen to inherit whatever bit pattern was in memory when storage for the variable was allocated. Much of the time, these garbage bit patterns laying around in memory don't correspond to a valid memory address. Attempting to *dereference* such a pointer (that is, access the data in memory at which it points) raises a Memory Access Violation exception.

Sometimes, however, those random bits in memory just happen to correspond to a valid memory location you can access. In this situation, the CPU will access the specified memory location without aborting the program. Although to a naive programmer this situation may seem preferable to aborting the program, in reality this is far worse because your defective program continues to run with a defect without alerting you to the problem. If you store data through an uninitialized pointer, you may very well overwrite the values of other important variables in memory. This defect can produce some very difficult to locate defects in your program.

The second problem programmers have with pointers is storing invalid address values into a pointer. The first problem, above, is actually a special case of this second problem (with garbage bits in memory supplying the invalid address rather than you producing via a miscalculation). The effects are the same; if you attempt to dereference a pointer containing an invalid address you will either get a Memory Access Violation exception or you will access an unexpected memory location.

The third problem listed above is also known as the dangling pointer problem. To understand this problem, consider the following code fragment:

```
malloc( 256 );    // Allocate some storage.
mov( eax, ptr ); // Save address away in a pointer variable.
.
.                // Code that use the pointer variable "ptr".
.
free( ptr );     // Free the storage associated with "ptr".
.
.                // Code that does not change the value in "ptr".
.
mov( ptr, ebx );
mov( al, [ebx] );
```

In this example you will note that the program allocates 256 bytes of storage and saves the address of that storage away in the `ptr` variable. Then the code uses this block of 256 bytes for a while and frees the storage, returning it to the system for other uses. Note that calling `free` does not change the value of `ptr` in any way; `ptr` still points at the block of memory allocated by `malloc` earlier. Indeed, `free` does not change any data in this block, so upon return from `free`, `ptr` still points at the data stored into the block by this code. However, note that the call to `free` tells the system that this 256-byte block of memory is no longer needed by the program and the system can use this region of memory for other purposes. The `free` function cannot enforce that fact that you will never access this data again, you are simply promising that you won't. Of course, the code fragment above breaks this promise; as you can see in the last two instructions above the program fetches the value in `ptr` and accesses the data it points at in memory.

The biggest problem with dangling pointers is that you can get away with using them a good part of the time. As long as the system doesn't reuse the storage you've free'd, using a dangling pointer produces no ill effects in your program. However, with each new call to `malloc`, the system may decide to reuse the memory released by that previous call to `free`. When this happens, any attempt to dereference the dangling pointer may produce some unintended consequences. The problems range from reading data that has been overwritten (by the new, legal, use of the data storage), to overwriting the new data, to (the worst case) overwriting

system heap management pointers (doing so will probably cause your program to crash). The solution is clear: *never use a pointer value once you free the storage associated with that pointer.*

Of all the problems, the fourth (failing to free allocated storage) will probably have the least impact on the proper operation of your program. The following code fragment demonstrates this problem:

```

malloc( 256 );
mov( eax, ptr );
.          // Code that uses the data where ptr is pointing.
.          // This code does not free up the storage
.          // associated with ptr.
malloc( 512 );
mov( eax, ptr );

// At this point, there is no way to reference the original
// block of 256 bytes pointed at by ptr.

```

In this example the program allocates 256 bytes of storage and references this storage using the *ptr* variable. At some later time, the program allocates another block of bytes and overwrites the value in *ptr* with the address of this new block. Note that the former value in *ptr* is lost. Since this address no longer exists in the program, there is no way to call *free* to return the storage for later use. As a result, this memory is no longer available to your program. While making 256 bytes of memory inaccessible to your program may not seem like a big deal, imagine now that this code is in a loop that repeats over and over again. With each execution of the loop the program loses another 256 bytes of memory. After a sufficient number of loop iterations, the program will exhaust the memory available on the heap. This problem is often called a *memory leak* because the effect is the same as though the memory bits were leaking out of your computer (yielding less and less available storage) during program execution¹¹.

Memory leaks are far less damaging than using dangling pointers. Indeed, there are only two problems with memory leaks: the danger of running out of heap space (which, ultimately, may cause the program to abort, though this is rare) and performance problems due to virtual memory page swapping. Nevertheless, you should get in the habit of always free all storage once you are done using it.

The last problem with pointers is the lack of type-safe access. HLA cannot and does not enforce pointer type checking. For example, consider the following program:

```

// Program to demonstrate use of
// lack of type checking in pointer
// accesses.

program BadTypePtrDemo;
#include( "stdlib.hhf" );

static
    ptr:pointer to char;
    cnt:uns32;

begin BadTypePtrDemo;

    // Allocate sufficient characters
    // to hold a line of text input
    // by the user:

    malloc( 256 );
    mov( eax, ptr );

```

11. Note that the storage isn't lost from your computer; once your program quits it returns all memory (including unfree'd storage) to the O/S. The next time the program runs it will start with a clean slate.

```

// Okay, read the text a character
// at a time by the user:

stdout.put( "Enter a line of text: " );
stdin.flushInput();
mov( 0, cnt );
mov( ptr, ebx );
repeat

    stdin.getc();// Read a character from the user.
    mov( al, [ebx] );// Store the character away.
    inc( cnt );// Bump up count of characters.
    inc( ebx );// Point at next position in memory.

until( stdin.eoln());

// Okay, we've read a line of text from the user,
// now display the data:

mov( ptr, ebx );
for( mov( cnt, ecx ); ecx > 0; dec( ecx )) do

    mov( [ebx], eax );
    stdout.put( "Current value is $", eax, nl );
    inc( ebx );

endfor;
free( ptr );

end BadTypePtrDemo;

```

Program 1.7 Type-Unsafe Pointer Access Example

This program reads in data from the user as character values and then displays the data as double word hexadecimal values. While a powerful feature of assembly language is that it lets you ignore data types at will and automatically coerce the data without any effort, this power is a two-edged sword. If you make a mistake and access indirect data using the wrong data type, HLA and the 80x86 may not catch the mistake and your program may produce inaccurate results. Therefore, you need to take care when using pointers and indirection in your programs that you use the data consistently with respect to data type.

1.8 Putting It All Together

This chapter contains an eclectic combination of subjects. It begins with a discussion of the `INTMUL`, `BOUND`, and `INTO` instructions that will prove useful throughout this text. Then this chapter discusses how to declare constants and data types, including enumerated data types. This chapter also introduces constant expressions and pointers. The following chapters in this text will make extensive use of these concepts.

Introduction to Character Strings

Chapter Two

2.1 Chapter Overview

This chapter discusses how to declare and use character strings in your programs. While not a complete treatment of this subject (a whole volume on this material appears later in this text), this chapter will provide sufficient information to allow basic string manipulation within your HLA programs.

2.2 Composite Data Types

Composite data types are those that are built up from other (generally scalar) data types. This chapter will cover one of the more important composite data types – the character string. A string is a good example of a composite data type – it is a data structure built up from a sequence of individual characters and some other data.

2.3 Character Strings

After integer values, character strings are probably the most popular data type that modern programs use. The 80x86 does support a handful of string instructions, but these instructions are really intended for block memory operations, not a specific implementation of a character string. Therefore, this section will concentrate mainly on the HLA definition of character strings and also discuss the string handling routines available in the HLA Standard Library.

In general, a *character string* is a sequence of ASCII characters that possesses two main attributes: a *length* and the *character data*. Different languages use different data structures to represent strings. To better understand the reasoning behind HLA strings, it is probably instructive to look at two different string representations popularized by various high level languages.

Without question, *zero-terminated strings* are probably the most common string representation in use today because this is the native string format for C/C++ and programs written in C/C++ (e.g., Windows). A zero terminated string consists of a sequence of zero or more ASCII characters ending with a byte containing zero. For example, in C/C++, the string “abc” requires four characters: the three characters ‘a’, ‘b’, and ‘c’ followed by a byte containing zero. As you’ll soon see, HLA character strings are upwards compatible with zero terminated strings, but in the meantime you should note that it is very easy to create zero terminated strings in HLA. The easiest place to do this is in the DATA section using code like the following:

```
data
  zeroTerminatedString: char;
    byte "This is the zero terminated string", 0;
```

Remember, in the DATA section no space is actually reserved for a variable declaration, so the *zeroTerminatedString* variable’s address in memory corresponds to the first character in the following BYTE directive. Whenever a character string appears in the BYTE directive as it does here, HLA emits each character in the string to successive memory locations. The zero value at the end of the string properly terminates this string.

Zero terminated strings have two principle attributes: they are very simple to implement and the strings can be any length. On the other hand, zero terminated string has a few drawbacks. First, though not usually important, zero terminated strings cannot contain the NUL character (whose ASCII code is zero). Generally, this isn’t a problem, but it does create havoc once in a great while. The second problem with zero terminated strings is that many operations on them are somewhat inefficient. For example, to compute the length of a zero terminated string you must scan the entire string looking for that zero byte (counting each character as you encounter it). The following program fragment demonstrates how to compute the length of the string above:

```

mov( &zeroTerminatedString, ebx );
mov( 0, eax );
while( (type byte [ebx]) <> 0 ) do

    inc( ebx );
    inc( eax );

endwhile;

// String length is now in EAX.

```

As you can see from this code, the time it takes to compute the length of the string is proportional to the length of the string; as the string gets longer it will take longer to compute its length.

A second string format, *length-prefixed strings*, overcomes some of the problems with zero terminated strings. Length-prefixed strings are common in languages like Pascal; they generally consist of a length byte followed by zero or more character values. The first byte specifies the length of the string, the remaining bytes (up to the specified length) are the character data itself. In a length-prefixed scheme, the string “abc” would consist of the four bytes \$03 (the string length) followed by ‘a’, ‘b’, and ‘c’. Once again, you can create length prefixed strings in HLA using code like the following:

```

data
    lengthPrefixedString:char;
        byte 3, "abc";

```

Counting the characters ahead of time and inserting them into the byte statement, as was done here, may seem like a major pain. Fortunately, there are ways to have HLA automatically compute the string length for you.

Length-prefixed strings solve the two major problems associated with zero-terminated strings. It is possible to include the NUL character in length-prefixed strings and those operations on zero terminated strings that are relatively inefficient (e.g., string length) are more efficient when using length prefixed strings. However, length prefixed strings suffer from their own drawbacks. The principal drawback to length-prefixed strings, as described, is that they are limited to a maximum of 255 characters in length.

HLA uses an expanded scheme for strings that is upwards compatible with both zero-terminated and length-prefixed strings. HLA strings enjoy the advantages of both zero-terminated and length-prefixed strings without the disadvantages. In fact, the only drawback to HLA strings over these other formats is that HLA strings consume a few additional bytes (the overhead for an HLA string is nine bytes compared to one byte for zero-terminated or length-prefixed strings; the overhead being the number of bytes needed above and beyond the actual characters in the string).

An HLA string value consists of four components. The first element is a double word value that specifies the maximum number of characters that the string can hold. The second element is a double word value specifying the current length of the string. The third component is the sequence of characters in the string. The final component is a zero terminating byte. You could create an HLA-compatible string in the data section using the following code¹:

```

data
    dword 11;
    dword 11;
    TheString: char;
        byte "Hello there";
        byte 0;

```

Note that the address associated with the HLA string is the address of the first character, not the maximum or current length values.

1. Actually, there are some restrictions on the placement of HLA strings in memory. This text will not cover those issues. See the HLA documentation for more details.

“So what is the difference between the current and maximum string lengths?” you’re probably wondering. Well, in a fixed string like the above they are usually the same. However, when you allocate storage for a string variable at run-time, you will normally specify the maximum number of characters that can go into the string. When you store actual string data into the string, the number of characters you store must be less than or equal to this maximum value. The HLA Standard Library string routines will raise an exception if you attempt to exceed this maximum length (something the C/C++ and Pascal formats can’t do).

The terminating zero byte at the end of the HLA string lets you treat an HLA string as a zero-terminated string if it is more efficient or more convenient to do so. For example, most calls to Windows require zero-terminated strings for their string parameters. Placing a zero at the end of an HLA string ensures compatibility with Windows and other library modules that use zero-terminated strings.

2.4 HLA Strings

As noted in the previous section, HLA strings consist of four components: a maximum length, a current string length, character data, and a zero terminating byte. However, HLA never requires you to create string data by manually emitting these components yourself. HLA is smart enough to automatically construct this data for you whenever it sees a string literal constant. So if you use a string constant like the following, understand that somewhere HLA is creating the four-component string in memory for you:

```
stdout.put( "This gets converted to a four-component string by HLA" );
```

HLA doesn’t actually work directly with the string data described in the previous section. Instead, when HLA sees a string object it always works with a *pointer* to that object rather than the object directly. Without question, this is the most important fact to know about HLA strings, and is the biggest source of problems beginning HLA programmers have with strings in HLA: *strings are pointers!* A string variable consumes exactly four bytes, the same as a pointer (because it *is* a pointer!). Having said all that, let’s take a look at a simple string variable declaration in HLA:

```
static
    StrVariable: string;
```

Since a string variable is a pointer, you must initialize it before you can use it. There are three general ways you may initialize a string variable with a legal string address: using static initializers, using the *stralloc* routine, or calling some other HLA Standard Library that initializes a string or returns a pointer to a string.

In one of the static declaration sections that allow initialized variables (STATIC, DATA, and READ-ONLY) you can initialize a string variable using the standard initialization syntax, e.g.,

```
static
    InitializedString: string := "This is my string";
```

Note that this does not initialize the string variable with the string data. Instead, HLA creates the string data structure (see the previous section) in a special, hidden, memory segment and initializes the Initialized-String variable with the address of the first character in this string (the “T” in “This”). *Remember, strings are pointers!*

Since string variables are pointers, you can load the value of a string variable into a 32-bit register. The pointer itself points at the first character position of the string. You can find the current string length in the double word four bytes prior to this address, you can find the maximum string length in the double word eight bytes prior to this address. The following program demonstrates one way to access this data².

```
// Program to demonstrate accessing Length and Maxlength fields of a string.
```

2. Note that this scheme is not recommended. If you need to extract the length information from a string, use the routines provided in the HLA string library for this purpose.

```

program StrDemo;
#include( "stdlib.hhf" );

static
    theString:string := "String of length 19";

begin StrDemo;

    mov( theString, ebx );// Get pointer to the string.

    mov( [ebx-4], eax );// Get current length
    mov( [ebx-8], ecx );// Get maximum length

    stdout.put
    (
        "theString = ", theString, "`", nl,
        "length( theString )= ", (type uns32 eax ), nl,
        "maxLength( theString )= ", (type uns32 ecx ), nl
    );

end StrDemo;

```

Program 2.1 Accessing the Length and Maximum Length Fields of a String

When accessing the various fields of a string variable it is not wise to access them using fixed numeric offsets as done in this example. In the future, the definition of an HLA string may change slightly. In particular, the offsets to the maximum length and length fields are subject to change. A safer way to access string data is to coerce your string pointer using the *str.strRec* data type. The *str.strRec* data type is a record data type (see “Records, Unions, and Name Spaces” on page 465) that defines symbolic names for the offsets of the length and maximum length fields in the string data type. Were the offsets to the length and maximum length fields to change in a future version of HLA, then the definitions in *str.strRec* would also change, so if you use *str.strRec* then recompiling your program would automatically make any necessary changes to your program.

To use the *str.strRec* data type properly, you must first load the string pointer into a 32-bit register, e.g., “MOV(SomeString, EBX);” Once the pointer to the string data is in a register, you can coerce that register to the *str.strRec* data type using the HLA construct “(type str.strRec [EBX])”. Finally, to access the length or maximum length fields, you would use either “(type str.strRec [EBX]).length” or “(type str.strRec [EBX]).MaxStrLen” (respectively). Although there is a little more typing involved (versus using simple offsets like “-4” or “-8”), these forms are far more descriptive and much safer than straight numeric offsets. The following program corrects the previous example by using the *str.strRec* data type.

```

// Program to demonstrate accessing Length and Maxlength fields of a string.

program LenMaxlenDemo;
#include( "stdlib.hhf" );

static
    theString:string := "String of length 19";

begin LenMaxlenDemo;

    mov( theString, ebx );// Get pointer to the string.

    mov( (type str.strRec [ebx]).length, eax );// Get current length
    mov( (type str.strRec [ebx]).MaxStrLen, ecx );// Get maximum length

```

```

stdout.put
(
    "theString = '", theString, "'", nl,
    "length( theString )= ", (type uns32 eax ), nl,
    "maxLength( theString )= ", (type uns32 ecx ), nl
);

end LenMaxLenDemo;

```

Program 2.2 Correct Way to Access Length and MaxStrLen Fields of a String

A second way to manipulate strings in HLA is to allocate storage on the heap to hold string data. Because strings can't directly use pointers returned by *malloc* (since strings need to access eight bytes prior to the pointer address), you shouldn't use *malloc* to allocate storage for string data. Fortunately, the HLA Standard Library memory module provides a memory allocation routine specifically designed to allocate storage for strings: *stralloc*. Like *malloc*, *stralloc* expects a single dword parameter. This value specifies the (maximum) number of characters needed in the string. The *stralloc* routine will allocate the specified number of bytes of memory, plus between nine and thirteen additional bytes to hold the extra string information³.

The *stralloc* routine will allocate storage for a string, initialize the maximum length to the value passed as the *stralloc* parameter, initialize the current length to zero, and store a zero (terminating byte) in the first character position of the string. After all this, *stralloc* returns the address of the zero terminating byte (that is, the address of the first character element) in the EAX register.

Once you've allocated storage for a string, you can call various string manipulation routines in the HLA Standard Library to operate upon the string. The next section will discuss the HLA string routines in detail; this section will introduce a couple of string related routines for the sake of example. The first such routine is the "stdin.gets(strvar)". This routine reads a string from the user and stores the string data into the string storage pointed at by the string parameter (*strvar* in this case). If the user attempts to enter more characters than you've allocated for the string, then *stdin.gets* raises the *ex.StringOverflow* exception. The following program demonstrates the use of *stralloc*.

```

// Program to demonstrate stralloc and stdin.gets.

program strallocDemo;
#include( "stdlib.hhf" );

static
    theString:string;

begin strallocDemo;

    stralloc( 16 );// Allocate storage for the string and store
    mov( eax, theString );// the pointer into the string variable.

    // Prompt the user and read the string from the user:

    stdout.put( "Enter a line of text (16 chars, max): " );
    stdin.flushInput();
    stdin.gets( theString );

    // Echo the string back to the user:

    stdout.put( "The string you entered was: ", theString, nl );

```

3. *Stralloc* may allocate more than nine bytes for the overhead data because the memory allocated to an HLA string must always be double word aligned and the total length of the data structure must be an even multiple of four.

```
end strallocDemo;
```

Program 2.3 Reading a String from the User

If you look closely, you see a slight defect in the program above. It allocates storage for the string by calling *stralloc* but it never frees the storage allocated. Even though the program immediately exits after the last use of the string variable, and Windows will deallocate the storage anyway, it's always a good idea to explicitly free up any storage you allocate. Doing so keeps you in the habit of freeing allocated storage (so you don't forget to do it when it's important) and, also, programs have a way of growing such that an innocent defect that doesn't affect anything in today's program becomes a show-stopping defect in tomorrow's version.

To free storage allocated via *stralloc*, you must call the corresponding *strfree* routine, passing the string pointer as the single parameter. The following program is a correction of the previous program with this minor defect corrected:

```
// Program to demonstrate stralloc, strfree, and stdin.gets.

program strfreeDemo;
#include( "stdlib.hhf" );

static
    theString:string;

begin strfreeDemo;

    stralloc( 16 );// Allocate storage for the string and store
    mov( eax, theString );// the pointer into the string variable.

    // Prompt the user and read the string from the user:

    stdout.put( "Enter a line of text (16 chars, max): " );
    stdin.flushInput();
    stdin.gets( theString );

    // Echo the string back to the user:

    stdout.put( "The string you entered was: ", theString, nl );

    // Free up the storage allocated by stralloc:

    strfree( theString );

end strfreeDemo;
```

Program 2.4 Corrected Program that Reads a String from the User

When looking at this corrected program, please take note that the *stdin.gets* routine expects you to pass it a string parameter that points at an allocated string object. Without question, one of the most common mistakes beginning HLA programmers make is to call *stdin.gets* and pass it a string variable that has not been initialized. This may be getting old now, but keep in mind that *strings are pointers!* Like pointers, if you do not initialize a string with a valid address, your program will probably crash when you attempt to manipulate that string object. The call to *stralloc* plus moving the returned result into *theString* is how the

programs above initialize the string pointer. If you are going to use string variables in your programs, you must ensure that you allocate storage for the string data prior to writing data to the string object.

Allocating storage for a string option is such a common operation that many HLA Standard Library routines will automatically do the allocation to save you the effort. Generally, such routines have an “a_” prefix as part of their name. For example, the *stdin.a_gets* combines a call to *stralloc* and *stdin.gets* into the same routine. This routine, which doesn’t have any parameters, reads a line of text from the user, allocates a string object to hold the input data, and then returns a pointer to the string in the EAX register. The following program is an adaptation of the previous two programs that uses *stdin.a_gets*:

```
// Program to demonstrate  strfree and stdin.a_gets.

program strfreeDemo2;
#include( "stdlib.hhf" );

static
    theString:string;

begin strfreeDemo2;

    // Prompt the user and read the string from the user:

    stdout.put( "Enter a line of text: " );
    stdin.flushInput();
    stdin.a_gets();
    mov( eax, theString );

    // Echo the string back to the user:

    stdout.put( "The string you entered was: ", theString, nl );

    // Free up the storage allocated by stralloc:

    strfree( theString );

end strfreeDemo2;
```

Program 2.5 Reading a String from the User with *stdin.a_gets*

Note that, as before, you must still free up the storage *stdin.a_gets* allocates by calling the *strfree* routine. One big difference between this routine and the previous two is the fact that HLA will automatically allocate exactly enough space for the string read from the user. In the previous programs, the call to *stralloc* only allocates 16 bytes. If the user types more than this then the program raises an exception and quits. If the user types less than 16 characters, then some space at the end of the string is wasted. The *stdin.a_gets* routine, on the other hand, always allocates the minimum necessary space for the string read from the user. Since it allocates the storage, there is little chance of overflow.

2.5 Accessing the Characters Within a String

Extracting individual characters from a string is a very common and easy task. In fact, it is so easy that HLA doesn’t provide any specific procedure or language syntax to accomplish this - it’s easy enough just to use machine instructions to accomplish this. Once you have a pointer to the string data, a simple indexed addressing mode will do the rest of the work for you.

Of course, the most important thing to keep in mind is that *strings are pointers*. Therefore, you cannot apply an indexed addressing mode directly to a string variable and expect to extract characters from the string. I.e, if *s* is a string variable, then “MOV(*s*[*ebx*], *al*);” does not fetch the character at position *EBX* in string *s* and place it in the *AL* register. Remember, *s* is just a pointer variable, an addressing mode like *s*[*ebx*] will simply fetch the byte at offset *EBX* in memory starting at the address of *s* (see Figure 2.1).

Figure 2.1 Incorrectly Indexing Off a String Variable

In Figure 2.1, assuming *EBX* contains three, “*s*[*ebx*]” does not access the fourth character in the string *s*, instead it fetches the fourth byte of the pointer to the string data. It is very unlikely that this is the desired effect you would want. Figure 2.2 shows the operation that is necessary to fetch a character from the string, assuming *EBX* contains the value of *s*:

Figure 2.2 Correctly Indexing Off the Value of a String Variable

In Figure 2.2 *EBX* contains the value of string *s*. The value of *s* is a pointer to the actual string data in memory. Therefore, *EBX* will point at the first character of the string when you load the value of *s* into *EBX*. The following code demonstrates how to access the fourth character of string *s* in this fashion:

```
mov( s, ebx );           // Get pointer to string data into EBX.
mov( [ebx+3], al );     // Fetch the fourth character of the string.
```

If you want to load the character at a variable, rather than fixed, offset into the string, then you can use one of the 80x86’s scaled indexed addressing modes to fetch the character. For example, if an *uns32* variable *index* contains the desired offset into the string, you could use the following code to access the character at *s*[*index*]:

```

mov( s, ebx );           // Get address of string data into EBX.
mov( index, ecx );      // Get desired offset into string.
mov( [ebx+ecx], al );   // Get the desired character into AL.

```

There is only one problem with the code above- it does not check to ensure that the character at offset *index* actually exists. If *index* is greater than the current length of the string, then this code will fetch a garbage byte from memory. Unless you can apriori determine that *index* is always less than the length of the string, code like this is dangerous to use. A better solution is to check the index against the string's current length before attempting to access the character. the following code provides one way to do this.

```

mov( s, ebx );
mov( index, ecx );
if( ecx < (type str.strRec [ebx]).Length ) then

    mov( [ebx+ecx], al );

else

    << error, string index is of bounds >>

endif;

```

In the ELSE portion of this IF statement you could take corrective action, print an error message, or raise an exception. If you want to explicitly raise an exception, you can use the HLA RAISE statement to accomplish this. The syntax for the RAISE statement is

```

raise( integer_constant );
raise( reg32 );

```

The value of the *integer_constant* or 32-bit register must be an exception number. Usually, this is one of the predefined constants in the `excepts.hhf` header file. An appropriate exception to raise when a string index is greater than the length of the string is *ex.StringIndexError*. The following code demonstrates raising this exception if the string index is out of bounds:

```

mov( s, ebx );
mov( index, ecx );
if( ecx < (type str.strRec [ebx]).Length ) then

    mov( [ebx+ecx], al );

else

    raise( ex.StringIndexError );

endif;

```

2.6 The HLA String Module and Other String-Related Routines

Although HLA provides a powerful definition for string data, the real power behind HLA's string capabilities lies in the HLA Standard Library, not in the definition of HLA string data. HLA provides several dozen string manipulation routines that far exceed the capabilities found in standard HLLs like C/C++, Java, or Pascal; indeed, HLA's string handling capabilities rival those in string processing languages like Icon or SNOBOL4. While it is premature to introduce all of HLA's character string handling routines, this chapter will discuss many of the string facilities that HLA provides.

Perhaps the most basic string operation you will need is to assign one string to another. There are three different ways to assign strings in HLA: by reference, by copying a string, and by duplicating a string. Of

these, assignment by reference is the fastest and easiest. If you have two strings and you wish to assign one string to the other, a simple and fast way to do this is to copy the string pointer. The following code fragment demonstrates this:

```
static
    string1:  string      := "Some String Data";
    string2:  string;
    .
    .
    .
    mov( string1, eax );
    mov( eax, string2 );
    .
    .
    .
```

String assignment by reference is very efficient because it only involves two simple MOV instructions, regardless of the actual length of the string. Assignment by reference works great if you never modify the string data after the assignment operation. Do keep in mind, though, that both string variables (string1 and string2 in the example above) *wind up pointing at the same data*. So if you make a change to the data pointed at by one string variable, you will change the string data pointed at by the second string object since both objects point at the same data. The following program demonstrates this problem:

```
// Program to demonstrate the problem
// with string assignment by reference.

program strRefAssignDemo;
#include( "stdlib.hhf" );

static
    string1:string;
    string2:string;

begin strRefAssignDemo;

    // Get a value into string1

    forever

        stdout.put( "Enter a string with at least three characters: " );
        stdin.a_gets();
        mov( eax, string1 );

        breakif( (type str.strRec [eax]).length >= 3 );

        stdout.put( "Please enter a string with at least three chars." nl );

    endfor;

    stdout.put( "You entered: '", string1, "'" nl );

    // Do the string assignment by copying the pointer

    mov( string1, ebx );
    mov( ebx, string2 );

    stdout.put( "String1= '", string1, "'" nl );
    stdout.put( "String2= '", string2, "'" nl );
```

```

// Okay, modify the data in string1 by overwriting
// the first three characters of the string (note that
// a string pointer always points at the first character
// position in the string and we know we've got at least
// three characters here).

mov( 'a', (type char [ebx]) );
mov( 'b', (type char [ebx+1]) );
mov( 'c', (type char [ebx+2]) );

// Okay, demonstrate the problem with assignment via
// pointer copy.

stdout.put
(
    "After assigning 'abc' to the first three characters in string1:"
    nl
    nl
);
stdout.put( "String1= '", string1, "' nl );
stdout.put( "String2= '", string2, "' nl );

strfree( string1 );// Don't free string2 as well!

end strRefAssignDemo;

```

Program 2.6 Problem with String Assignment by Copying Pointers

Since both *string1* and *string2* point at the same string data in this example, any change you make to one string is reflected in the other. While this is sometimes acceptable, most programmers expect assignment to produce a different copy of a string; they expect the semantics of string assignment to produce two unique copies of the string data.

An important point to remember when using *copy by reference* (this term means copying a pointer rather than copying the actual data) is that you have created an *alias* to the string data. The term “alias” means that you have two names for the same object in memory (e.g., in the program above, *string1* and *string2* are two different names for the same string data). When you read a program it is reasonable to expect that different variables refer to different memory objects. Aliases violate this rule, thus making your program harder to read and understand because you’ve got to remember that aliases do not refer to different objects in memory. Failing to keep this in mind can lead to subtle bugs in your program. For instance, in the example above you have to remember that *string1* and *string2* are aliases so as not to free both objects at the end of the program. Worse still, you to remember that *string1* and *string2* are aliases so that you don’t continue to use *string2* after freeing *string1* in this code since *string2* would be a dangling reference at that point.

Since using copy by reference makes your programs harder to read and increases the possibility that you might introduce subtle defects in your programs, you might wonder why someone would use copy by reference at all. There are two reasons for this: first, copy by reference is very efficient; it only involves the execution of two MOV instructions. Second, some algorithms actually depend on copy by reference semantics. Nevertheless, you should carefully consider whether copying string pointers is the appropriate way to do a string assignment in your program before using this technique.

The second way to assign one string to another is to actually copy the string data. The HLA Standard Library *str.cpy* routine provides this capability. A call to the *str.cpy* procedure using the following form:

```
str.cpy( source_string, destination_string );
```

The source and destination strings must be string variables (pointers) or 32-bit registers containing the addresses of the string data in memory.

The *strcpy* routine first checks the maximum length field of the destination string to ensure that it is at least as big as the current length of the source string. If it is not, then *strcpy* raises the *ex.StringOverflow* exception. If the maximum string length field of the destination string is at least as big as the current string length of the source string, then *strcpy* copies the string length, the characters, and the zero terminating byte from the source string to the data area at which the destination string points. When this process is complete, the two strings point at identical data, but they do not point at the same data in memory⁴. The following program is a rework of the previous example using *strcpy* rather than copy by reference.

```
// Program to demonstrate string assignment using strcpy.

program strcpyDemo;
#include( "stdlib.hhf" );

static
    string1:string;
    string2:string;

begin strcpyDemo;

    // Allocate storage for string2:

    stralloc( 64 );
    mov( eax, string2 );

    // Get a value into string1

    forever

        stdout.put( "Enter a string with at least three characters: " );
        stdin.a_gets();
        mov( eax, string1 );

        breakif( (type str.strRec [eax]).length >= 3 );

        stdout.put( "Please enter a string with at least three chars." nl );

    endfor;

    // Do the string assignment via strcpy

    str.cpy( string1, string2 );

    stdout.put( "String1= ", string1, "" nl );
    stdout.put( "String2= ", string2, "" nl );

    // Okay, modify the data in string1 by overwriting
    // the first three characters of the string (note that
    // a string pointer always points at the first character
    // position in the string and we know we've got at least
    // three characters here).

    mov( string1, ebx );
```

4. Unless, of course, both string pointers contained the same address to begin with, in which case *strcpy* copies the string data over the top of itself.

```

mov( 'a', (type char [ebx]) );
mov( 'b', (type char [ebx+1]) );
mov( 'c', (type char [ebx+2]) );

// Okay, demonstrate that we have two different strings
// since we used str.cpy to copy the data:

stdout.put
(
    "After assigning 'abc' to the first three characters in string1:"
    nl
    nl
);
stdout.put( "String1= ", string1, "" nl );
stdout.put( "String2= ", string2, "" nl );

// Note that we have to free the data associated with both
// strings since they are not aliases of one another.

strfree( string1 );
strfree( string2 );

end strcpyDemo;

```

Program 2.7 Copying Strings using str.cpy

There are two really important things to note about this program. First, note that this program begins by allocating storage for *string2*. Remember, the *str.cpy* routine does not allocate storage for the destination string, it assumes that the destination string already has storage allocated to it. Keep in mind that *str.cpy* does not initialize *string2*, it only copies data to the location where *string2* is pointing. It is the program's responsibility to initialize the string by allocating sufficient memory before calling *str.cpy*. The second thing to notice here is that the program calls *strfree* to free up the storage for both *string1* and *string2* before the program quits.

Allocating storage for a string variable prior to calling *str.cpy* is so common that the HLA Standard Library provides a routine that allocates and copies the string: *str.a_cpy*. This routine uses the following call syntax:

```
str.a_cpy( source_string );
```

Note that there is no destination string. This routine looks at the length of the source string, allocates sufficient storage, makes a copy of the string, and then returns a pointer to the new string in the EAX register. The following program demonstrates the current example using the *str.a_cpy* procedure.

```

// Program to demonstrate string assignment using str.a_cpy.

program stra_cpyDemo;
#include( "stdlib.hhf" );

static
    string1:string;
    string2:string;

begin stra_cpyDemo;

```

```

// Get a value into string1

forever

    stdout.put( "Enter a string with at least three characters: " );
    stdin.a_gets();
    mov( eax, string1 );

    breakif( (type str.strRec [eax]).length >= 3 );

    stdout.put( "Please enter a string with at least three chars." nl );

endfor;

// Do the string assignment via str.a_cpy

str.a_cpy( string1 );
mov( eax, string2 );

stdout.put( "String1= '", string1, "'" nl );
stdout.put( "String2= '", string2, "'" nl );

// Okay, modify the data in string1 by overwriting
// the first three characters of the string (note that
// a string pointer always points at the first character
// position in the string and we know we've got at least
// three characters here).

mov( string1, ebx );
mov( 'a', (type char [ebx]) );
mov( 'b', (type char [ebx+1]) );
mov( 'c', (type char [ebx+2]) );

// Okay, demonstrate that we have two different strings
// since we used str.cpy to copy the data:

stdout.put
(
    "After assigning 'abc' to the first three characters in string1:"
    nl
    nl
);
stdout.put( "String1= '", string1, "'" nl );
stdout.put( "String2= '", string2, "'" nl );

// Note that we have to free the data associated with both
// strings since they are not aliases of one another.

strfree( string1 );
strfree( string2 );

end stra_cpyDemo;

```

Program 2.8 Copying Strings using str.a_cpy

Warning: Whenever using copy by reference or *str.a_cpy* to assign a string, don't forget to free the storage associated with the destination string if you have previously allocated storage and have not yet freed the previous string. Failure to do so may produce a memory leak if you do not have another pointer to the previous string data laying around.

Obtaining the length of a character string is such a common need that the HLA Standard Library provides a *str.length* routine specifically for this purpose. Of course, you can fetch the length by using the *str.strRec* data type to access the length field directly, but constant use of this mechanism can be tiring since it involves a lot of typing. The *str.length* routine provides a more compact and convenient way to fetch the length information. You call *str.length* using one of the following two formats:

```
str.length( Reg32 );
str.length( string_variable );
```

This routine returns the current string length in the EAX register.

Another pair of useful string routines are the *str.cat* and *str.a_cat* procedures. They use the following calling sequence:

```
str.cat( srcStr, destStr );
str.a_cat( src1Str, src2Str );
```

These two routines concatenate two strings (that is, they create a new string by joining the two strings together). The *str.cat* procedure concatenates the source string to the end of the destination string. Before the concatenation actually takes place, *str.cat* checks to make sure that the destination string is large enough to hold the concatenated result, it raises the *ex.StringOverflow* exception if the destination string is too small.

The *str.a_cat*, as its name suggests, allocates storage for the resulting string before doing the concatenation. This routine will allocate sufficient storage to hold the concatenated result, then it will copy the *src1Str* to the allocated storage, finally it will append the string data pointed at by *src2Str* to the end of this new string and return a pointer to the new string in the EAX register.

Warning: note a potential source of confusion. The *str.cat* procedure concatenates its first operand to the end of the second operand. Therefore, *str.cat* follows the standard (src, dest) operand format present in many HLA statements. The *str.a_cat* routine, on the other hand, has two source operands rather than a source and destination operand. The *str.a_cat* routine concatenates its two operands in an intuitive left-to-right fashion. This is the opposite of *str.cat*. Keep this in mind when using these two routines.

The following program demonstrates the use of the *str.cat* and *str.a_cat* routines:

```
// Program to demonstrate str.cat and str.a_cat.

program strcatDemo;
#include( "stdlib.hhf" );

static
    UserName:string;
    Hello: string;
    a_Hello:string;

begin strcatDemo;

    // Allocate storage for the concatenated result:

    stralloc( 1024 );
    mov( eax, Hello );

    // Get some user input to use in this example:

    stdout.put( "Enter your name: " );
    stdin.flushInput();
    stdin.a_gets();
```

```

mov( eax, UserName );

// Use str.cat to combine the two strings:

str.cpy( "Hello ", Hello );
str.cat( UserName, Hello );

// Use str.a_cat to combine the string strings:

str.a_cat( "Hello ", UserName );
mov( eax, a_Hello );

stdout.put( "Concatenated string #1 is '", Hello, "'" nl );
stdout.put( "Concatenated string #2 is '", a_Hello, "'" nl );

strfree( UserName );
strfree( a_Hello );
strfree( Hello );

end strcatDemo;

```

Program 2.9 Demonstration of str.cat and str.a_cat Routines

The *str.insert* and *str.a_insert* routines are closely related to the string concatenation procedures. However, the *str.insert* and *str.a_insert* routines let you insert one string anywhere into another string, not just at the end of the string. The calling sequence for these two routines is

```

str.insert( src, dest, index );
str.a_insert( StrToInsert, StrToInsertInto, index );

```

These two routines insert the source string (*src* or *StrToInsert*) into the destination string (*dest* or *StrToInsertInto*) starting at character position *index*. The *str.insert* routine inserts the source string directly into the destination string; if the destination string is not large enough to hold both strings, *str.insert* raises an *ex.StringOverflow* exception. The *str.a_insert* routine first allocates a new string on the heap, copies the destination string (*StrToInsertInto*) to the new string, and then inserts the source string (*StrToInsert*) into this new string at the specified offset; *str.a_insert* returns a pointer to the new string in the EAX register.

Indexes into a string are zero-based. This means that if you supply the value zero as the index in *str.insert* or *str.a_insert*, then these routines will insert the source string before the first character of the destination string. Likewise, if the index is equal to the length of the string minus one, then these routines will simply concatenate the source string to the end of the destination string. Note: if the index is greater than the length of the string, the *str.insert* and *str.a_insert* procedures will not raise an exception; instead, they will simply append the source string to the end of the destination string.

The *str.delete* and *str.a_delete* routines let you remove characters from a string. They use the following calling sequence:

```

str.delete( str, StartIndex, Length );
str.a_delete( str, StartIndex, Length );

```

Both routines delete *Length* characters starting at character position *StartIndex* in string *str*. The difference between the two is that *str.delete* deletes the characters directly from *str* whereas *str.a_delete* first allocates storage and copies *str*, then deletes the characters from the new string (leaving *str* untouched). The *str.a_delete* routine returns a pointer to the new string in the EAX register.

The *str.delete* and *str.a_delete* routines are very forgiving with respect to the values you pass in *StartIndex* and *Length*. If *StartIndex* is greater than the current length of the string, these routines do not delete any characters from the string. If *StartIndex* is less than the current length of the string, but *StartIndex+Length* is

greater than the length of the string, then these routines will delete all characters from *StartIndex* to the end of the string.

Another very common string operation is the need to copy a portion of a string to a different string without otherwise affecting the source string. The *str.substr* and *str.a_substr* routines provide this capability. These routines use the following calling sequence:

```
str.substr( src, dest, StartIndex, Length );
str.a_substr( src, StartIndex, Length );
```

The *str.substr* routine copies length characters, starting at position *StartIndex*, from the *src* string to the *dest* string. The *dest* string must have sufficient storage allocated to hold the new string or *str.substr* will raise an *ex.StringOverflow* exception. If the *StartIndex* value is greater than the length of the string, then *str.substr* will raise an *ex.StringIndexError* exception. If *StartIndex+Length* is greater than the length of the source string, but *StartIndex* is less than the length of the string, then *str.substr* will extract only those characters from *StartIndex* to the end of the string.

The *str.a_substr* procedure behaves in a fashion nearly identical to *str.substr* except it allocates storage on the heap for the destination string. Other than overflow never occurs, *str.a_substr* handles exceptions the identically to *str.substr*⁵. As you can probably guess by now, *str.a_substr* returns a pointer to the newly allocated string in the EAX register.

After you begin working with string data for a little while, the need will invariably arise to compare two strings. A first attempt at string comparison, using the standard HLA relational operators, will compile but not necessarily produce the desired results:

```
mov( s1, eax );
if( eax = s2 ) then

    << code to execute if the strings are equal >>

else

    << code to execute if the strings are not equal >>

endif;
```

As stated above, this code will compile and execute just fine. However, it's probably not doing what you expect it to do. Remember *strings are pointers*. This code compares the two pointers to see if they are equal. If they are equal, clearly the two strings are equal (since both *s1* and *s2* point at the exact same string data). However, the fact that the two pointers are different doesn't necessarily mean that the strings are not equivalent. Both *s1* and *s2* could contain different values (that is, they point at different addresses in memory) yet the string data at those two different addresses could be identical. Most programmers expect a string comparison for equality to be true if the data for the two strings is the same. Clearly a pointer comparison does not provide this type of comparison. To overcome this problem, the HLA Standard Library provides a set of string comparison routines that will compare the string data, not just their pointers. These routines use the following calling sequence:

```
str.eq( src1, src2 );
str.ne( src1, src2 );
str.lt( src1, src2 );
str.le( src1, src2 );
str.gt( src1, src2 );
str.ge( src1, src2 );
```

Each of these routines compares the *src1* string to the *src2* string and return true (1) or false (0) in the EAX register depending on the comparison. For example, "str.eq(s1, s2);" returns true in EAX if *s1* is equal to *s2*. HLA provides a small extension that allows you to use the string comparison routines within an IF state-

5. Technically, *str.a_substr*, like all routines that call *malloc* to allocate storage, can raise an *ex.MemoryAllocationFailure* exception, but this is very unlikely to occur.

ment⁶. The following code demonstrates the use of some of these comparison routines within an IF statement:

```

stdout.put( "Enter a single word: " );
stdin.a_gets();
if( str.eq( eax, "Hello" ) ) then

    stdout.put( "You entered 'Hello'", nl );

endif;
strfree( eax );

```

Note that the string the user enters in this example must exactly match “Hello”, including the use of an upper case “H” (rather than lower case) at the beginning of the string. When processing user input, it is best to ignore alphabetic case in string comparisons because different users have different ideas about when they should be pressing the shift key on the keyboard. An easy solution is to use the HLA case insensitive string comparison functions. These routines compare two strings ignoring any differences in alphabetic case. These routines use the following calling sequence:

```

str.ieq( src1, src2 );
str.ine( src1, src2 );
str.ilt( src1, src2 );
str.ile( src1, src2 );
str.igt( src1, src2 );
str.ige( src1, src2 );

```

Other than they treat upper case characters the same as their lower case equivalents, these routines behave exactly like the former routines, returning true or false in EAX depending on the result of the comparison.

Like most high level languages, HLA compares strings using *lexicographical ordering*. This means that two strings are equal if and only if their lengths are the same and the corresponding characters in the two strings are exactly the same. For less than or greater than comparisons, lexicographical ordering corresponds to the way words appear in a dictionary. That is, “a” is less than “b” is less than “c” etc. Actually, HLA compares the strings using the ASCII numeric codes for the characters, so if you are unsure whether “a” is less than a period, simply consult the ASCII character chart (incidentally, “a” is greater than a period in the ASCII character set, just in case you were wondering).

If two strings have different lengths, lexicographical ordering only worries about the length if the two strings exactly match up through the length of the shorter string. If this is the case, then the longer string is greater than the shorter string (and, conversely, the shorter string is less than the longer string). Note, however, that if the characters in the two strings do not match, then HLA’s string comparison routines ignore the length of the string; e.g., “z” is always greater than “aaaaa” even though it has a shorter length.

The *str.eq* routine checks to see if two strings are equal. Sometimes, however, you might want to know whether one string *contains* another string. For example, you may want to know if some string contains the substring “north” or “south” to determine some action to take in a game. The HLA *str.index* routine lets you check to see if one string is contained as a substring of another. The *str.index* routine uses the following calling sequence:

```
str.index( StrToSearch, SubstrToSearchFor );
```

This function returns, in EAX, the offset into *StrToSearch* where *SubstrToSearchFor* appears. This routine returns -1 in EAX if *SubstrToSearchFor* is not present in *StrToSearch*. Note that *str.index* will do a case sensitive search. Therefore the strings must exactly match. There is no case insensitive variant of *str.index* you can use⁷.

6. This extension is actually a little more general than this section describes. The next chapter will explain it fully.

7. However, HLA does provide routines that will convert all the characters in a string to one case or another. So you can make copies of the strings, convert all the characters in both copies to lower case, and then search using these converted strings. This will achieve the same result.

The HLA strings module contains many additional routines besides those this section presents. Space limitations and prerequisite knowledge prevent the presentation of all the string functions here; however, this does not mean that the remaining string functions are unimportant. You should definitely take a look at the HLA documentation to learn everything you can about the powerful HLA string library routines. The chapters on advanced string handling contain more information on HLA string and pattern matching routines.

2.7 In-Memory Conversions

The HLA Standard Library's string module contains dozens of routines for converting between strings and other data formats. Although it's a little premature in this text to present a complete description of those functions, it would be rather criminal not to discuss at least one of the available functions: the *str.put* routine. This one routine (which is actually a macro) encapsulates the capabilities of all the other string conversion functions, so if you learn how to use this one, you'll have most of the capabilities of those other routines at your disposal. For more information on the other string conversions, see the volume on Advanced String Handling.

You use the *str.put* routine in a manner very similar to the *stdout.put* routine. The only difference is that the *str.put* routine "writes" its data to a string instead of the standard output device. A call to *str.put* has the following syntax:

```
str.put( destString, values_to_convert );
```

Example of a call to *str.put*:

```
str.put( destString, "I =", i:4, " J= ", j, " s=", s );
```

Note: generally you would not put a newline character sequence at the end of the string as you would if you were printing the string to the standard output device.

The *destString* parameter at the beginning of the *str.put* parameter list must be a string variable and it must already have storage associated with it. If *str.put* attempts to store more characters than allowed into the *destString* parameter, then this function raises the *ex.StringOverflow* exception.

Most of the time you won't know the length of the string that *str.put* will produce. In those instances, you should simply allocate sufficient storage for a really large string, one that is way larger than you expect, and use this string data as the first parameter of the *str.put* call. This will prevent an exception from crashing your program. Generally, if you expect to produce about one screen line of text, you should probably allocate at least 256 characters for the destination string. If you're creating longer strings, you should probably use a default of 1024 characters (or more, if you're going to produce *really* large strings).

Example:

```
static
  s: string;
  .
  .
  .
  mov( stralloc( 256 ), s );
  .
  .
  .
  str.put( s, "R: ", r:16:4, " strval: '", strval:-10, "' );
```

You can use the *str.put* routine to convert any data to a string that you can print using *stdout.put*. You will probably find this routine invaluable for common value-to-string conversions.

At the time this is being written, there is no corresponding *str.get* routine that will read values from an input string (this routine will probably appear in a future version of the HLA Standard Library, so watch out for it). In the meantime, the HLA strings and conversions modules in the Standard Library do provide lots of

stand-alone conversion functions you can use to convert string data to some other format. See the chapter on “Advanced String Handling” for more details about these routines.

2.8 Putting It All Together

There are many different ways to represent character strings. This chapter began by discussing how the C/C++ and Pascal languages represent strings using zero-terminated and length prefixed strings. HLA uses a hybrid representation for its string. HLA strings consist of a pointer to a zero terminated sequence of character with a pair of prefix length values. HLA's format offers all the advantages of the other two forms with the slight disadvantage of a few extra bytes of overhead.

After discussing string formats, this chapter discussed how to operate on string data. In addition to accessing the characters in a string directly (which is easy, you just index off the pointer to the string data), this chapter described how to manipulate strings using several routines from the HLA Standard Library. This chapter provides a very basic introduction to string handling in HLA. To learn more about string manipulation in assembly language (and the use of the routines in the HLA Standard Library), see the separate volume on “Advanced String Handling” in this text.

Characters and Character Sets

Chapter Three

3.1 Chapter Overview

This chapter completes the discussion of the character data type by describing several character translation and classification functions found in the HLA Standard Library. These functions provide most of the character operations that aren't trivial to realize using a few 80x86 machine instructions.

This chapter also introduces another composite data type based on the character – the character set data type. Character sets and their associated operations, let you quickly test characters to see if they belong to some set. These operations also let you manipulate sets of characters using familiar operations like set union, intersection, and difference.

3.2 The HLA Standard Library CHARS.HHF Module

The HLA Standard Library `chars.hhf` module provides a couple of routines that convert characters from one form to another and several routines that classify characters according to their graphic representation. These functions are especially useful for processing user input to verify that it is correct.

The first two routines we will consider are the translation/conversion functions. These functions are *chars.toUpper* and *chars.toLower*. These functions use the following syntax:

```
chars.toLower( characterValue ); // Returns converted character in AL.
chars.toUpper( characterValue ); // Returns converted character in AL.
```

These two functions require a byte-sized parameter (typically a register or a *char* variable). They check the character to see if it is an alphabetic character; if it is not, then these functions return the unmodified parameter value in the AL register. If the character is an alphabetic character, then these functions may translate the value depending on the particular function. The *chars.toUpper* function translates lower case alphabetic characters to upper case; it returns upper case character unmodified. The *chars.toLower* function does the converse – it translates upper case characters to lower case characters and leaves lower case characters alone.

These two functions are especially useful when processing user input containing alphabetic characters. For example, suppose you expect a “Y” or “N” answer from the user at some point in your program. You code might look like the following:

```
forever
    stdout.put( "Answer 'Y' or 'N':" );
    stdin.FlushInput(); // Force input of new line of text.
    stdin.getc(); // Read user input in AL.
    breakif( al = 'Y' );
    breakif( al = 'N' );
    stdout.put( "Illegal input, please reenter", nl );
endfor;
```

The problem with this program is that the user must answer exactly “Y” or “N” (using upper case) or the program will reject the user's input. This means that the program will reject “y” and “n” since the ASCII codes for these characters are different than “Y” and “N”.

One way to solve this problem is to include two additional `BREAKIF` statements in the code above that test for “y” and “n” as well as “Y” and “N”. The problem with this approach is that AL will still contain one of four different characters, complicating tests of AL once the program exits the loop. A better solution is to use either *chars.toUpper* or *chars.toLower* to translate all alphabetic characters to a single case. Then you can test AL for a single pair of characters, both in the loop and outside the loop. The resulting code would look like the following:

```

forever

    stdout.put( "Answer 'Y' or 'N':" );
    stdin.FlushInput(); // Force input of new line of text.
    stdin.getc();       // Read user input in AL.
    chars.toUpper( al ); // Convert "y" and "n" to "Y" and "N".
    breakif( al = 'Y' );
    breakif( al = 'N' );
    stdout.put( "Illegal input, please reenter", nl );

endfor;
<< test for "Y" or "N" down here to determine user input >>

```

As you can see from this example, the case conversion functions can be quite useful when processing user input. As a final example, consider a program that presents a menu of options to the user and the user selects an option using an alphabetic character. Once again, you can use *chars.toUpper* or *chars.toLower* to map the input character to a single case so that it is easier to process the user's input:

```

stdout.put( "Enter selection (A-G):" );
stdin.FlushInput();
stdin.getc();
chars.toLower( al );
if( al = 'a' ) then

    << Handle Menu Option A >>

elseif( al = 'b' ) then

    << Handle Menu Option B >>

elseif( al = 'c' ) then

    << Handle Menu Option C >>

elseif( al = 'd' ) then

    << Handle Menu Option D >>

elseif( al = 'e' ) then

    << Handle Menu Option E >>

elseif( al = 'f' ) then

    << Handle Menu Option F >>

elseif( al = 'g' ) then

    << Handle Menu Option G >>

else

    stdout.put( "Illegal input!" nl );

endif;

```

The remaining functions in the *chars.hhf* module all return a boolean result depending on the type of the character you pass them as a parameter. These classification functions let you quickly and easily test a character to determine if it's type is valid for the some intended use. These functions expect a single byte (char)

parameter and they return true (1) or false (0) in the EAX register. These functions use the following calling syntax:

```

chars.isAlpha( c );    // Returns true if c is alphabetic
chars.isUpper( c );   // Returns true if c is upper case alphabetic.
chars.isLower( c );   // Returns true if c is lower case alphabetic.
chars.isAlphaNum( c ); // Returns true if c is alphabetic or numeric.
chars.isDigit( c );   // Returns true if c is a decimal digit.
chars.isXDigit( c );  // Returns true if c is a hexadecimal digit.
chars.isGraphic( c ); // See notes below.
chars.isSpace( c );   // Returns true if c is a whitespace character.
chars.isASCII( c );   // Returns true if c is in the range #$00..#$7f.
chars.isCtrl( c );    // Returns true if c is a control character.

```

Notes: Graphic characters are the printable characters whose ASCII codes fall in the range \$21..\$7E. Note that a space is not considered a graphic character (nor are the control characters). Whitespace characters are the space, the tab, the carriage return, and the linefeed. Control characters are those characters whose ASCII code is in the range \$00..\$1E and \$7F.

These classification functions are great for validating user input. For example, if you want to check to ensure that a user has entered nothing but numeric characters in a string you read from the standard input, you could use code like the following:

```

stdin.a_gets(); // Read line of text from the user.
mov( eax, ebx ); // save ptr to string in EBX.
mov( ebx, ecx ); // Another copy of string pointer to test each char.
while( (type char [ecx]) <> #0 ) do // Repeat while not at end of string.

    breakif( !chars.isDigit( (type char [ecx] ) ) );
    inc( ecx ); // Move on to the next character;

endwhile;
if( (type char [ecx] ) = #0 ) then

    << Valid string, process it >>

else

    << invalid string >>

endif;

```

Although the chars.hhf module's classification functions handle many common situations, you may find that you need to test a character to see if it belongs in a class that the chars.hhf module does not handle. Fear not, checking for such characters is very easy. The next section will explain how to do this.

3.3 Character Sets

Character sets are another composite data type, like strings, built upon the character data type. A character set is a mathematical set of characters with the most important attribute being membership. That is, a character is either a member of a set or it is not a member of a set. The concept of sequence (e.g., whether one character comes before another, as in a string) is completely foreign to a character set. If two characters are members of a set, their order in the set is irrelevant. Also, membership is a binary relation; a character is either in the set or it is not in the set; you cannot have multiple copies of the same character in a character set. Finally, there are various operations that are possible on character sets including the mathematical set operations of union, intersection, difference, and membership test. HLA implements a restricted form of character sets that allows set members to be any of the 128 standard ASCII characters (i.e., HLA's character set facilities do not support extended character codes in the range #128..#255). Despite this restriction, however, HLA's character set facilities are very powerful and are very handy when writing programs that work

with string data. The following sections describe the implementation and use of HLA's character set facilities so you may take advantage of character sets in your own programs.

3.4 Character Set Implementation in HLA

There are many different ways to represent character sets in an assembly language program. HLA implements character sets by using an array of 128 boolean values. Each boolean value determines whether the corresponding character is or is not a member of the character set; i.e., a true boolean value indicates that the specified character is a member of the set, a false value indicates that the corresponding character is not a member of the set. To conserve memory, HLA allocates only a single bit for each character in the set; therefore, HLA character sets consume 16 bytes of memory since there are 128 bits in 16 bytes. This array of 128 bits is organized in memory as shown in Figure 3.1.

Figure 3.1 Bit Layout of a Character Set Object

Bit zero of byte zero corresponds to ASCII code zero (the NUL character). If this bit is one, then the character set contains the NUL character; if this bit contains false, then the character set does not contain the NUL character. Likewise, bit zero of byte one (the eighth bit in the 128-bit array) corresponds to the back-space character (ASCII code is eight). Finally bit one of byte eight corresponds to ASCII code 65, an upper case 'A'. Bit 65 will contain a one if 'A' is a current member of the character set, it will contain zero if 'A' is not a member of the set.

While there are other possible ways to implement character sets, this bit vector implementation has the advantage that it is very easy to implement set operations like union, intersection, difference comparison, and membership tests.

HLA supports character set variables using the *cset* data type. To declare a character set variable, you would use a declaration like the following:

```
static
    CharSetVar: cset;
```

This declaration will reserve 16 bytes of storage to hold the 128 bits needed to represent an ASCII character set.

Although it is possible to manipulate the bits in a character set using instructions like AND, OR, XOR, etc., the 80x86 instruction set includes several bit test, set, reset, and complement instructions that are nearly perfect for manipulating character sets. The BT (bit test) instruction, for example will copy a single bit in memory to the carry flag. The BT instruction allows the following syntactical forms:

```
bt ( BitNumber, BitsToTest );

bt ( reg16, reg16 );
bt ( reg32, reg32 );
bt ( constant, reg16 );
bt ( constant, reg32 );

bt ( reg16, mem16 );
```

```

    bt( reg32, mem32 );
    bt( constant, mem16 );
    bt( constant, mem32 );

```

The first operand holds a bit number, the second operand specifies a register or memory location whose bit should be copied into the carry flag. If the second operand is a register, the first operand must contain a value in the range $0..n-1$, where n is the number of bits in the second operand. If the first operand is a constant and the second operand is a memory location, the constant must be in the range $0..255$. Here are some examples of these instructions:

```

    bt( 7, ax );           // Copies bit #7 of AX into the carry flag (CF).
    mov( 20, eax );
    bt( eax, ebx );       // Copies bit #20 of EBX into CF.

// Copies bit #0 of the byte at CharSetVar+3 into CF.

    bt( 24, CharSetVar );

// Copies bit #4 of the byte at DWmem+2 into CF.

    bt( eax, CharSetVar );

```

The BT instruction turns out to be quite useful for testing set membership. For example, to see if the character 'A' is a member of a character set, you could use a code sequence like the following:

```

    bt( 'A', CharSetVar );
    if( @c ) then

        << Do something if 'A' is a member of the set >>

    endif;

```

The BTS (bit test and set), BTR (bit test and reset), and BTC (bit test and complement) instructions are also quite useful for manipulating character set variables. Like the BT instruction, these instructions copy the specified bit into the carry flag; after copying the specified bit, these instructions will set, clear, or invert (respectively) the specified bit. Therefore, you can use the BTS instruction to add a character to a character set via set union (that is, it adds a character to the set if the character was not already a member of the set, otherwise the set is unaffected). You can use the BTR instruction to remove a character from a character set via set intersection (That is, it removes a character from the set if and only if it was previously in the set; otherwise it has no effect on the set). The BTC instruction lets you add a character to the set if it wasn't previously in the set, it removes the character from the set if it was previously a member (that is, it toggles the membership of that character in the set).

The HLA Standard Library provides lots of character set handling routines. See “Character Set Support in the HLA Standard Library” on page 427. for more details about HLA's character set facilities.

3.5 HLA Character Set Constants and Character Set Expressions

HLA supports literal character set constants. These *cset* constants make it easy to initialize *cset* variables at compile time and they make it very easy to pass character set constants as procedure parameters. An HLA character set constant takes the following form:

```
{ Comma_separated_list_of_characters_and_character_ranges }
```

The following is an example of a simple character set holding the numeric digit characters:

```
{ '0', '1', '2', '3', '4', '5', '6', '7', '8', '9' }
```

When specifying a character set literal that has several contiguous values, HLA lets you concisely specify the values using only the starting and ending values of the range thusly:

```
{ '0'..'9' }
```

You may combine characters and various ranges within the same character set constant. For example, the following character set constant is all the alphanumeric characters:

```
{ '0'..'9', 'a'..'z', 'A'..'Z' }
```

You can use these *cset* literal constants in the `CONST` and `VAL` sections. The following example demonstrates how to create the symbolic constant *AlphaNumeric* using the character set above:

```
const
  AlphaNumeric: cset := { '0'..'9', 'a'..'z', 'A'..'Z' };
```

After the above declaration, you can use the identifier *AlphaNumeric* anywhere the character set literal is legal.

You can also use character set literals (and, of course, character set symbolic constants) as the initializer field for a `STATIC`, `DATA`, or `READONLY` variable. The following code fragment demonstrates this:

```
static
  Alphabetic: cset := { 'a'..'z', 'A'..'Z' };
```

Anywhere you can use a character set literal constant, a character set constant expression is also legal. HLA supports the following operators in character set constant expressions:

| | |
|-------------------------------------|--|
| <i>CSetConst</i> + <i>CSetConst</i> | Computes the union of the two sets ¹ . |
| <i>CSetConst</i> * <i>CSetConst</i> | Computes the intersection of the two sets ² . |
| <i>CSetConst</i> - <i>CSetConst</i> | Computes the set difference of the two sets ³ . |
| - <i>CSetConst</i> | Computes the set complement ⁴ . |

Note that these operators only produce compile-time results. That is, the expressions above are computed by the compiler during compilation, they do not emit any machine code. If you want to perform these operations on two different sets while your program is running, the HLA Standard Library provides routines you can call to achieve the results you desire. HLA also provides other compile-time character set operators. See the chapter on the compile-time language and macros for more details.

3.6 The IN Operator in HLA HLL Boolean Expressions

The HLA `IN` operator can dramatically reduce the logic in your HLA programs. This text has waited until now to discuss this operator because certain forms require a knowledge of character sets and character set constants. Now that you've seen character set constants, there is no need to delay the introduction of this important language feature.

In addition to the standard boolean expressions in `IF`, `WHILE`, `REPEAT..UNTIL`, and other statements, HLA also supports boolean expressions that take the following forms:

```
reg8 in CSetConstant
reg8 not in CSetConstant
reg8 in CSetVariable
reg8 not in CSetVariable
```

-
1. The set union is the set of all characters that are in either set.
 2. The set intersection is the set of all characters that appear in both operand sets.
 3. The set difference is the set of characters that appear in the first set but do not appear in the second set.
 4. The set complement is the set of all characters not in the set.

These four forms of the IN and NOT IN operators check to see if a character in an eight-bit register is a member of a character set (either a character set constant or a character set variable). The following code fragment demonstrates these operators:

```
const
  Alphabetic: cset := {'a'..'z', 'A'..'Z'};
  .
  .
  .
stdin.getc();
if( al in Alphabetic ) then

    stdout.put( "You entered an alphabetic character" nl );

elseif( al in {'0'..'9'} ) then

    stdout.put( "You entered a numeric character" nl );

endif;
```

3.7 Character Set Support in the HLA Standard Library

As noted in the previous sections, the HLA Standard Library provides several routines that provide character set support. The character set support routines fall into four categories: standard character set functions, character set tests, character set conversions, and character set I/O. This section describes these routines in the HLA Standard Library.

To begin with, let's consider the Standard Library routines that help you construct character sets. These routines include: *cs.empty*, *cs.cpy*, *cs.charToCset*, *cs.unionChar*, *cs.removeChar*, *cs.rangeChar*, *cs.strToCset*, and *cs.unionStr*. These procedures let you build up character sets at run-time using character and string objects.

The *cs.empty* procedure initializes a character set variable to the empty set by setting all the bits in the character set to zero. This procedure call uses the following syntax (*CSvar* is a character set variable):

```
cs.empty( CSvar );
```

The *cs.cpy* procedure copies one character set to another, replacing any data previously held by the destination character set. The syntax for *cs.cpy* is

```
cs.cpy( srcCsetValue, destCsetVar );
```

The *cs.cpy* source character set can be either a character set constant or a character set variable. The destination character set must be a character set variable.

The *cs.unionChar* procedure adds a character to a character set. It uses the following calling sequence:

```
cs.unionChar( CharVar, CSvar );
```

This call will add the first parameter, a character, to the set via set union. Note that you could use the BTS instruction to achieve this same result although the *cs.unionChar* call is often more convenient (though slower).

The *cs.charToCset* function creates a singleton set (a set containing a single character). The calling format for this function is

```
cs.charToCset( CharValue, CSvar );
```

The first operand, the character value *CharValue*, can be an eight-bit register, a constant, or a character variable. The second operand (*CSvar*) must be a character set variable. This function clears the destination character set to all zeros and then adds the specified character to the character set.

The *cs.removeChar* procedure lets you remove a single character from a character set without affecting the other characters in the set. This function uses the same syntax as *cs.charToCset* and the parameters have the same attributes. The calling sequence is

```
cs.removeChar( CharValue, CSVar );
```

The *cs.rangeChar* constructs a character set containing all the characters between two characters you pass as parameters. This function sets all bits outside the range of these two characters to zero. The calling sequence is

```
cs.rangeChar( LowerBoundChar, UpperBoundChar, CSVar );
```

The *LowerBoundChar* and *UpperBoundChar* parameters can be constants, registers, or character variables. *CSVar*, the destination character set, must be a *cset* variable.

The *cs.strToCset* procedure creates a new character set containing the union of all the characters in a character string. This procedure begins by setting the destination character set to the empty set and then it unions in the characters in the string one by one until it exhausts all characters in the string. The calling sequence is

```
cs.strToCset( StringValue, CSVar );
```

Technically, the *StringValue* parameter can be a string constant as well as a string variable, however, it doesn't make any sense to call *cs.strToCset* in this fashion since *cs.cpy* is a much more efficient way to initialize a character set with a constant set of characters. As usual, the destination character set must be a *cset* variable. Typically, you'd use this function to create a character set based on a string input by the user.

The *cs.unionStr* procedure will add the characters in a string to an existing character set. Like *cs.strToCset*, you'd normally use this function to union characters into a set based on a string input by the user. The calling sequence for this is

```
cs.unionStr( StringValue, CSVar );
```

Standard set operations include union, intersection, and set difference. The HLA Standard Library routines *cs.setunion*, *cs.intersection*, and *cs.difference* provide these operations, respectively⁵. These routines all use the same calling sequence:

```
cs.setunion( srcCset, destCset );
cs.intersection( srcCset, destCset );
cs.difference( srcCset, destCset );
```

The first parameter can be a character set constant or a character set variable. The second parameter must be a character set variable. These procedures compute “*destCset := destCset op srcCset*” where *op* represents set union, intersection, or difference, depending on the function call.

The third category of character set routines test character sets in various ways. They typically return a boolean value indicating the result of the test. The HLA character set routines in this category include *cs.IsEmpty*, *cs.member*, *cs.subset*, *cs.psubset*, *cs.superset*, *cs.psuperset*, *cs.eq*, and *cs.ne*.

The *cs.IsEmpty* function tests a character set to see if it is the empty set. The function returns true or false in the EAX register. This function uses the following calling sequence:

```
cs.IsEmpty( CSetValue );
```

The single parameter may be a constant or a character set variable, although it doesn't make much sense to pass a character set constant to this procedure (since you would know at compile-time whether this set is empty or not empty).

The *cs.member* function tests to see if a character value is a member of a set. This function returns true in the EAX register if the supplied character is a member of the specified set. Note that you can use the BT instruction to (more efficiently) test this same condition. However, the *cs.member* function is probably a little more convenient to use. The calling sequence for *cs.member* is

5. “*cs.setunion*” was used rather than “*cs.union*” because “union” is an HLA reserved word.

```
cs.member( CharValue, CsetValue );
```

The first parameter is a register, character variable, or a constant. The second parameter is either a character set constant or a character set variable. It would be unusual for both parameters to be constants.

The *cs.subset*, *cs.psubset* (proper subset), *cs.superset*, and *cs.psuperset* (proper superset) functions let you check to see if one character set is a subset or superset of another. The calling sequence for these four routines is nearly identical, it is one of the following:

```
cs.subset( CsetValue1, CsetValue2 );
cs.psubset( CsetValue1, CsetValue2 );
cs.superset( CsetValue1, CsetValue2 );
cs.psuperset( CsetValue1, CsetValue2 );
```

These routines compare the first parameter against the second parameter and return true or false in the EAX register depending upon the result of the comparison. One set is a subset of another if all the members of the first character set can be found in the second character set. It is a proper subset if the second character set also contains characters not found in the first (left) character set. Likewise, one character set is a superset of another if it contains all the characters in the second (right) set. A proper superset contains additional characters above and beyond those found in the second set. The parameters can be either character set variables or character set constants; however, it would be unusual for both parameters to be character set constants.

The *cs.eq* and *cs.ne* check to see if two sets are equal or not equal. These functions return true or false in EAX depending upon the set comparison. The calling sequence is identical to the sub/superset functions above:

```
cs.eq( CsetValue1, CsetValue2 );
cs.ne( CsetValue1, CsetValue2 );
```

The *cs.extract* routine removes an arbitrary character from a character set and returns that character in the EAX register⁶. The calling sequence is the following:

```
cs.extract( CsetVar );
```

The single parameter must be a character set variable. Note that this function will modify the character set variable by removing some character from the character set. This function returns \$FFFF_FFFF in EAX if the character set was empty prior to the call.

In addition to the routines found in the *cs* (character set) library module, the string and standard output modules also provide functions that allow or expect character set parameters. For example, if you supply a character set value as a parameter to *stdout.put*, the *stdout.put* routine will print the characters currently in the set. See the HLA Standard Library documentation for more details on character set handling procedures.

3.8 Using Character Sets in Your HLA Programs

Character sets are valuable for many different applications in your programs. For example, in the volume on advanced string handling you'll discover how to use character sets to match complex patterns. However, such use of character sets is a little beyond the scope of this chapter, so at this point we'll concentrate on another common use of character sets: validating user input. This section will also present a couple of other applications for character sets to help you start thinking about how you could use them in your program.

Consider the following short code segment that gets a yes/no type answer from the user:

```
static
  answer: char;
  .
  .
  .
```

6. This routine returns the character in AL and zeros out the H.O. three bytes of EAX.

```

repeat
    .
    .
    .
    stdout.put( "Would you like to play again? " );
    stdin.FlushInput();
    stdin.get( answer );

until( answer = 'n' );

```

A major problem with this code sequence is that it will only stop if the user presses a lower case 'n' character. If they type anything other than 'n' (including upper case 'N') the program will treat this as an affirmative answer and transfer back to the beginning of the repeat..until loop. A better solution would be to validate the user input before the UNTIL clause above to ensure that the user has only typed "n", "N", "y", or "Y". The following code sequence will accomplish this:

```

repeat
    .
    .
    .
repeat
    stdout.put( "Would you like to play again? " );
    stdin.FlushInput();
    stdin.get( answer );

until( cs.member( answer, { 'n', 'N', 'Y', 'y' } ) );
if( answer = 'N' ) then
    mov( 'n', answer );

endif;

until( answer = 'n' );

```

While an excellent use for character sets is to validate user input, especially when you must restrict the user to a small set of non-contiguous input characters, you should not use the *cs.member* function to test to see if a character value is within literal set. For example, you should never do something like the following:

```

repeat
    stdout.put( "Enter a character between 0..9: " );
    stdin.getc();

until( cs.member( al, { '0'..'9' } ) );

```

While there is nothing logically wrong with this code, keep in mind that HLA run-time boolean expressions allow simple membership tests using the IN operator. You could write the code above far more efficiently using the following sequence:

```

repeat
    stdout.put( "Enter a character between 0..9: " );
    stdin.getc();

until( al in '0'..'9' );

```

The place where the *cs.member* function becomes useful is when you need to see if an input character is within a set of characters that you build at run time.

3.9 Low-level Implementation of Set Operations

Although the HLA Standard Library character set module simplifies the use of character sets within your assembly language programs, it is instructive to look at how all these functions operate so you know the cost associated with each function. Also, since many of these functions are quite trivial, you might want to implement them in-line for performance reasons. The following subsections describe how each of the functions operate.

3.9.1 Character Set Functions That Build Sets

The first group of functions we will look at in the Character Set module are those that construct or copy character sets. These functions are *cs.empty*, *cs.cpy*, *cs.charToCset*, *cs.unionChar*, *cs.removeChar*, *cs.rangeChar*, *cs.strToCset*, and *cs.unionStr*.

Creating an empty set is, perhaps, the easiest of all the operations. To create an empty set all we need to is zero out all 128 bits in the *cset* object. Program 3.1 provides the implementation of this function.

```
// Program that demonstrates the implmentation of
// the cs.empty function.

program csEmpty;
#include( "stdlib.hhf" )

static
    csetDest: cset;
    csetSrc: cset := { 'a'..'z', 'A'..'Z' };

begin csEmpty;

    // How to create an empty set (cs.empty):
    // (Zero out all bits in the cset)

    mov( 0, eax );
    mov( eax, (type dword csetDest) );
    mov( eax, (type dword csetDest[4]) );
    mov( eax, (type dword csetDest[8]) );
    mov( eax, (type dword csetDest[12]) );

    stdout.put( "Empty set = {", csetDest, "}" nl );

end csEmpty;
```

Program 3.1 cs.empty Implementation

Note that *cset* objects are 16 bytes long. Therefore, this code zeros out those 16 bytes by storing EAX into the four consecutive double words that comprise the object. Note the use of type coercion in the MOV statements; this is necessary since *cset* objects are not the same size as *dword* objects.

To copy one character set to another is only a little more difficult than creating an empty set. All we have to do is copy the 16 bytes from the source character set to the destination character set. We can accomplish this with four pairs of double word MOV statements. Program 3.2 provides the sample implementation.

```

// Program that demonstrates the implementation of
// the cs.empty function.

program csCpy;
#include( "stdlib.hhf" )

static
    csetDest: cset;
    csetSrc: cset := {'a'..'z', 'A'..'Z'};

begin csCpy;

    // How to create an empty set (cs.empty):
    // (Zero out all bits in the cset)

    mov( (type dword csetSrc), eax );
    mov( eax, (type dword csetDest) );

    mov( (type dword csetSrc[4]), eax );
    mov( eax, (type dword csetDest[4]) );

    mov( (type dword csetSrc[8]), eax );
    mov( eax, (type dword csetDest[8]) );

    mov( (type dword csetSrc[12]), eax );
    mov( eax, (type dword csetDest[12]) );

    stdout.put( "Copied set = {" , csetDest, "}" nl );

end csCpy;

```

Program 3.2 cs.cpy Implementation

The *cs.charToCset* function creates a singleton set containing the specified character. To implement this function we first begin by creating an empty set (using the same code as *cs.empty*) and then we set the bit corresponding to the single character in the character set. We can use the BTS (bit test and set) instruction to easily set the specified bit in the *cset* object. Program 3.3 provides the implementation of this function.

```

// Program that demonstrates the implementation of
// the cs.charToCset function.

program cscharToCset;
#include( "stdlib.hhf" )

static
    csetDest: cset;
    chrValue: char := 'a';

begin cscharToCset;

    // Begin by creating an empty set:

    mov( 0, eax );
    mov( eax, (type dword csetDest) );

```

```

mov( eax, (type dword csetDest[4] ));
mov( eax, (type dword csetDest[8] ));
mov( eax, (type dword csetDest[12] ));

// Okay, use the BTS instruction to set the specified bit in
// the character set.

movzx( chrValue, eax );
bts( eax, csetDest );

stdout.put( "Singleton set = {", csetDest, "}" nl );

end cscharToCset;

```

Program 3.3 cs.charToCset Implementation

If you study this code carefully, you will note an interesting fact: the BTS instruction's operands are not the same size (*dword* and *cset*). Since programmers often use the BTx instructions to manipulate items in a character set, HLA allows you to specify a *cset* object as the destination operand of a BTx(reg₃₂, mem) instruction. Technically, the memory operand should be a double word object; HLA automatically coerces *cset* objects to *dword* for these instructions. Note that BTS requires a 16 or 32-bit register. Therefore, this code zero extends the character's value into EAX prior to executing the BTS instruction. Note that the value in EAX must not exceed 127 or this code will manipulate data beyond the end of the character set in memory. The use of a BOUND instruction might be warranted here if you can't ensure that the *chrValue* variable contains a value in the range 0..127.

The *cs.unionChar* adds a single character to the character set (if that character was not already present in the character set). This code is actually a bit simpler than the *cs.charToCset* function; the only difference is that the code does not clear the set to begin with – it simply sets the bit corresponding to the given character. Program 3.4 provides the implementation.

```

// Program that demonstrates the implementation of
// the cs.unionChar function.

program csUnionChar;
#include( "stdlib.hhf" )

static
    csetDest: cset := {'0'..'9'};
    chrValue: char := 'a';

begin csUnionChar;

    // Okay, use the BTS instruction to add the specified bit to
    // the character set.

    movzx( chrValue, eax );
    bts( eax, csetDest );

    stdout.put( "New set = {", csetDest, "}" nl );

end csUnionChar;

```

Program 3.4 cs.unionChar Implementation

Once again, note that this code assumes that the character value is in the range 0..127. If it is possible for the character to fall outside this range, you should check the value before attempting to union the character into the character set. You can use an IF statement or the BOUND instruction for this check.

The *cs.removeChar* function removes a character from a character set, provided that character was a member of the set. If the character was not originally in the character set, then *cs.removeChar* does not affect the original character set. To accomplish this, the code must clear the bit associated with the character to remove from the set. Program 3.5 uses the BTR (bit test and reset) instruction to achieve this.

```
// Program that demonstrates the implementation of
// the cs.removeChar function.

program csRemoveChar;
#include( "stdlib.hhf" )

static
  csetDest: cset := {'0'..'9'};
  chrVal1: char := '0';
  chrVal2: char := 'a';

begin csRemoveChar;

  // Okay, use the BTC instruction to remove the specified bit from
  // the character set.

  movzx( chrVal1, eax );
  btr( eax, csetDest );

  stdout.put( "Set w/o '0' = {", csetDest, "}" nl );

  // Now remove a character not in the set to demonstrate
  // that removal of a non-existent character doesn't affect
  // the set:

  movzx( chrVal2, eax );
  btr( eax, csetDest );
  stdout.put( "Final set = {", csetDest, "}" nl );

end csRemoveChar;
```

Program 3.5 cs.removeChar Implementation

Don't forget to use a BOUND instruction or an IF statement in Program 3.5 if it is possible for the character's value to fall outside the range 0..127. This will prevent the code from manipulating memory beyond the end of the character set.

The *cs.rangeChar* function creates a set containing all the characters between two specified boundaries. This function begins by creating an empty set; then it loops over the range of character to insert, inserting each character into the set as appropriate. Program 3.6 provides an example implementation of this function.

```

// Program that demonstrates the implementation of
// the cs.rangeChar function.

program csRangeChar;
#include( "stdlib.hhf" )

static
    csetDest: cset;
    startRange: char := 'a';
    endRange: char := 'z';

begin csRangeChar;

    // Begin by creating the empty set:

    mov( 0, eax );
    mov( eax, (type dword csetDest) );
    mov( eax, (type dword csetDest[4]) );
    mov( eax, (type dword csetDest[8]) );
    mov( eax, (type dword csetDest[12]) );

    // Run the following loop for each character between
    // 'startRange' and 'endRange' and set the corresponding
    // bit in the cset for each character in the range.

    movzx( startRange, eax );
    while( al <= endRange ) do

        bts( eax, csetDest );
        inc( al );

    endwhile;
    stdout.put( "Final set = {" , csetDest, "}" nl );

end csRangeChar;

```

Program 3.6 cs.rangeChar Implementation

One interesting thing to note about the code in Program 3.6 is how it takes advantage of the fact that AL contains the actual character index even though it has to use EAX with the BTS instruction. As usual, you should check the range of the two values if there is any possibility that they could be outside the range 0..127.

One problem with this particular implementation of the `cs.rangeChar` function is that it is not particularly efficient if you ask it to create a set with a lot of characters in it. As you can see by studying the code, the execution time of this function is proportional to the number of characters in the range. In particular, the loop in this function iterates once for each character in the range. So if the range is large the loop executes many more times than if the range is small. There is a more efficient solution to this problem using table lookups whose execution time is independent of the size of the character set it creates. For more details on using table lookups, see “Calculation Via Table Lookups” on page 625.

The `cs.strToCset` function scans through an HLA string character by character and creates a new character set by adding each character in the string to an empty character set.

```

// Program that demonstrates the implementation of
// the cs.strToCset function.

program csStrToCset;
#include( "stdlib.hhf" )

static
  StrToAdd: string := "Hello_World";
  csetDest: cset;

begin csStrToCset;

  // Begin by creating the empty set:

  mov( 0, eax );
  mov( eax, (type dword csetDest) );
  mov( eax, (type dword csetDest[4]) );
  mov( eax, (type dword csetDest[8]) );
  mov( eax, (type dword csetDest[12]) );

  // For each character in the source string, add that character
  // to the set.

  mov( StrToAdd, eax );
  while( (type char [eax]) <> #0 ) do // While not at end of string.

    movzx( (type char [eax]), ebx );
    bts( ebx, csetDest );
    inc( eax );

  endwhile;
  stdout.put( "Final set = {", csetDest, "}" nl );

end csStrToCset;

```

Program 3.7 cs.strToCset Implementation

This code begins by fetching the pointer to the first character in the string. The loop repeats for each character in the string up to the zero terminating byte of the string. For each character, this code uses the BTS instruction to set the corresponding bit in the destination character set. As usual, don't forget to use an IF statement or BOUND instruction if it is possible for the characters in the string to have values outside the range 0..127.

The *cs.unionStr* function is very similar to the *cs.strToCset* function; in fact, the only difference is that it doesn't create an empty character set prior to adding the characters in a string to the destination character set.

```

// Program that demonstrates the implementation of
// the cs.unionStr function.

program csUnionStr;
#include( "stdlib.hhf" )

```

```

static
  StrToAdd: string := "Hello_World";
  csetDest: cset := {'0'..'9'};

begin csUnionStr;

  // For each character in the source string, add that character
  // to the set.

  mov( StrToAdd, eax );
  while( (type char [eax]) <> #0 ) do // While not at end of string.

    movzx( (type char [eax]), ebx );
    bts( ebx, csetDest );
    inc( eax );

  endwhile;
  stdout.put( "Final set = {", csetDest, "}" nl );

end csUnionStr;

```

3.9.2 Traditional Set Operations

The previous section describes how to construct character sets from characters and strings. In this section we'll take a look at how you can manipulate character sets using the traditional set operations of intersection, union, and difference.

The union of two sets A and B is the collection of all items that are in set A, set B, or both. In the bit array representation of a set, this means that a bit in the destination character set will be one if either or both of the corresponding bits in sets A or B are set. This of course, corresponds to the logical OR operation. Therefore, we can easily create the set union of two sets by logically ORing their bytes together. Program 3.9 provides the complete implementation of this function.

```

// Program that demonstrates the implementation of
// the cs.setunion function.

program cssetUnion;
#include( "stdlib.hhf" )

static
  csetSrc1: cset := {'a'..'z'};
  csetSrc2: cset := {'A'..'Z'};
  csetDest: cset;

begin cssetUnion;

  // To compute the union of csetSrc1 and csetSrc2 all we have
  // to do is logically OR the two sets together.

  mov( (type dword csetSrc1), eax );
  or( (type dword csetSrc2), eax );

```

```

mov( eax, (type dword csetDest));

mov( (type dword csetSrc1[4]), eax );
or( (type dword csetSrc2[4]), eax );
mov( eax, (type dword csetDest[4]));

mov( (type dword csetSrc1[8]), eax );
or( (type dword csetSrc2[8]), eax );
mov( eax, (type dword csetDest[8]));

mov( (type dword csetSrc1[12]), eax );
or( (type dword csetSrc2[12]), eax );
mov( eax, (type dword csetDest[12]));

stdout.put( "Final set = {", csetDest, "}" nl );

end cssetUnion;

```

Program 3.9 cs.setunion Implementation

The intersection of two sets is those elements that are members of both sets. In the bit array representation of character sets that HLA uses, this means that a bit is set in the destination character set if the corresponding bit is set in both the source sets; this corresponds to the logical AND operation; therefore, to compute the set intersection of two character sets, all you need do is logically AND the 16 bytes of the two source sets together. Program 3.10 provides a sample implementation.

```

// Program that demonstrates the implmentation of
// the cs.intersection function.

program csIntersection;
#include( "stdlib.hhf" )

static
  csetSrc1: cset := {'a'..'z'};
  csetSrc2: cset := {'A'..'z'};
  csetDest: cset;

begin csIntersection;

  // To compute the intersection of csetSrc1 and csetSrc2 all we have
  // to do is logically AND the two sets together.

  mov( (type dword csetSrc1), eax );
  and( (type dword csetSrc2), eax );
  mov( eax, (type dword csetDest));

  mov( (type dword csetSrc1[4]), eax );
  and( (type dword csetSrc2[4]), eax );
  mov( eax, (type dword csetDest[4]));

  mov( (type dword csetSrc1[8]), eax );
  and( (type dword csetSrc2[8]), eax );
  mov( eax, (type dword csetDest[8]));

  mov( (type dword csetSrc1[12]), eax );
  and( (type dword csetSrc2[12]), eax );

```

```

mov( eax, (type dword csetDest[12]));

stdout.put( " Set A = {" , csetSrc1, "}" nl );
stdout.put( " Set B = {" , csetSrc2, "}" nl );
stdout.put( "Intersection of A and B = {" , csetDest, "}" nl );

end csIntersection;

```

Program 3.10 cs.intersection Implementation

The difference of two sets is all the elements in the first set that are not also present in the second set. To compute this result we must logically AND the values from the first set with the inverted values of the second set; i.e., to compute $C := A - B$ we use the following expression:

$$C := A \text{ and } (\text{not } B);$$

Program 3.11 provides the code to implement this operation.

```

// Program that demonstrates the implmentation of
// the cs.difference function.

program csDifference;
#include( "stdlib.hhf" )

static
  csetSrc1: cset := {'0'..'9', 'a'..'z'};
  csetSrc2: cset := {'A'..'z'};
  csetDest: cset;

begin csDifference;

  // To compute the difference of csetSrc1 and csetSrc2 all we have
  // to do is logically AND A and NOT B together.

  mov( (type dword csetSrc2), eax );
  not( eax );
  and( (type dword csetSrc1), eax );
  mov( eax, (type dword csetDest));

  mov( (type dword csetSrc2[4]), eax );
  not( eax );
  and( (type dword csetSrc1[4]), eax );
  mov( eax, (type dword csetDest[4]));

  mov( (type dword csetSrc2[8]), eax );
  not( eax );
  and( (type dword csetSrc1[8]), eax );
  mov( eax, (type dword csetDest[8]));

  mov( (type dword csetSrc2[12]), eax );
  not( eax );
  and( (type dword csetSrc1[12]), eax );
  mov( eax, (type dword csetDest[12]));

  stdout.put( " Set A = {" , csetSrc1, "}" nl );
  stdout.put( " Set B = {" , csetSrc2, "}" nl );

```

```

        stdout.put( "Difference of A and B = {", csetDest, "}" nl );
end csDifference;

```

3.9.3 Testing Character Sets

In addition to manipulating the members of a character set, the need often arises to compare character sets, check to see if a character is a member of a set, and check to see if a set is empty. In this section we'll discuss how HLA implements the relational operations on character sets.

Occasionally you'll want to check a character set to see if it contains any members. Although you could achieve this by creating a static *cset* variable with no elements and comparing the set in question against this empty set, there is a more efficient way to do this – just check to see if all the bits in the set in question are zero. An easy way to do this, that uses, is to logically OR the four double words in a *cset* object together. If the result is zero, then all the bits in the *cset* variable are zero and, hence, the character set is empty.

```

// Program that demonstrates the implementation of
// the cs.IsEmpty function.

program csIsEmpty;
#include( "stdlib.hhf" )

static
    csetSrc1: cset := {};
    csetSrc2: cset := {'A'..'Z'};

begin csIsEmpty;

    // To see if a set is empty, simply OR all the dwords
    // together and see if the result is zero:

    mov( (type dword csetSrc1[0]), eax );
    or( (type dword csetSrc1[4]), eax );
    or( (type dword csetSrc1[8]), eax );
    or( (type dword csetSrc1[12]), eax );

    if( @z ) then

        stdout.put( "csetSrc1 is empty ({", csetSrc1, "}" nl );

    else

        stdout.put( "csetSrc1 is not empty ({", csetSrc1, "}" nl );

    endif;

    // Repeat the test for csetSrc2:

    mov( (type dword csetSrc2[0]), eax );
    or( (type dword csetSrc2[4]), eax );
    or( (type dword csetSrc2[8]), eax );
    or( (type dword csetSrc2[12]), eax );

```

```

if( @z ) then
    stdout.put( "csetSrc2 is empty ({", csetSrc2, "})" nl );
else
    stdout.put( "csetSrc2 is not empty ({", csetSrc2, "})" nl );
endif;
end csIsEmpty;

```

Program 3.12 Implementation of cs.IsEmpty

Perhaps the most common check on a character set is set membership; that is, checking to see if some character is a member of a given character set. As you've seen already (see "Character Set Implementation in HLA" on page 424), the BT instruction is perfect for this. Since we've already discussed how to use the BT instruction (along with, perhaps, a MOVZX instruction), there is no need to repeat the implementation of this operation here.

Two sets are equal if and only if all the bits are equal in the two set objects. Therefore, we can implement the cs.ne and cs.eq (set inequality and set equality) functions by comparing the four double words in a *cset* object and noting if there are any differences. Program 3.13 demonstrates how you can do this.

```

// Program that demonstrates the implementation of
// the cs.eq and cs.ne functions.

program cseqne;
#include( "stdlib.hhf" )

static
    csetSrc1: cset := {'a'..'z'};
    csetSrc2: cset := {'a'..'z'};
    csetSrc3: cset := {'A'..'Z'};

begin cseqne;

    // To see if a set equal to another, check to make sure
    // all four dwords are equal. One sneaky way to do this
    // is to use the XOR operator (XOR is "not equals" as you
    // may recall).

    mov( (type dword csetSrc1[0]), eax ); // Set EAX to zero if these
    xor( (type dword csetSrc2[0]), eax ); // two dwords are equal
    mov( eax, ebx ); // Accumulate result here.

    mov( (type dword csetSrc1[4]), eax );
    xor( (type dword csetSrc2[4]), eax );
    or( eax, ebx );

    mov( (type dword csetSrc1[8]), eax );
    xor( (type dword csetSrc2[8]), eax );
    or( eax, ebx );

    mov( (type dword csetSrc1[12]), eax );

```

```

xor( (type dword csetSrc2[12]), eax );
or( eax, ebx );

// At this point, EBX is zero if the two csets are equal
// (also, the zero flag is set if they are equal).

if( @z ) then

    stdout.put( "csetSrc1 is equal to csetSrc2" nl );

else

    stdout.put( "csetSrc1 is not equal to csetSrc2" nl );

endif;

// Implementation of cs.ne:

mov( (type dword csetSrc1[0]), eax ); // Set EAX to zero if these
xor( (type dword csetSrc3[0]), eax ); // two dwords are equal
mov( eax, ebx ); // Accumulate result here.

mov( (type dword csetSrc1[4]), eax );
xor( (type dword csetSrc3[4]), eax );
or( eax, ebx );

mov( (type dword csetSrc1[8]), eax );
xor( (type dword csetSrc3[8]), eax );
or( eax, ebx );

mov( (type dword csetSrc1[12]), eax );
xor( (type dword csetSrc3[12]), eax );
or( eax, ebx );

// At this point, EBX is non-zero if the two csets are not equal
// (also, the zero flag is clear if they are not equal).

if( @nz ) then

    stdout.put( "csetSrc1 is not equal to csetSrc3" nl );

else

    stdout.put( "csetSrc1 is equal to csetSrc3" nl );

endif;

end cseqne;

```

Program 3.13 Implementation of cs.ne and cs.eq

The remaining tests on character sets roughly correspond to tests for less than or greater than; though in set theory we refer to these as superset and subset. One set is a subset of another if the second set contains all the elements of the first set; the second set may contain additional elements. The subset relationship is roughly equivalent to “less than or equal.” The proper subset relation of two sets states that the elements of

one set are all present in a second set and the two sets are not equal (i.e., the second set contains additional elements). This is roughly equivalent to the “less than” relationship.

Testing for a subset is an easy task. All you have to do is take the set intersection of the two sets and verify that the intersection of the two is equal to the first set. That is, $A \leq B$ if and only if:

$$A == (A * B) \quad "*" \text{ denotes set intersection}$$

Testing for a proper subset is a little more work. The same relationship above must hold but the resulting inspection must not be equal to B. That is, $A < B$ if and only if,

$$(A == (A * B)) \text{ and } (B <> (A * B))$$

The algorithms for superset and proper superset are nearly identical. They are:

$$\begin{array}{ll} B == (A * B) & A \geq B \\ (B == (A * B)) \text{ and } (A <> (A * B)) & A > B \end{array}$$

The implementation of these four relational operations is left as an exercise.

3.10 Putting It All Together

This chapter describes HLA’s implementation of character sets. Character sets are a very useful tool for validating user input and for other character scanning and manipulation operations. HLA uses a bit array implementation for character set objects. HLA’s implementation allows for 128 different character values in a character set.

The HLA Standard Library provides a wide set of functions that let you build, manipulate, and compare character sets. Although these functions are convenient to use, most of the character set operations are so simple that you can implement them directly using in-line code. This chapter provided the implementation of many of the HLA Standard Library character set functions.

Note that this chapter does not cover all the uses of character sets in an assembly language program. In the volume on “Advanced String Handling” you will see many more uses for character sets in your programs.

4.1 Chapter Overview

This chapter discusses how to declare and use arrays in your assembly language programs. This is probably the most important chapter on composite data structures in this text. Even if you elect to skip the chapters on Strings, Character Sets, Records, and Dates and Times, be sure you read and understand the material in this chapter. Much of the rest of the text depends on your understanding of this material.

4.2 Arrays

Along with strings, arrays are probably the most commonly used composite data type. Yet most beginning programmers have a very weak understanding of how arrays operate and their associated efficiency trade-offs. It's surprising how many novice (and even advanced!) programmers view arrays from a completely different perspective once they learn how to deal with arrays at the machine level.

Abstractly, an array is an aggregate data type whose members (elements) are all the same type. Selection of a member from the array is by an integer index¹. Different indices select unique elements of the array. This text assumes that the integer indices are contiguous (though this is by no means required). That is, if the number x is a valid index into the array and y is also a valid index, with $x < y$, then all i such that $x < i < y$ are valid indices into the array.

Whenever you apply the indexing operator to an array, the result is the specific array element chosen by that index. For example, $A[i]$ chooses the i^{th} element from array A . Note that there is no formal requirement that element i be anywhere near element $i+1$ in memory. As long as $A[i]$ always refers to the same memory location and $A[i+1]$ always refers to its corresponding location (and the two are different), the definition of an array is satisfied.

In this text, we will assume that array elements occupy contiguous locations in memory. An array with five elements will appear in memory as shown in Figure 4.1

Figure 4.1 Array Layout in Memory

The *base address* of an array is the address of the first element on the array and always appears in the lowest memory location. The second array element directly follows the first in memory, the third element follows the second, etc. Note that there is no requirement that the indices start at zero. They may start with any number as long as they are contiguous. However, for the purposes of discussion, it's easier to discuss accessing array elements if the first index is zero. This text generally begins most arrays at index zero unless

1. Or some value whose underlying representation is integer, such as character, enumerated, and boolean types.

there is a good reason to do otherwise. However, this is for consistency only. There is no efficiency benefit one way or another to starting the array index at some value other than zero.

To access an element of an array, you need a function that translates an array index to the address of the indexed element. For a single dimension array, this function is very simple. It is

$$\text{Element_Address} = \text{Base_Address} + ((\text{Index} - \text{Initial_Index}) * \text{Element_Size})$$

where *Initial_Index* is the value of the first index in the array (which you can ignore if zero) and the value *Element_Size* is the size, in bytes, of an individual element of the array.

4.3 Declaring Arrays in Your HLA Programs

Before you access elements of an array, you need to set aside storage for that array. Fortunately, array declarations build on the declarations you've seen thus far. To allocate *n* elements in an array, you would use a declaration like the following in one of the variable declaration sections:

```
ArrayName: basetype[n];
```

ArrayName is the name of the array variable and *basetype* is the type of an element of that array. This sets aside storage for the array. To obtain the base address of the array, just use *ArrayName*.

The “[n]” suffix tells HLA to duplicate the object *n* times. Now let's look at some specific examples:

```
static
```

```
CharArray: char[128];           // Character array with elements 0..127.
IntArray: integer[ 8 ];        // "integer" array with elements 0..7.
ByteArray: byte[10];           // Array of bytes with elements 0..9.
PtrArray: dword[4];            // Array of double words with elements 0..3.
```

The second example, of course, assumes that you have defined the *integer* data type in the TYPE section of the program.

These examples all allocate storage for uninitialized arrays. You may also specify that the elements of the arrays be initialized to a single value using declarations like the following in the STATIC and READ-ONLY sections:

```
RealArray: real32[8] := [ 1.0, 1.0, 1.0, 1.0, 1.0, 1.0, 1.0, 1.0 ];
IntegerAry: integer[8] := [ 1, 1, 1, 1, 1, 1, 1, 1 ];
```

These definitions both create arrays with eight elements. The first definition initializes each four-byte real value to 1.0, the second declaration initializes each integer element to one. Note that the number of constants within the square brackets must match the size you declare for the array.

This initialization mechanism is fine if you want each element of the array to have the same value. What if you want to initialize each element of the array with a (possibly) different value? No sweat, just specify a different set of values in the list surrounded by the square brackets in the example above:

```
RealArray: real32[8] := [ 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0 ];
IntegerAry: integer[8] := [ 1, 2, 3, 4, 5, 6, 7, 8 ];
```

4.4 HLA Array Constants

The last few examples in the last section demonstrate the use of HLA array constants. An HLA array constant is nothing more than a list of values (all the same time) surrounded by a pair of brackets. The following are all legal array constants:

```
[ 1, 2, 3, 4 ]
[ 2.0, 3.14159, 1.0, 0.5 ]
[ 'a', 'b', 'c', 'd' ]
```

```
[ "Hello", "world", "of", "assembly" ]
```

(note that this last array constant contains four double word pointers to the four HLA strings appearing elsewhere in memory.)

As you saw in the previous section you can use array constants in the `STATIC`, `READONLY`, and `DATA` sections to provide initial values for array variables. Of course, the number of comma separated items in an array constant must exactly match the number of array elements in the variable declaration. Likewise, the type of the array constant's elements must match the type of the elements in the array variable.

Using array constants to initialize small arrays is very convenient. Of course, if your array has several thousand elements in it, typing them all in will not be very much fun. Most arrays initialized this way have no more than a couple hundred entries, and generally far less than 100. It is reasonable to use an array constant to initialize such variables. However, at some point it will become far too tedious and error-prone to initialize arrays in this fashion. It is doubtful, for example, that you would want to manually initialize an array with 1,000 different elements using an array constant². However, if you want to initialize all the elements of an array with the same value, HLA does provide a special array constant syntax for doing so. Consider the following declaration:

```
BigArray: uns32[ 1000 ] := 1000 dup [ 1 ] ;
```

This declaration creates a 1,000 element integer array initializing each element of the array with the value one. The "1000 dup [1]" expression tells HLA to create an array constant by duplicating the single value "[1]" one thousand times. You can even use the `DUP` operator to duplicate a series of values (rather than a single value) as the following example indicates:

```
SixteenInts: int32[16] := 4 dup [1,2,3,4] ;
```

This example initializes *SixteenInts* with four copies of the sequence "1, 2, 3, 4" yielding a total of sixteen different integers (i.e., 1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 3, 4).

You will see some more possibilities with the `DUP` operator when looking at multidimensional arrays a little later.

4.5 Accessing Elements of a Single Dimension Array

To access an element of a zero-based array, you can use the simplified formula:

$$\text{Element_Address} = \text{Base_Address} + \text{index} * \text{Element_Size}$$

For the *Base_Address* entry you can use the name of the array (since HLA associates the address of the first element of an array with the name of that array). The *Element_Size* entry is the number of bytes for each array element. If the object is an array of bytes, the *Element_Size* field is one (resulting in a very simple computation). If each element of the array is a word (or other two-byte type) then *Element_Size* is two. And so on. To access an element of the *SixteenInts* array in the previous section, you'd use the formula:

$$\text{Element_Address} = \text{Squares} + \text{index} * 4$$

The 80x86 code equivalent to the statement "EAX:=SixteenInts[index]" is

```
mov( index, ebx );
shl( 2, ebx );           //Sneaky way to compute 4*ebx
mov( SixteenInts[ ebx ], eax );
```

There are two important things to notice here. First of all, this code uses the `SHL` instruction rather than the `INTMUL` instruction to compute $4 * \text{index}$. The main reason for choosing `SHL` is that it was more efficient. It turns out that `SHL` is a *lot* faster than `INTMUL` on many processors.

2. In the chapter on Macros and the HLA Run-Time Language you will learn how to automate the initialization of large array objects. So initializing large objects is not completely out of the question.

The second thing to note about this instruction sequence is that it does not explicitly compute the sum of the base address plus the index times two. Instead, it relies on the indexed addressing mode to implicitly compute this sum. The instruction “`mov(SixteenInts[ebx], eax);`” loads EAX from location *SixteenInts*+EBX which is the base address plus *index**4 (since EBX contains *index**4). Sure, you could have used

```
lea( eax, SixteenInts );
mov( index, ebx );
shl( 2, ebx );           //Sneaky way to compute 4*ebx
add( eax, ebx );        //Compute base address plus index*4
mov( SixteenInts[ ebx ], eax );
```

in place of the previous sequence, but why use five instructions where three will do the same job? This is a good example of why you should know your addressing modes inside and out. Choosing the proper addressing mode can reduce the size of your program, thereby speeding it up.

Of course, as long as we’re discussing efficiency improvements, it’s worth pointing out that the 80x86 scaled indexed addressing modes let you automatically multiply an index by one, two, four, or eight. Since this current example multiplies the index by four, we can simplify the code even farther by using the scaled indexed addressing mode:

```
mov( index, ebx );
mov( SixteenInts[ ebx*4 ], eax );
```

Note, however, that if you need to multiply by some constant other than one, two, four, or eight, then you cannot use the scaled indexed addressing modes. Similarly, if you need to multiply by some element size that is not a power of two, you will not be able to use the SHL instruction to multiply the index by the element size; instead, you will have to use INTMUL or some other instruction sequence to do the multiplication.

The indexed addressing mode on the 80x86 is a natural for accessing elements of a single dimension array. Indeed, it’s syntax even suggests an array access. The only thing to keep in mind is that you must remember to multiply the index by the size of an element. Failure to do so will produce incorrect results.

Before moving on to multidimensional arrays, a couple of additional points about addressing modes and arrays are in order. The above sequences work great if you only access a single element from the *SixteenInts* array. However, if you access several different elements from the array within a short section of code, and you can afford to dedicate another register to the operation, you can certainly shorten your code and, perhaps, speed it up as well. Consider the following code sequence:

```
lea( ebx, SixteenInts );
mov( index, esi );
mov( [ebx+esi*4], eax );
```

Now EBX contains the base address and ESI contains the *index* value. Of course, this hardly appears to be a good trade-off. However, when accessing additional elements if *SixteenInts* you do not have to reload EBX with the base address of *SixteenInts* for the next access. The following sequence is a little shorter than the comparable sequence that doesn’t load the base address into EBX:

```
lea( ebx, SixteenInts );
mov( index, esi );
mov( [ebx+esi*4], eax );
.
.                               //Assumption: EBX is left alone
.                               //                      through this code.
mov( index2, esi );
mov( [ebx+esi*4], eax );
```

This code is slightly shorter because the “`mov([ebx+esi*4], eax);`” instruction is slightly shorter than the “`mov(SixteenInts[ebx*4], eax);`” instruction. Of course the more accesses to *SixteenInts* you make without reloading EBX, the greater your savings will be. Tricky little code sequences such as this one sometimes pay off handsomely. However, the savings depend entirely on which processor you’re using. Code

sequences that run faster on one 80x86 CPU might actually run *slower* on a different CPU. Unfortunately, if speed is what you're after there are no hard and fast rules. In fact, it is very difficult to predict the speed of most instructions on the 80x86 CPUs.

4.5.1 Sorting an Array of Values

Almost every textbook on this planet gives an example of a sort when introducing arrays. Since you've probably seen how to do a sort in high level languages already, it's probably instructive to take a quick look at a sort in HLA. The example code in this section will use a variant of the Bubble Sort which is great for short lists of data and lists that are nearly sorted, but horrible for just about everything else³.

```

const
  NumElements:= 16;

static
  DataToSort: uns32[ NumElements ] :=
    [
      1, 2, 16, 14,
      3, 9, 4, 10,
      5, 7, 15, 12,
      8, 6, 11, 13
    ];

  NoSwap: boolean;

  .
  .
  .

// Bubble sort for the DataToSort array:

repeat

  mov( true, NoSwap );
  for( mov( 0, ebx ); ebx <= NumElements-2; inc( ebx ) ) do

    mov( DataToSort[ ebx*4], eax );
    if( eax > DataToSort[ ebx*4 + 4] ) then

      mov( DataToSort[ ebx*4 + 4 ], ecx );
      mov( ecx, DataToSort[ ebx*4 ] );
      mov( eax, DataToSort[ ebx*4 + 4 ] ); // Note: EAX contains
      mov( false, NoSwap );              // DataToSort[ ebx*4 ]

    endif;

  endfor;

until( NoSwap );

```

The bubble sort works by comparing adjacent elements in an array. The interesting thing to note in this code fragment is how it compares adjacent elements. You will note that the IF statement compares EAX (which contains DataToSort[ebx*4]) against DataToSort[EBX*4 + 4]. Since each element of this array is four bytes (*uns32*), the index [EBX*4 + 4] references the next element beyond [EBX*4].

3. Fear not, you'll see some better sorting algorithms in the next chapter once we cover procedures and recursion.

As is typical for a bubble sort, this algorithm terminates if the innermost loop completes without swapping any data. If the data is already presorted, then the bubble sort is very efficient, making only one pass over the data. Unfortunately, if the data is not sorted (worst case, if the data is sorted in reverse order), then this algorithm is extremely inefficient. Indeed, although it is possible to modify the code above so that, on the average, it runs about twice as fast, such optimizations are wasted on such a poor algorithm. However, the Bubble Sort is very easy to implement and understand (which is why introductory texts continue to use it in examples). Fortunately, you will learn about more advanced sorts later in this text, so you won't be stuck with it for very long.

4.6 Multidimensional Arrays

The 80x86 hardware can easily handle single dimension arrays. Unfortunately, there is no magic addressing mode that lets you easily access elements of multidimensional arrays. That's going to take some work and lots of instructions.

Before discussing how to declare or access multidimensional arrays, it would be a good idea to figure out how to implement them in memory. The first problem is to figure out how to store a multi-dimensional object into a one-dimensional memory space.

Consider for a moment a Pascal array of the form "A:array[0..3,0..3] of char;". This array contains 16 bytes organized as four rows of four characters. Somehow you've got to draw a correspondence with each of the 16 bytes in this array and 16 contiguous bytes in main memory. Figure 4.2 shows one way to do this:

Figure 4.2 Mapping a 4x4 Array to Sequential Memory Locations

The actual mapping is not important as long as two things occur: (1) each element maps to a unique memory location (that is, no two entries in the array occupy the same memory locations) and (2) the mapping is consistent. That is, a given element in the array always maps to the same memory location. So what you really need is a function with two input parameters (row and column) that produces an offset into a linear array of sixteen memory locations.

Now any function that satisfies the above constraints will work fine. Indeed, you could randomly choose a mapping as long as it was unique. However, what you really want is a mapping that is efficient to compute at run time and works for any size array (not just 4x4 or even limited to two dimensions). While there are a large number of possible functions that fit this bill, there are two functions in particular that most programmers and most high level languages use: *row major ordering* and *column major ordering*.

4.6.1 Row Major Ordering

Row major ordering assigns successive elements, moving across the rows and then down the columns, to successive memory locations. The mapping is best described in Figure 4.3:

Figure 4.3 Row Major Array Element Ordering

Row major ordering is the method employed by most high level programming languages including Pascal, C, Ada, Modula-2, etc. It is very easy to implement and easy to use in machine language. The conversion from a two-dimensional structure to a linear array is very intuitive. You start with the first row (row number zero) and then concatenate the second row to its end. You then concatenate the third row to the end of the list, then the fourth row, etc. (see Figure 4.4).

Figure 4.4 Another View of Row-Major Ordering for a 4x4 Array

For those who like to think in terms of program code, the following nested Pascal loop also demonstrates how row major ordering works:

```

index := 0;
for colindex := 0 to 3 do
  for rowindex := 0 to 3 do
    begin
      memory [index] := rowmajor [colindex] [rowindex];
      index := index + 1;
    end;
  end;
end;

```

The important thing to note from this code, that applies regardless of the number of dimensions, is that the rightmost index increases the fastest. That is, as you allocate successive memory locations you increment the rightmost index until you reach the end of the current row. Upon reaching the end, you reset the index back to the beginning of the row and increment the next successive index by one (that is, move down to the next row.). This works equally well for any number of dimensions⁴. The following Pascal segment demonstrates row major organization for a 4x4x4 array:

```

index := 0;
for depthindex := 0 to 3 do
  for colindex := 0 to 3 do
    for rowindex := 0 to 3 do begin
      memory [index] := rowmajor [depthindex] [colindex] [rowindex];
      index := index + 1;
    end;
  end;
end;

```

The actual function that converts a list of index values into an offset doesn't involve loops or much in the way of fancy computations. Indeed, it's a slight modification of the formula for computing the address of an element of a single dimension array. The formula to compute the offset for a two-dimension row major ordered array declared in Pascal as "A:array [0..3,0..3] of integer" is

$$\text{Element_Address} = \text{Base_Address} + (\text{colindex} * \text{row_size} + \text{rowindex}) * \text{Element_Size}$$

As usual, *Base_Address* is the address of the first element of the array (*A[0][0]* in this case) and *Element_Size* is the size of an individual element of the array, in bytes. *Colindex* is the leftmost index, *rowindex* is the rightmost index into the array. *Row_size* is the number of elements in one row of the array (four, in this case, since each row has four elements). Assuming *Element_Size* is one, this formula computes the following offsets from the base address:

| Column index | Row Index | Offset into Array |
|-----------------|--------------|-------------------|
| 0 | 0 | 0 |
| 0 | 1 | 1 |
| 0 | 2 | 2 |
| 0 | 3 | 3 |
| 1 | 0 | 4 |
| 1 | 1 | 5 |
| 1 | 2 | 6 |
| 1 | 3 | 7 |
| 2 | 0 | 8 |
| 2 | 1 | 9 |
| 2 | 2 | 10 |
| 2 | 3 | 11 |
| 3 | 0 | 12 |
| 3 | 1 | 13 |
| 3 | 2 | 14 |
| 3 | 3 | 15 |

For a three-dimensional array, the formula to compute the offset into memory is the following:

$$\text{Address} = \text{Base} + ((\text{depthindex} * \text{col_size} + \text{colindex}) * \text{row_size} + \text{rowindex}) * \text{Element_Size}$$

4. By the way, the number of dimensions of an array is its *arity*.

Col_size is the number of items in a column, *row_size* is the number of items in a row. In C/C++, if you've declared the array as "type A[i] [j] [k];" then *row_size* is equal to *k* and *col_size* is equal to *j*.

For a four dimensional array, declared in C/C++ as "type A[i] [j] [k] [m];" the formula for computing the address of an array element is

```
Address =
Base + (((LeftIndex * depth_size + depthindex) * col_size + colindex) * row_size +
rowindex) * Element_Size
```

Depth_size is equal to *j*, *col_size* is equal to *k*, and *row_size* is equal to *m*. *LeftIndex* represents the value of the leftmost index.

By now you're probably beginning to see a pattern. There is a generic formula that will compute the offset into memory for an array with *any* number of dimensions, however, you'll rarely use more than four.

Another convenient way to think of row major arrays is as arrays of arrays. Consider the following single dimension Pascal array definition:

```
A: array [0..3] of sometype;
```

Assume that *sometype* is the type "sometype = array [0..3] of char;".

A is a single dimension array. Its individual elements happen to be arrays, but you can safely ignore that for the time being. The formula to compute the address of an element of a single dimension array is

```
Element_Address = Base + Index * Element_Size
```

In this case *Element_Size* happens to be four since each element of *A* is an array of four characters. So what does this formula compute? It computes the base address of each row in this 4x4 array of characters (see Figure 4.5):

Figure 4.5 Viewing a 4x4 Array as an Array of Arrays

Of course, once you compute the base address of a row, you can reapply the single dimension formula to get the address of a particular element. While this doesn't affect the computation at all, conceptually it's probably a little easier to deal with several single dimension computations rather than a complex multidimensional array element address computation.

Consider a Pascal array defined as "A:array [0..3] [0..3] [0..3] [0..3] [0..3] of char;" You can view this five-dimension array as a single dimension array of arrays. The following Pascal code demonstrates such a definition:

```
type
  OneD = array [0..3] of char;
```

```

TwoD = array [0..3] of OneD;
ThreeD = array [0..3] of TwoD;
FourD = array [0..3] of ThreeD;
var
  A : array [0..3] of FourD;

```

The size of *OneD* is four bytes. Since *TwoD* contains four *OneD* arrays, its size is 16 bytes. Likewise, *ThreeD* is four *TwoDs*, so it is 64 bytes long. Finally, *FourD* is four *ThreeDs*, so it is 256 bytes long. To compute the address of “A [b, c, d, e, f]” you could use the following steps:

- Compute the address of *A [b]* as “Base + *b* * size”. Here size is 256 bytes. Use this result as the new base address in the next computation.
- Compute the address of *A [b, c]* by the formula “Base + *c**size”, where *Base* is the value obtained immediately above and size is 64. Use the result as the new base in the next computation.
- Compute the address of *A [b, c, d]* by “Base + *d**size” with *Base* coming from the above computation and size being 16.
- Compute the address of *A [b, c, d, e]* with the formula “Base + *e**size” with *Base* from above and size being four. Use this value as the base for the next computation.
- Finally, compute the address of *A [b, c, d, e, f]* using the formula “Base + *f**size” where base comes from the above computation and size is one (obviously you can simply ignore this final multiplication). The result you obtain at this point is the address of the desired element.

Not only is this scheme easier to deal with than the fancy formulae given earlier, but it is easier to compute (using a single loop) as well. Suppose you have two arrays initialized as follows

$$A1 = [256, 64, 16, 4, 1] \quad \text{and} \quad A2 = [b, c, d, e, f]$$

then the Pascal code to perform the element address computation becomes:

```

for i := 0 to 4 do
  base := base + A1[i] * A2[i];

```

Presumably *base* contains the base address of the array before executing this loop. Note that you can easily extend this code to any number of dimensions by simply initializing *A1* and *A2* appropriately and changing the ending value of the for loop.

As it turns out, the computational overhead for a loop like this is too great to consider in practice. You would only use an algorithm like this if you needed to be able to specify the number of dimensions at run time. Indeed, one of the main reasons you won't find higher dimension arrays in assembly language is that assembly language displays the inefficiencies associated with such access. It's easy to enter something like “A [b,c,d,e,f]” into a Pascal program, not realizing what the compiler is doing with the code. Assembly language programmers are not so cavalier – they see the mess you wind up with when you use higher dimension arrays. Indeed, good assembly language programmers try to avoid two dimension arrays and often resort to tricks in order to access data in such an array when its use becomes absolutely mandatory. But more on that a little later.

4.6.2 Column Major Ordering

Column major ordering is the other function frequently used to compute the address of an array element. FORTRAN and various dialects of BASIC (e.g., older versions of Microsoft BASIC) use this method to index arrays.

In row major ordering the rightmost index increased the fastest as you moved through consecutive memory locations. In column major ordering the leftmost index increases the fastest. Pictorially, a column major ordered array is organized as shown in Figure 4.6:

language array declaration syntax, so C/C++, BASIC, and Pascal programmers will feel right at home. To declare a multidimensional array in HLA, you use a declaration like the following:

```
ArrayName: elementType [ comma_separated_list_of_dimension_bounds ];
```

For example, here is a declaration for a 4x4 array of characters:

```
GameGrid: char[ 4, 4 ];
```

Here is another example that shows how to declare a three dimensional array of strings:

```
NameItems: string[ 2, 3, 3 ];
```

Remember, string objects are really pointers, so this array declaration reserves storage for 18 double word pointers ($2*3*3=18$).

As was the case with single dimension arrays, you may initialize every element of the array to a specific value by following the declaration with the assignment operator and an array constant. Array constants ignore dimension information; all that matters is that the number of elements in the array constant correspond to the number of elements in the actual array. The following example shows the *GameGrid* declaration with an initializer:

```
GameGrid: char[ 4, 4 ] :=
[
    'a', 'b', 'c', 'd',
    'e', 'f', 'g', 'h',
    'i', 'j', 'k', 'l',
    'm', 'n', 'o', 'p'
];
```

Note that HLA ignores the indentation and extra whitespace characters (e.g., newlines) appearing in this declaration. It was laid out to enhance readability (which is always a good idea). HLA does not interpret the four separate lines as representing rows of data in the array. Humans do, which is why it's good to lay out the initial data in this manner, but HLA completely ignores the physical layout of the declaration. All that matters is that there are 16 ($4*4$) characters in the array constant. You'll probably agree that this is much easier to read than

```
GameGrid: char[ 4,4 ] :=
[ 'a', 'b', 'c', 'd', 'e', 'f', 'g', 'h', 'i', 'j', 'k', 'l', 'm',
  'n', 'o', 'p' ];
```

Of course, if you have a large array, an array with really large rows, or an array with many dimensions, there is little hope for winding up with something reasonable. That's when comments that carefully explain everything come in handy.

As with single dimension arrays, you can use the DUP operator to initialize each element of a really large array with the same value. The following example initializes a 256x64 array of bytes so that each byte contains the value \$FF:

```
StateValue: byte[ 256, 64 ] := 256*64 dup [$ff];
```

Note the use of a constant expression to compute the number of array elements rather than simply using the constant 16,384 ($256*64$). The use of the constant expression more clearly suggests that this code is initializing each element of a 256x64 element array than does the simple literal constant 16,384.

Another HLA trick you can use to improve the readability of your programs is to use *nested array constants*. The following is an example of an HLA nested array constant:

```
[ [0, 1, 2], [3, 4], [10, 11, 12, 13] ]
```

Whenever HLA encounters an array constant nested inside another array constant, it simply removes the brackets surrounding the nested array constant and treats the whole constant as a single array constant. For example, HLA converts the nested array constant above to the following:

```
[ 0, 1, 2, 3, 4, 10, 11, 12, 13 ]
```

You can take advantage of this fact to help make your programs a little more readable. For multidimensional array constants you can enclose each row of the constant in square brackets to denote that the data in each row is grouped and separate from the other rows. As an example, consider the following declaration for the *GameGrid* array that is identical (as far as HLA is concerned) to the previous declaration:

```
GameGrid: char[ 4, 4 ] :=
    [
        [ 'a', 'b', 'c', 'd' ],
        [ 'e', 'f', 'g', 'h' ],
        [ 'i', 'j', 'k', 'l' ],
        [ 'm', 'n', 'o', 'p' ]
    ];
```

This declaration makes it clearer that the array constant is a 4x4 array rather than just a 16-element one-dimensional array whose elements wouldn't fit all on one line of source code. Little aesthetic improvements like this are what separate mediocre programmers from good programmers.

4.8 Accessing Multidimensional Array Elements in Assembly Language

Well, you've seen the formulae for computing the address of an array element. You've even looked at some Pascal code you could use to access elements of a multidimensional array. Now it's time to see how to access elements of those arrays using assembly language.

The MOV, SHL, and INTMUL instructions make short work of the various equations that compute offsets into multidimensional arrays. Let's consider a two dimension array first:

```
static
    i:      int32;
    j:      int32;
    TwoD:   int32[ 4, 8 ];
    .
    .
    .

// To perform the operation TwoD[i,j] := 5; you'd use code like the following.
// Note that the array index computation is (i*8 + j)*4.

    mov( i, ebx );
    shl( 3, ebx );      // Multiply by eight (shl by 3 is a multiply by 8).
    add( j, ebx );
    mov( 5, TwoD[ ebx*4 ] );
```

Note that this code does *not* require the use of a two register addressing mode on the 80x86. Although an addressing mode like *TwoD[ebx][esi]* looks like it should be a natural for accessing two dimensional arrays, that isn't the purpose of this addressing mode.

Now consider a second example that uses a three dimension array:

```
static
    i:      int32;
    j:      int32;
    k:      int32;
    ThreeD: int32[ 3, 4, 5 ];
    .
    .
    .

// To perform the operation ThreeD[i,j,k] := ESI; you'd use the following code
```

```
// that computes ((i*4 + j)*5 + k)*4 as the address of ThreeD[i,j,k].
mov( i, ebx );
shl( 2, ebx );      // Four elements per column.
add( j, ebx );
intmul( 5, ebx );   // Five elements per row.
add( k, ebx );
mov( esi, ThreeD[ ebx*4 ] );
```

Note that this code uses the INTMUL instruction to multiply the value in EBX by five. Remember, the SHL instruction can only multiply a register by a power of two. While there are ways to multiply the value in a register by a constant other than a power of two, the INTMUL instruction is more convenient⁵.

4.9 Large Arrays and MASM

There is a defect in later versions of MASM v6.x that create some problems when you declare large static arrays in your programs. Now you may be wondering what this has to do with you since we're using HLA, but don't forget that HLA v1.x compiles to MASM assembly code and then runs MASM to assemble this output. Therefore, any defect in MASM is going to be a problem for HLA users.

The problem occurs when the total number of array elements you declare in a static section (STATIC, READONLY, or STORAGE) starts to get large. Large in this case is CPU dependent, but it falls somewhere between 128,000 and one million elements for most systems. MASM, for whatever reason, uses a very slow algorithm to emit array code to the object file; by the time you declare 64K array elements, MASM starts to produce a noticeable delay while compiling your code. After that point, the delay grows linearly with the number of array elements (i.e., as you double the number of array elements you double the assembly time) until the data saturates MASM's internal buffers and the cache. Then there is a big jump in execution time. For example, on a 300 MHz Pentium II processor, compiling a program with an array with 256,000 elements takes about 30 seconds, compiling a program with an array having 512,000 element takes several minutes. Compiling a program with a one-megabyte array seems to take forever.

There are a couple of ways to solve this problem. First, of course, you can limit the size of your arrays in your program. Unfortunately, this isn't always an option available to you. The second possibility is to use MASM v6.11; the defect was introduced in MASM after this version. The problem with MASM v6.11 is that it doesn't support the MMX instruction set, so if you're going to compile MMX instructions (or other instructions that MASM v6.11 doesn't support) with HLA you will not be able to use this option. A third option is to put your arrays in a VAR section rather than a static declaration section; HLA processes arrays you declare in the VAR section so MASM never sees them. Hence, arrays you declare in the VAR section don't suffer from this problem.

4.10 Dynamic Arrays in Assembly Language

One problem with arrays up to this point is that their size is static. That is, the number of elements in all of the examples is chosen when writing the program, it is not set while the program is running (i.e., dynamically). Alas, sometimes you simply don't know how big an array needs to be when you're writing the program; you can only determine the size of the array while the program is running. This section describes how to allocate storage for arrays dynamically so you can set their size at run time.

Allocating storage for a single dimension array, and accessing elements of that array, is a nearly trivial task at run time. All you need to do is call the HLA Standard Library *malloc* routine specifying the size of the array, in bytes. *Malloc* will return a pointer to the base address of the new array in the EAX register. Typically, you would save this address in a pointer variable and use that value as the base address of the array in all future array accesses.

5. A full discussion of multiplication by constants other than a power of two appears in the chapter on arithmetic.

To access an element of a single dimensional dynamic array, you would generally load the base address into a register and compute the index in a second register. Then you could use the based indexed addressing mode to access elements of that array. This is not a whole lot more work than accessing elements of a statically allocated array. The following code fragment demonstrates how to allocate and access elements of a single dimension dynamic array:

```
static
    ArySize:      uns32;
    BaseAdrs:    pointer to uns32;
    .
    .
    .
    stdout.put( "How many elements do you want in your array? " );
    stdin.getu32();
    mov( eax, ArySize;          // Save away the upper bounds on this array.
    shl( 2, eax );             // Multiply eax by four to compute the number of bytes.
    malloc( eax );             // Allocate storage for the array.
    mov( eax, BaseAdrs );      // Save away the base address of the new array.
    .
    .
    .

// Zero out each element of the array:

mov( BaseAdrs, ebx );
mov( 0, eax );
for( mov(0, esi); esi < ArySize; inc( esi ) ) do

    mov( eax, [ebx + esi*4 ]);

endfor;
```

Dynamically allocating storage for a multidimensional array is fairly straight-forward. The number of elements in a multidimensional array is the product of all the dimension values; e.g., a 4x5 array has 20 elements. So if you get the bounds for each dimension from the user, all you need do is compute the product of all of these bound values and multiply the final result by the size of a single element. This computes the total number of bytes in the array, the value that *malloc* expects.

Accessing elements of multidimensional arrays is a little more problematic. The problem is that you need to keep the dimension information (that is, the bounds on each dimension) around because these values are needed when computing the row major (or column major) index into the array⁶. The conventional solution is to store these bounds into a static array (generally you know the *arity*, or number of dimensions, at compile-time, so it is possible to statically allocate storage for this array of dimension bounds). This array of dynamic array bounds is known as a *dope vector*. The following code fragment shows how to allocate storage for a two-dimensional dynamic array using a simple dope vector.

```
var
    ArrayPtr:  pointer to uns32;
    ArrayDims: uns32 [2];
    .
    .
    .
    // Get the array bounds from the user:

    stdout.put( "Enter the bounds for dimension #1: " );
    stdin.get( ArrayDims [0] );
```

6. Technically, you don't need the value of the left-most dimension bound to compute an index into the array, however, if you want to check the index bounds using the BOUND instruction (or some other technique), you will need this value around at run-time as well.

```

stdout.put( "Enter the bounds for dimension #2: " );
stdin.get( ArrayDims[1*4] );

// Allocate storage for the array:

mov( ArrayDims[0], eax );
intmul( ArrayDims[1*4], eax );
shl( 2, eax );          // Multiply by four since each element is 4 bytes.
malloc( eax );          // Allocate storage for the array and
mov( eax, ArrayPtr );   // save away the pointer to the array.

// Initialize the array:

mov( 0, edx );
mov( ArrayPtr, edi );
for( mov( 0, ebx ); ebx < ArrayDims[0]; inc( ebx ) ) do

    for( mov( 0, ecx ); ecx < ArrayDims[1*4]; inc( ecx ) ) do

        // Compute the index into the array
        // as esi := ( ebx * ArrayDims[1*4] + ecx ) * 4
        // (Note that the final multiplication by four is
        // handled by the scaled indexed addressing mode below.)

        mov( ebx, esi );
        intmul( ArrayDims[1*4], esi );
        add( ecx, esi );

        // Initialize the current array element with edx.

        mov( edx, [edi+esi*4] );
        inc( edx );

    endfor;

endfor;

```

4.11 HLA Standard Library Array Support

The HLA Standard Library provides an array module that helps reduce the effort needed to support static and dynamic arrays in your program. The “arrays.hhf” library module provides code to declare and allocate dynamic arrays, compute the index into an array, copy arrays, perform row reductions, transpose arrays, and more. This section will explore some of the more useful features the arrays module provides.

One of the more interesting features of the HLA Standard Library arrays module is that most of the array manipulation procedures support both statically allocated and dynamically allocated arrays. In fact, the HLA array procedures can automatically figure out if an array is static or dynamic and generate the appropriate code for that array. There is one catch, however. In order for HLA to be able to differentiate statically and dynamically allocated arrays, you must use the dynamic array declarations found in the arrays package. This won’t be a problem because HLA’s dynamic array facilities are powerful and very easy to use.

To declare a dynamic array with the HLA arrays package, you use a variable declaration like the following:

```
variableName: array.dArray( elementType, Arity );
```

The *elementType* parameter is a regular HLA data type identifier (e.g., *int32* or some type identifier you've defined in the TYPE section). The *Arity* parameter is a constant that specifies the number of dimensions for the array (*arity* is the formal name for "number of dimensions"). Note that you do not specify the bounds of each dimension in this declaration. Storage allocation occurs later, at run time. The following is an example of a declaration for a dynamically allocated two-dimensional matrix:

```
ScreenBuffer: array.dArray( char, 2 );
```

The *array.dArray* data type is actually an HLA macro⁷ that expands the above to the following:

```
ScreenBuffer: record
    dataPtr:      dword;
    dopeVector:   uns32[ 2 ];
    elementType: char;
endrecord;
```

The *dataPtr* field will hold the base address of the array once the program allocates storage for it. The *dopeVector* array has one element for each array dimension (the macro uses the second parameter of the *array.dArray* type as the number of dimensions for the *dopeVector* array). The *elementType* field is a single object that has the same type as an element of the dynamic array. HLA provides a couple of built-in functions that you can use on these fields to extract important information. The *@Elements* function returns the number of elements in an array. Therefore, "*@Elements(ScreenBuffer.dopeVector)*" will return the number of elements (two) in the *ScreenBuffer.dopeVector* array. Since this array contains one element for each dimension in the dynamic array, you can use the *@Elements* function with the *dopeVector* field to determine the arity of the array. You can use the HLA *@Size* function on the *ScreenBuffer.elementType* field to determine the size of an array element in the dynamic array. Most of the time you will know the arity and type of your dynamic arrays (after all, you declared them), so you probably won't use these functions often until you start writing macros that process dynamic arrays.

After you declare a dynamic array, you must initialize the dynamic array object before attempting to use the array. The HLA Standard Library *array.daAlloc* routine handles this task for you. This routine uses the following syntax:

```
array.daAlloc( arrayName, comma_separated_list_of_array_bounds );
```

To allocate storage for the *ScreenBuffer* variable in the previous example you could use a call like the following:

```
array.daAlloc( ScreenBuffer, 20, 40 );
```

This call will allocate storage for a 20x40 array of characters. It will store the base address of the array into the *ScreenBuffer.dataPtr* field. It will also initialize *ScreenBuffer.dopeVector[0]* with 20 and *ScreenBuffer.dopeVector[1*4]* with 40. To access elements of the *ScreenBuffer* array you can use the techniques of the previous section, or you could use the *array.index* function.

The *array.index* function automatically computes the address of an array element for you. This function uses the following call syntax:

```
array.index( reg32, arrayName, comma_separated_list_of_index_values );
```

The first parameter must be a 32-bit register. The *array.index* function will store the address of the specified array element in this register. The second *array.index* parameter must be the name of an array; this can be either a statically allocated array or an array you've declared with *array.dArray* and allocated dynamically with *array.daAlloc*. Following the array name parameter is a list of one or more array indices. The number of array indices must match the arity of the array. These array indices can be constants, *dword* memory variables, or registers (however, you must not specify the same register that appears in the first parameter as one of the array indices). Upon return from this function, you may access the specified array element using the register indirect addressing mode and the register appearing as the first parameter.

7. See the chapter on Macros and the HLA Compile-Time Language for details on macros.

One last routine you'll want to know about when manipulating HLA dynamic arrays is the *array.daFree* routine. This procedure expects a single parameter that is the name of an HLA dynamic array. Calling *array.daFree* will free the storage associated with the dynamic array. The following code fragment is a rewrite of the example from the previous section that uses HLA dynamic arrays:

```
var
    da:      array.dArray( uns32, 2 );
    Bnd1:    uns32;
    Bnd2:    uns32;
    .
    .
    .
// Get the array bounds from the user:

stdout.put( "Enter the bounds for dimension #1: " );
stdin.get( Bnd1 );

stdout.put( "Enter the bounds for dimension #2: " );
stdin.get( Bnd2 );

// Allocate storage for the array:

array.daAlloc( da, Bnd1, Bnd2 );

// Initialize the array:

mov( 0, edx );
for( mov( 0, ebx ); ebx < Bnd1; inc( ebx ) ) do

    for( mov( 0, ecx ); ecx < Bnd2; inc( ecx ) ) do

        // Initialize the current array element with edx.
        // Use array.index to compute the address of the array element.

        array.index( edi, da, ebx, ecx );
        mov( edx, [edi] );
        inc( edx );

    endfor;

endfor;
```

Another extremely useful library module is the *array.cpy* routine. This procedure will copy the data from one array to another. The calling syntax is:

```
array.cpy( sourceArrayName, destArrayName );
```

The source and destination arrays can be static or dynamic arrays. The *array.cpy* automatically adjusts and emits the proper code for each combination of parameters. With most of the array manipulation procedures in the HLA Standard Library, you pay a small performance penalty for the convenience of these library modules. Not so with *array.cpy*. This procedure is very, very fast; much faster than writing a loop to copy the data element by element.

4.12 Putting It All Together

Accessing elements of an array is a very common operation in assembly language programs. This chapter provides the basic information you need to efficiently access array elements. After mastering the material

in this chapter you should know how to declare arrays in HLA and access elements of those arrays in your programs.

Records, Unions, and Name Spaces

Chapter Five

5.1 Chapter Overview

This chapter discusses how to declare and use record (structures), unions, and name spaces in your programs. After strings and arrays, records are among the most commonly used composite data types; indeed, records are the mechanism you use to create user-defined composite data types. Many assembly language programmers never bother to learn how to use records in assembly language, yet would never consider not using them in high level language programs. This is somewhat inconsistent since records (structures) are just as useful in assembly language programs as in high level language programs. Given that you use records in assembly language (and especially HLA) in a manner quite similar to high level languages, there really is no reason for excluding this important tool from your programmer's tool chest. Although you'll use unions and name spaces far less often than records, their presence in the HLA language is crucial for many advanced applications. This brief chapter provides all the information you need to successfully use records, unions, and name spaces within your HLA programs.

5.2 Records

Another major composite data structure is the Pascal *record* or C/C++ *structure*¹. The Pascal terminology is probably better, since it tends to avoid confusion with the more general term *data structure*. Since HLA uses the term "record" we'll adopt that term here.

Whereas an array is homogeneous, whose elements are all the same, the elements in a record can be of any type. Arrays let you select a particular element via an integer index. With records, you must select an element (known as a *field*) by name.

The whole purpose of a record is to let you encapsulate different, but logically related, data into a single package. The Pascal record declaration for a student is probably the most typical example:

```
student =
  record
    Name: string [64];
    Major: integer;
    SSN: string[11];
    Midterm1: integer;
    Midterm2: integer;
    Final: integer;
    Homework: integer;
    Projects: integer;
  end;
```

Most Pascal compilers allocate each field in a record to contiguous memory locations. This means that Pascal will reserve the first 65 bytes for the name², the next two bytes hold the major code, the next 12 the Social Security Number, etc.

In HLA, you can also create structure types using the RECORD/ENDRECORD declaration. You would encode the above record in HLA as follows:

```
type
  student: record
    Name: char [65];
    Major: int16;
    SSN: char [12];
    Midterm1: int16;
```

1. It also goes by some other names in other languages, but most people recognize at least one of these names.
2. Strings require an extra byte, in addition to all the characters in the string, to encode the length.

```

Midterm2: int16;
Final: int16;
Homework: int16;
Projects: int16;
endrecord;

```

As you can see, the HLA declaration is very similar to the Pascal declaration. Note that, to be true to the Pascal declaration, this example uses character arrays rather than strings for the *Name* and *SSN* (U.S Social Security Number) fields. In a real HLA record declaration you'd probably use a string type for at least the name (keeping in mind that a string variable is only a four byte pointer).

The field names within the record must be unique. That is, the same name may not appear two or more times in the same record. However, all field names are local to that record. Therefore, you may reuse those field names elsewhere in the program.

The RECORD/ENDRECORD type declaration may appear in a variable declaration section (e.g., STATIC or VAR) or in a TYPE declaration section. In the previous example the *Student* declaration appears in the TYPE section, so this does not actually allocate any storage for a *Student* variable. Instead, you have to explicitly declare a variable of type *Student*. The following example demonstrates how to do this:

```

var
  John: Student;

```

This allocates 81 bytes of storage laid out in memory as shown in Figure 5.1.

Figure 5.1 Student Data Structure Storage in Memory

If the label *John* corresponds to the *base address* of this record, then the *Name* field is at offset *John+0*, the *Major* field is at offset *John+65*, the *SSN* field is at offset *John+67*, etc.

To access an element of a structure you need to know the offset from the beginning of the structure to the desired field. For example, the *Major* field in the variable *John* is at offset 65 from the base address of *John*. Therefore, you could store the value in AX into this field using the instruction

```

mov( ax, (type word John[65]) );

```

Unfortunately, memorizing all the offsets to fields in a record defeats the whole purpose of using them in the first place. After all, if you've got to deal with these numeric offsets why not just use an array of bytes instead of a record?

Well, as it turns out, HLA lets you refer to field names in a record using the same mechanism C/C++ and Pascal use: the dot operator. To store AX into the *Major* field, you could use "mov(ax, John.Major);" instead of the previous instruction. This is much more readable and certainly easier to use.

Note that the use of the dot operator does *not* introduce a new addressing mode. The instruction "mov(ax, John.Major);" still uses the displacement only addressing mode. HLA simply adds the base address of *John* with the offset to the *Major* field (65) to get the actual displacement to encode into the instruction.

Like any type declaration, HLA requires all record type declarations to appear in the program before you use them. However, you don't have to define all records in the TYPE section to create record variables. You can use the RECORD/ENDRECORD declaration directly in a variable declaration section. This is convenient if you have only one instance of a given record object in your program. The following example demonstrates this:

```
storage
```

```
OriginPoint: record
    x: uns8;
    y: uns8;
    z: uns8;
endrecord;
```

5.3 Record Constants

HLA lets you define record constants. In fact, HLA supports both symbolic record constants and literal record constants. Record constants are useful as initializers for static record variables. They are also quite useful as compile-time data structures when using the HLA compile-time language (see the chapters on Macros and the HLA Compile-Time Language). This section discusses how to create record constants.

A record literal constant takes the following form:

```
RecordTypeName: [ List_of_comma_separated_constants ]
```

The *RecordTypeName* is the name of a record data type you've defined in an HLA TYPE section prior to this point. To create a record constant you must have previously defined the record type in a TYPE section of your program.

The constant list appearing between the brackets are the data items for each of the fields in the specified record. The first item in the list corresponds to the first field of the record, the second item in the list corresponds to the second field, etc. The data types of each of the constants appearing in this list must match their respective field types. The following example demonstrates how to use a literal record constant to initialize a record variable:

```
type
    point: record
        x:int32;
        y:int32;
        z:int32;
    endrecord;

static
    Vector: point := point:[ 1, -2, 3 ];
```

This declaration initializes *Vector.x* with 1, *Vector.y* with -2, and *Vector.z* with 3.

You can also create symbolic record constants by declaring record objects in the CONST or VAL sections of your program. You access fields of these symbolic record constants just as you would access the field of a record variable, using the dot operator. Since the object is a constant, you can specify the field of a record constant anywhere a constant of that field's type is legal. You can also employ symbolic record constants as record variable initializers. The following example demonstrates this:

```
type
    point: record
        x:int32;
        y:int32;
        z:int32;
    endrecord;

const
    PointInSpace: point := point:[ 1, 2, 3 ];
```

```
static
    Vector: point := PointInSpace;
    XCoord: int32 := PointInSpace.x;
    .
    .
```

```

    .
    stdout.put( "Y Coordinate is ", PointInSpace.y, nl );
    .
    .
    .

```

5.4 Arrays of Records

It is a perfectly reasonable operation to create an array of records. To do so, you simply create a record type and then use the standard array declaration syntax when declaring an array of that record type. The following example demonstrates how you could do this:

```

type
  recElement:
    record
      << fields for this record >>
    endrecord;
  .
  .
  .
static
  recArray: recElement[4];

```

To access an element of this array you use the standard array indexing techniques found in the chapter on arrays. Since *recArray* is a single dimension array, you'd compute the address of an element of this array using the formula "baseAddress + index*@size(recElement)." For example, to access an element of *recArray* you'd use code like the following:

```

// Access element i of recArray:

  intmul( @size( recElement ), i, ebx ); // ebx := i*@size( recElement )
  mov( recArray.someField[ebx], eax );

```

Note that the index specification follows the entire variable name; remember, this is assembly not a high level language (in a high level language you'd probably use "recArray[i].someField").

Naturally, you can create multidimensional arrays of records as well. You would use the standard row or column major order functions to compute the address of an element within such records. The only thing that really changes (from the discussion of arrays) is that the size of each element is the size of the record object.

```

static
  rec2D: recElement[ 4, 6 ];
  .
  .
  .
// Access element [i,j] of rec2D and load "someField" into EAX:

  intmul( 6, i, ebx );
  add( j, ebx );
  intmul( @size( recElement ), ebx );
  mov( rec2D.someField[ ebx ], eax );

```

5.5 Arrays/Records as Record Fields

Records may contain other records or arrays as fields. Consider the following definition:

```

type

```

```

Pixel:
  record
    Pt:      point;
    color:   dword;
  endrecord;

```

The definition above defines a single point with a 32 bit color component. When initializing an object of type *Pixel*, the first initializer corresponds to the *Pt* field, *not the x-coordinate field*. **The following definition is incorrect:**

```

static
  ThisPt: Pixel := Pixel:[ 5, 10 ]; // Syntactically incorrect!

```

The value of the first field (“5”) is not an object of type *point*. Therefore, the assembler generates an error when encountering this statement. HLA will allow you to initialize the fields of *Pixel* using declarations like the following:

```

static
  ThisPt: Pixel := Pixel:[ point:[ 1, 2, 3 ], 10 ];
  ThatPt: Pixel := Pixel:[ point:[ 0, 0, 0 ], 5 ];

```

Accessing *Pixel* fields is very easy. Like a high level language you use a single period to reference the *Pt* field and a second period to access the *x*, *y*, and *z* fields of *point*:

```

  stdout.put( "ThisPt.Pt.x = ", ThisPt.Pt.x, nl );
  stdout.put( "ThisPt.Pt.y = ", ThisPt.Pt.y, nl );
  stdout.put( "ThisPt.Pt.z = ", ThisPt.Pt.z, nl );
  .
  .
  .
  mov( eax, ThisPt.Color );

```

You can also declare *arrays* as record fields. The following record creates a data type capable of representing an object with eight points (e.g., a cube):

```

type
  Object8:
    record
      Pts:      point [8];
      Color:    dword;
    endrecord;

```

This record allocates storage for eight different points. Accessing an element of the *Pts* array requires that you know the size of an object of type *point* (remember, you must multiply the index into the array by the size of one element, 12 in this particular case). Suppose, for example, that you have a variable *CUBE* of type *Object8*. You could access elements of the *Pts* array as follows:

```

// CUBE.Pts[i].x := 0;

  mov( i, ebx );
  intmul( 12, ebx );
  mov( 0, CUBE.Pts.x[ebx] );

```

The one unfortunate aspect of all this is that you must know the size of each element of the *Pts* array. Fortunately, HLA provides a built-in function that will compute the size of an array element (in bytes) for you: the *@size* function. You can rewrite the code above using *@size* as follows:

```

// CUBE.Pts[i].x := 0;

  mov( i, ebx );
  intmul( @size( point ), ebx );
  mov( 0, CUBE.Pts.x[ebx] );

```

This solution is much better than multiplying by the literal constant 12. Not only does HLA figure out the size for you (so you don’t have to), it automatically substitutes the correct size if you ever change the def-

inition of the *point* record in your program. For this reason, you should always use the @size function to compute the size of array element objects in your programs.

Note in this example that the index specification (“[ebx]”) follows the whole object name even though the array is *Pts*, not *x*. Remember, the “[ebx]” specification is an indexed addressing mode, not an array index. Indexes always follow the entire name, you do not attach them to the array component as you would in a high level language like C/C++ or Pascal. This produces the correct result because addition is commutative, and the dot operator (as well as the index operator) corresponds to addition. In particular, the expression “CUBE.Pts.x[ebx]” tells HLA to compute the sum of *CUBE* (the base address of the object) plus the offset to the *Pts* field, plus the offset to the *x* field plus the value of EBX. Technically, we’re really computing $\text{offset}(\text{CUBE}) + \text{offset}(\text{Pts}) + \text{EBX} + \text{offset}(x)$ but we can rearrange this since addition is commutative.

You can also define two-dimensional arrays within a record. Accessing elements of such arrays is no different than any other two-dimensional array other than the fact that you must specify the array’s field name as the base address for the array. E.g.,

```
type
  RecW2DArray:
    record
      intField: int32;
      aField: int32 [4,5];
      .
      .
      .
    endrecord;

static
  recVar: RecW2DArray;
  .
  .
  .
  // Access element [i,j] of the aField field using Row-major ordering:

  mov( i, ebx );
  intmul( 5, ebx );
  add( j, ebx );
  mov( recVar.aField[ ebx*4 ], eax );
  .
  .
  .
```

The code above uses the standard row-major calculation to index into a 4x5 array of double words. The only difference between this example and a stand alone array access is the fact that the base address is *recVar.aField*.

There are two common ways to nest record definitions. As noted earlier in this section, you can create a record type in a TYPE section and then use that type name as the data type of some field within a record (e.g., the *Pt:point* field in the *Pixel* data type above). It is also possible to declare a record directly within another record without creating a separate data type for that record; the following example demonstrates this:

```
type
  NestedRecs:
    record
      iField: int32;
      sField: string;
      rField:
        record
          i:int32;
          u:uns32;
        endrecord;
      cField:char;
    endrecord;
```

Generally, it's a better idea to create a separate type rather than embed records directly in other records, but nesting them is perfectly legal and a reasonable thing to do on occasion.

If you have an array of records and one of the fields of that record type is an array, you must compute the indexes into the arrays independently of one another and then use the sum of these indexes as the ultimate index. The following example demonstrates how to do this:

```

type
  recType:
    record
      arrayField: dword[4,5];
      << Other Fields >>
    endrecord;

static
  aryOfRecs: recType[3,3];
  .
  .
  .
  // Access aryOfRecs[i,j].arrayField[k,l]:

  intmul( 5, i, ebx );           // Computes index into aryOfRecs
  add( j, ebx );                // as (i*5 + j)*@size( recType ).
  intmul( @size( recType ), ebx );

  intmul( 3, k, eax );          // Computes index into aryOfRecs
  add( l, eax );                // as (k*3 + j) (*4 handled later).

  mov( aryOfRecs.arrayField[ ebx + eax*4 ], eax );

```

Note the use of the base plus scaled indexed addressing mode to simplify this operation.

5.6 Controlling Field Offsets Within a Record

By default, whenever you create a record, HLA automatically assigns the offset zero to the first field of that record. This corresponds to records in a high level language and is the intuitive default condition. In some instances, however, you may want to assign a different starting offset to the first field of the record. HLA provides a mechanism that lets you set the starting offset of the first field in the record.

The syntax to set the first offset is

```

name:
  record := startingOffset
    << Record Field Declarations >>
  endrecord;

```

Using the syntax above, the first field will have the starting offset specified by the *startingOffset int32* constant expression. Since this is an *int32* value, the starting offset value can be positive, zero, or negative.

One circumstance where this feature is invaluable is when you have a record whose base address is actually somewhere within the data structure. The classic example is an HLA string. An HLA string uses a record declaration similar to the following:

```

record
  MaxStrLen: dword;
  length: dword;
  charData: char[xxxx];
endrecord;

```

As you're well aware by now, HLA string pointers do not contain the address of the *MaxStrLen* field; they point at the *charData* field. The `str.strRec` record type found in the HLA Standard Library Strings module uses a record declaration similar to the following:

```
type
  strRec:
    record := -8
      MaxStrLen: dword;
      length: dword;
      charData: char;
    endrecord;
```

The starting offset for the *MaxStrLen* field is -8. Therefore, the offset for the *length* field is -4 (four bytes later) and the offset for the *charData* field is zero. Therefore, if EBX points at some string data, then “(type `str.strRec [ebx]`).length” is equivalent to “[`ebx-4`]” since the *length* field has an offset of -4.

Generally, you will not use HLA's ability to specify the starting field offset when creating your own record types. Instead, this feature finds most of its use when you are mapping an HLA data type over the top of some other predefined data type in memory (strings are a good example, but there are many other examples as well).

5.7 Aligning Fields Within a Record

To achieve maximum performance in your programs, or to ensure that HLA's records properly map to records or structures in some high level language, you will often need to be able to control the alignment of fields within a record. For example, you might want to ensure that a *dword* field's offset is an even multiple of four. You use the `ALIGN` directive to do this, the same way you would use `ALIGN` in the `STATIC` declaration section of your program. The following example shows how to align some fields on important boundaries:

```
type
  PaddedRecord:
    record
      c:char;
      align(4);
      d:dword;
      b:boolean;
      align(2);
      w:word;
    endrecord;
```

Whenever HLA encounters the `ALIGN` directive within a record declaration, it automatically adjusts the following field's offset so that it is an even multiple of the value the `ALIGN` directive specifies. It accomplishes this by increasing the offset of that field, if necessary. In the example above, the fields would have the following offsets: *c*:0, *d*:4, *b*:8, *w*:10. Note that HLA inserts three bytes of padding between *c* and *d* and it inserts one byte of padding between *b* and *w*. It goes without saying that you should never assume that this padding is present. If you want to use those extra bytes, then declare fields for them.

Note that specifying alignment within a record declaration does not guarantee that the field will be aligned on that boundary in memory; it only ensures that the field's offset is aligned on the specified boundary. If a variable of type *PaddedRecord* starts at an odd address in memory, then the *d* field will also start at an odd address (since any odd address plus four is an odd address). If you want to ensure that the fields are aligned on appropriate boundaries in memory, you must also use the `ALIGN` directive before variable declarations of that record type, e.g.,

```
static
  .
  .
  .
  align(4);
```

```
PRvar: PaddedRecord;
```

The value of the `ALIGN` operand should be an even value that is evenly divisible by the largest `ALIGN` expression within the record type (four is the largest value in this case, and it's already evenly divisible by two).

If you want to ensure that the record's size is a multiple of some value, then simply stick an `ALIGN` directive as the last item in the record declaration. HLA will emit an appropriate number of bytes of padding at the end of the record to fill it in to the appropriate size. The following example demonstrates how to ensure that the record's size is a multiple of four bytes:

```
type
  PaddedRec:
    record
      << some field declarations >>

      align(4);
    endrecord;
```

5.8 Pointers to Records

During execution, your program may refer to structure objects directly or indirectly using a pointer. When you use a pointer to access fields of a structure, you must load one of the 80x86's 32-bit registers with the address of the desired record. Suppose you have the following variable declarations (assuming the *Object8* structure from "Arrays/Records as Record Fields" on page 468):

```
static
  Cube:      Object8;
  CubePtr:   pointer to Object8 := &Cube;
```

CubePtr contains the address of (i.e., it is a pointer to) the *Cube* object. To access the *Color* field of the *Cube* object, you could use an instruction like "mov(Cube.Color, eax);". When accessing a field via a pointer you need to load the address of the object into a 32-bit register such as EBX. The instruction "mov(CubePtr EBX);" will do the trick. After doing so, you can access fields of the *Cube* object using the [EBX+offset] addressing mode. The only problem is "How do you specify which field to access?" Consider briefly, the following *incorrect* code:

```
mov( CubePtr, ebx );
mov( [ebx].Color, eax );    // This does not work!
```

There is one major problem with the code above. Since field names are local to a structure and it's possible to reuse a field name in two or more structures, how does HLA determine which offset *Color* represents? When accessing structure members directly (e.g., "mov(Cube.Color, EAX);") there is no ambiguity since *Cube* has a specific type that the assembler can check. "[EBX]", on the other hand, can point at *anything*. In particular, it can point at any structure that contains a *Color* field. So the assembler cannot, on its own, decide which offset to use for the *Color* symbol.

HLA resolves this ambiguity by requiring that you explicitly supply a type. To do this, you must coerce "[EBX]" to type *Cube*. Once you do this, you can use the normal dot operator notation to access the *Color* field:

```
mov( CubePtr, ebx );
mov( (type Cube [ebx]).Color, eax );
```

By specifying the record name, HLA knows which offset value to use for the *Color* symbol.

If you have a pointer to a record and one of that record's fields is an array, the easiest way to access elements of that field is by using the base plus indexed addressing mode. To do so, you just load the pointer to the record into one register and compute the index into the array in a second register. Then you combine these two registers in the address expression. In the example above, the *Pts* field is an array of eight *point* objects. To access field *x* of the *i*th element of the *Cube.Pts* field, you'd use code like the following:

```

mov( CubePtr, ebx );
intmul( @size( point ), i, esi ); // Compute index into point array.
mov( (type Object8 [ebx]).Pts.x[ esi*4 ], eax );

```

As usual, the index appears after all the field names.

If you use a pointer to a particular record type frequently in your program, typing a coercion operator like “(type Object8 [ebx])” can get old pretty quick. One way to reduce the typing needed to coerce EBX is to use a TEXT constant. For example, consider the following statement in a program:

```

const
  O8ptr: text := "(type Object8 [ebx])";

```

With this statement at the beginning of your program you can use *O8ptr* in place of the type coercion operator and HLA will automatically substitute the appropriate text. With a text constant like the above, the former example becomes a little more readable and writable:

```

mov( CubePtr, ebx );
intmul( @size( point ), i, esi ); // Compute index into point array.
mov( O8Ptr.Pts.x[ esi*4 ], eax );

```

5.9 Unions

A record definition assigns different offsets to each field in the record according to the size of those fields. This behavior is quite similar to the allocation of memory offsets in a VAR or STATIC section. HLA provides a second type of structure declaration, the UNION, that does not assign different addresses to each object; instead, each field in a UNION declaration has the same offset – zero. The following example demonstrates the syntax for a UNION declaration:

```

type
  unionType:
    union
      << fields (syntactically identical to record declarations) >>
    endunion;

```

You access the fields of a UNION exactly the same way you access the fields of a record: using dot notation and field names. The following is a concrete example of a UNION type declaration and a variable of the UNION type:

```

type
  numeric:
    union
      i: int32;
      u: uns32;
      r: real64;
    endunion;
    .
    .
    .
static
  number: numeric;
    .
    .
    .
  mov( 55, number.u );
    .
    .
    .
  mov( -5, number.i );
    .

```

```
stdout.put( "Real value = ", number.r, nl );
```

The important thing to note about UNION objects is that all the fields of a UNION have the same offset in the structure. In the example above, the *number.u*, *number.i*, and *number.r* fields all have the same offset: zero. Therefore, the fields of a UNION overlap one another in memory; this is very similar to the way the eight, sixteen, and thirty-two bit registers overlap one another. Usually, access to the fields of a UNION are mutually exclusive; that is, you do not manipulate separate fields of a particular UNION variable concurrently because writing to one field overwrites the other fields. In the example above, any modification of *number.u* would also change *number.i* and *number.r*.

Programmers typically use UNIONS for two different reasons: to conserve memory or to create aliases. Memory conservation is the intended use of this data structure facility. To see how this works, let's compare the *numeric* UNION above with a corresponding record type:

```
type
  numericRec:
    record
      i: int32;
      u: uns32;
      r: real64;
    endrecord;
```

If you declare a variable, say *n*, of type *numericRec*, you access the fields as *n.i*, *n.u*, and *n.r*; exactly as though you had declared the variable to be type *numeric*. The difference between the two is that *numericRec* variables allocate separate storage for each field of the record while *numeric* objects allocate the same storage for all fields. Therefore, *@size(numericRec)* is 16 since the record contains two double word fields and a quad word (*real64*) field. *@size(numeric)*, however, is eight. This is because all the fields of a UNION occupy the same memory locations and the size of a UNION object is the size of the largest field of that object (see Figure 5.2).

Figure 5.2 Layout of a UNION versus a RECORD Variable

In addition to conserving memory, programmers often use UNIONS to create aliases in their code. As you may recall, an alias is a different name for the same memory object. Aliases are often a source of confusion in a program so you should use them sparingly; sometimes, however, using an alias can be quite convenient. For example, in some section of your program you might need to constantly use type coercion to refer to an object using a different type. Although you can use an HLA TEXT constant to simplify this process,

another way to do this is to use a UNION variable with the fields representing the different types you want to use for the object. As an example, consider the following code:

```
type
  CharOrUns:
    union
      c:char;
      u:uns32;
    endrecord;

static
  v:CharOrUns;
```

With a declaration like the above, you can manipulate an *uns32* object by accessing *v.u*. If, at some point, you need to treat the L.O. byte of this *uns32* variable as a character, you can do so by simply accessing the *v.c* variable, e.g.,

```
mov( eax, v.u );
stdout.put( "v, as a character, is '", v.c, "' nl );
```

You can use UNIONS exactly the same way you use RECORDs in an HLA program. In particular, UNION declarations may appear as fields in RECORDs, RECORD declarations may appear as fields in UNIONS, array declarations may appear within UNIONS, you can create arrays of UNIONS, etc.

5.10 Anonymous Unions

Within a RECORD declaration you can place a UNION declaration without specifying a fieldname for the union object. The following example demonstrates the syntax for this:

```
type
  HasAnonUnion:
    record
      r:real64;
      union
        u:uns32;
        i:int32;
      endunion;
      s:string;
    endrecord;

static
  v: HasAnonUnion;
```

Whenever an anonymous union appears within an RECORD you can access the fields of the UNION as though they were direct fields of the RECORD. In the example above, for example, you would access *v's u* and *i* fields using the syntax "*v.u*" and "*v.i*", respectively. The *u* and *i* fields have the same offset in the record (eight, since they follow a *real64* object). The fields of *v* have the following offsets from *v's* base address:

```
v.r    0
v.u    8
v.i    8
v.s   12
```

@*size(v)* is 16 since the *u* and *i* fields only consume four bytes between them.

Warning: HLA gets confused if you attempt to create a record constant when that record has anonymous unions (HLA doesn't allow UNION constants). So don't create record constants of a record if that record contains anonymous unions as fields.

5.11 Variant Types

One big use of UNIONS in programs is to create *variant* types. A variant variable can change its type dynamically while the program is running. A variant object can be an integer at one point in the program, switch to a string at a different part of the program, and then change to a real value at a later time. Many very high level language systems use a dynamic type system (i.e., variant objects) to reduce the overall complexity of the program; indeed, proponents of many very high level languages insist that the use of a dynamic typing system is one of the reasons you can write complex programs in so few lines. Of course, if you can create variant objects in a very high level language, you can certainly do it in assembly language. In this section we'll look at how we can use the UNION structure to create variant types.

Of course, at any one given instant during program execution a variant object has a specific type, but under program control the variable can switch to a different type. Therefore, when the program processes a variant object it must use an IF statement or SWITCH statement to execute a different sequence of instructions based on the object's current type. Very high level languages do this transparently to the program. In assembly language you will have to provide the code to test the type yourself. To achieve this, the variant type needs some additional information beyond the object's value. Specifically, the variant object needs a field that specifies the current type of the object. This field (often known as the *tag* field) is a small enumerated type or integer that specifies the type of the object at any given instant. The following code demonstrates how to create a variant type:

```
type
  VariantType:
    record
      tag:uns32; // 0-uns32, 1-int32, 2-real64
      union
        u:uns32;
        i:int32;
        r:real64;
      endunion;
    endrecord;

static
  v:VariantType;
```

The program would test the *v.tag* field to determine the current type of the *v* object. Based on this test, the program would manipulate the *v.i*, *v.u*, or *v.r* field.

5.12 Namespaces

One really nice feature of RECORDS and UNIONS is that the field names are local to a given RECORD or UNION declaration. That is, you can reuse field names in different RECORDS or UNIONS. This is an important feature of HLA because it helps avoid *name space pollution*. Name space pollution occurs when you use up all the “good” names within the current scope and you have to start creating non-descriptive names for some object because you've already used the most appropriate name for something else. Because you can reuse names in different RECORD/UNION definitions (and you can even reuse those names outside of the RECORD/UNION definitions) you don't have to dream up new names for the objects that have less meaning. We use the term *namespace* to describe how HLA associates names with a particular object. The field names of a RECORD have a namespace that is limited to objects of that record type. HLA provides a generalization of this namespace mechanism that lets you create arbitrary namespaces. These namespace objects let you shield the names of constants, types, variables, and other objects so their names do not interfere with other declarations in your program.

An HLA NAMESPACE section encapsulates a set of generic declarations in much the same way that a RECORD encapsulates a set of variable declarations. A NAMESPACE declaration takes the following form:

```
namespace name;

    << declarations >>

end name;
```

The *name* identifier provides the name for the NAMESPACE. The identifier after the END clause must exactly match the identifier after NAMESPACE. You may have several NAMESPACE declarations within a program as long as the identifiers for the name spaces are all unique. Note that a NAMESPACE declaration section is a section unto itself. It does not have to appear in a TYPE or VAR section. A NAMESPACE may appear anywhere one of the HLA declaration sections is legal. A program may contain any number of NAMESPACE declarations; in fact, the name space identifiers don't even have to be unique as you will soon see.

The declarations that appear between the NAMESPACE and END clauses are all the standard HLA declaration sections except that you cannot nest name space declarations. You may, however, put CONST, VAL, TYPE, STATIC, DATA, READONLY, STORAGE, and VAR sections within a namespace³. The following code provides an example of a typical NAMESPACE declaration in an HLA program:

```
namespace myNames;

    type
        integer: int32;

    static
        i:integer;
        j:uns32;

    const
        pi:real64 := 3.14159;

end myNames;
```

To access the fields of a name space you use the same dot notation that records and unions use. For example, to access the fields of *myNames* outside of the name space you'd use the following identifiers:

```
myNames.integer - A type declaration equivalent to int32.
myNames.i - An integer variable (int32).
myNames.j - An uns32 variable.
myNames.pi - A real64 constant.
```

This example also demonstrates an important point about NAMESPACE declarations: within a name space you may reference other identifiers in that same NAMESPACE declaration without using the dot notation. For example, the *i* field above uses type *integer* from the *myNames* name space without the "mynames." prefix.

What is not obvious from the example above is that NAMESPACE declarations create a clean symbol table whenever you open up a declaration. The only external symbols that HLA recognizes in a NAMESPACE declaration are the predefined type identifiers (e.g., *int32*, *uns32*, and *char*). HLA does not recognize any symbols you've declared outside the NAMESPACE while it is processing your namespace declaration. This creates a problem if you want to use symbols outside the NAMESPACE when declaring other symbols inside the NAMESPACE. For example, suppose the type *integer* had been defined outside *myNames* as follows:

```
type
    integer: int32;

namespace myNames;
```

3. Procedure and macro declarations, the subjects of later chapters, are also legal within a name space declaration section.

```

static
  i:integer;
  j:uns32;

const
  pi:real64 := 3.14159;

end myNames;

```

If you were to attempt to compile this code, HLA would complain that the symbol *integer* is undefined. Clearly *integer* is defined in this program, but HLA hides all external symbols when creating a name space so that you can reuse (and redefine) those symbols within the name space. Of course, this doesn't help much if you actually want to use a name that you've defined outside *myNames* within that name space. HLA provides a solution to this problem: the *@global:* operator. If, within a name space declaration section, you prefix a name with "@global:" then HLA will use the global definition of that name rather than the local definition (if a local definition even exists). To correct the problem in the previous example, you'd use the following code:

```

type
  integer: int32;

namespace myNames;

static
  i:@global:integer;
  j:uns32;

const
  pi:real64 := 3.14159;

end myNames;

```

With the *@global:* prefix, the *i* variable will be type *int32* even if a different declaration of *integer* appears within the *myNames* name space.

You cannot nest NAMESPACE declarations⁴. However, you can have multiple NAMESPACE declarations in the same program that use the same name space identifier, e.g.,

```

namespace ns;

  << declaration group #1 >>

end ns;
.
.
.
namespace ns;

  << declaration group #2 >>

end ns;

```

When HLA encounters a second NAMESPACE declaration for a given identifier, it simply appends the declarations in the second group to the end of the symbol list it created for the first group. Therefore, after processing the two NAMESPACE declarations about, the *ns* name space would contain the set of all symbols you've declared in both the name space blocks.

4. There really doesn't seem to be a need to do this; hence its omission from HLA.

Perhaps the most common use of name spaces is in library modules. If you create a set of library routines to use in various projects or distribute to others, you have to be careful about the names you choose for your functions and other objects. If you use common names like *get* and *put*, the users of your module will complain when your names collide with theirs. An easily solution is to put all your code in a NAMESPACE block. Then the only name you have to worry about is the name of the NAMESPACE itself. This is the only name that will collide with other users' code. That can happen, but it's much less likely to happen than if you don't use a name space and your library module introduces dozens, if not hundreds, of new names into the global name space⁵. The HLA Standard Library provides many good examples of name spaces in use. The HLA Standard Library defines several name spaces like *stdout*, *stdin*, *str*, *cs*, and *console*. You refer to functions in these name spaces using names like *stdout.put*, *stdin.get*, *cs.intersection*, *str.eq*, and *console.gotoxy*. The use of name spaces in the HLA Standard Library prevents conflicts with similar names in your own programs.

5.13 Putting It All Together

One of the more amazing facts about programmer psychology is the fact that a high level language programmer would refuse to use a high level language that doesn't support records or structures; then that same programmer won't bother to learn how to use them in assembly language (all the time, grumbling about their absence). You use records in assembly language for the same reason you use them in high level languages. Given that most programmers consider records and structure essential in high level languages, it is surprising they aren't as concerned about using them in assembly language.

This short chapter demonstrates that it doesn't take much effort to master the concept of records in an assembly language program. Taken together with UNIONS and NAMESPACEs, RECORDs can help you write HLA programs that are far more readable and easier to understand. Therefore, you should use these language features as appropriate when writing assembly code.

Dates and Times

Chapter Six

6.1 Chapter Overview

This chapter discusses dates and times as a data type. In particular, this chapter discusses the data/time data structures the HLA Standard Library defines and it also discusses date arithmetic and other operations on dates and times.

6.2 Dates

For the first 50 years, or so, of the computer's existence, programmers did not give much thought to date calculations. They either used a date/time package provided with their programming language, or they kludged together their own date processing libraries. It wasn't until the Y2K¹ problem came along that programmers began to give dates serious consideration in their programs. The purpose of this chapter is two-fold. First, this chapter teaches that date manipulation is not as trivial as most people would like to believe – it takes a lot of work to properly compute various date functions. Second, this chapter presents the HLA date and time formats found in the “datetime.hhf” library module. Hopefully this chapter will convince you that considerable thought has gone into the HLA datetime.hhf module so you'll be inclined to use it rather than trying to create your own date/time formats and routines.

Although date and time calculations may seem like they should be trivial, they are, in fact, quite complex. Just remember the Y2K problem to get a good idea of the kinds of problems your programs may create if they don't calculate date and time values correctly. Fortunately, you don't have to deal with the complexities of date and time calculations, the HLA Standard Library does the hard stuff for you.

The HLA Standard Library date routines produce valid results for dates between January 1, 1583 and December 31, 9999². HLA represents dates using the following record definition (in the *date* namespace):

```
type
  daterec:
    record
      day:uns8;
      month:uns8;
      year:uns16;
    endrecord;
```

This format (*date.daterec*) compactly represents all legal dates using only four bytes. Note that this is the same date format Volume One presents for the extended data format (see “Bit Fields and Packed Data” on page 71). You should use the *date.daterec* data type when declaring date objects in your HLA programs, e.g.,

```
static
  TodaysDate: date.daterec;
  Century21: date.daterec := date.daterec:[ 1, 1, 2001 ]; // note: d, m ,y
```

As the second example above demonstrates, keep in mind that the first field is the day field and the second field is the month field if you use a *date.daterec* constant to initialize a static *date.daterec* object.

1. For those who missed it, the Y2K (or Year 2000) problem occurred when programmers used two digits for the date and assumed that the H.O. two digits were “19”. Clearly this code malfunctioned when the year 2000 came along.

2. The Gregorian Calendar came into existence in Oct, 1582, so any dates earlier than this are meaningless as far as date calculations are concerned. The last legal date, 9999, was chosen arbitrarily as a trap for wild dates entering the calculation. This means, of course, that code calling the HLA Standard Library Date/Time package will suffer from the Y10K problem. However, you'll probably not consider this a severe limitation!

The HLA *date.daterec* format has a couple of advantages. First, it is a trivial matter to convert between the internal and external representations of a date. All you have to do is extract the *d*, *m*, and *y* fields and manipulate them as integers of the appropriate sizes. Second, this format makes it very easy to compare two dates to see if one date follows another in time; all you've got to do is compare the *date.daterec* object as though it were a 32-bit unsigned integer and you'll get the correct result. The Standard Library *date.daterec* format does have a few disadvantages. Specifically, certain calculations like computing the number of days between two dates is a bit difficult. Fortunately, the HLA Standard Library Date module provides most of the functions you'll ever need for date calculations, so this won't prove to be much of a disadvantage.

A second disadvantage to the *date.daterec* format is that the resolution is only one day. Some calculations need to maintain the time of day (down to some fraction of a second) as well as the calendar date. The HLA Standard Library also provides a TIME data structure. By combining these two structures together you should be able to handle any problem that comes along.

Before going on and discussing the functions available in the HLA Standard Library's Date module, it's probably worthwhile to briefly discuss some other date formats that find common use. Perhaps the most common date format is to use an integer value that specifies the number of days since an *epoch*, or starting, date. The advantage to this scheme is that it's very easy to do certain kinds of date arithmetic (e.g., to compute the number of days between two dates you simply subtract them) and it's also very easy to compare these dates. The disadvantages to this scheme include the fact that it is difficult to convert between the internal representation and an external representation like "xx/yy/zzzz." Another problem with this scheme, which it shares with the HLA scheme, is that the granularity is one day. You cannot represent time with any more precision than one day.

Another popular format combines dates and times into the same value. For example, the representation of time on most UNIX systems measures the number of seconds that have passed since Jan 1, 1970. Unfortunately, many UNIX systems only use a 32-bit signed integer; therefore, those UNIX systems will experience their own "Y2.038K" problem in the year 2038 when these signed integers roll over from 2,147,483,637 seconds to -2,147,483,638 seconds. Although this format does maintain time down to seconds, it does not handle fractions of a second very well. Most UNIX systems include an extra field in their date/time format to handle milliseconds, but this extra field is a kludge. One could just as easily add a time field to an existing date format if you're willing to kludge.

For those who want to be able to accurately measure dates and times, a good solution is to use a 64-bit unsigned integer to count the number of microseconds since some epoch date. A 64-bit unsigned integer will provide microsecond accuracy for a little better than 278,000 years. Probably sufficient for most needs. If you need better than microsecond accuracy, you can get nanosecond accuracy that is good for about 275 years (beyond the epoch date) with a 64-bit integer. Of course, if you want to use such a date/time format, you will have to write the routines that manipulate such dates yourself; the HLA Standard Library's Date/Time module doesn't use that format.

6.3 A Brief History of the Calendar

Man has been interested in keeping track of time since the time man became interested in keeping track of history. To understand why we need to perform various calculations, you'll need to know a little bit about the history of the calendar. So this section will digress a bit from computers and discuss that history.

What exactly is time? Time is a concept that we are all intuitively familiar with, but try and state a concrete definition that does not define time in terms of itself. Before you run off and grab a dictionary, you should note that many of the definitions of time in a typical dictionary contain a circular reference (that is, they define time in terms of itself). The *American Heritage Dictionary of the English Language* provides the following definition:

A nonspatial continuum in which events occur in apparently irreversible succession from the past through the present to the future.

As horrible as this definition sounds, it is one of the few that doesn't define time by how we measure it or by a sequence of observable events.

Why are we so obsessed with keeping track of time? This question is much more easily answered. We need to keep track of time so we can predict certain future events. Historically, important events the human race has needed to predict include the arrival of spring (for planting), the observance of religious anniversaries (e.g., Christmas, Passover), or the gestation period for livestock (or even humans). Of course, modern life may seem much more complex and tracking time more important, but we track time for the same reasons the human race always has, to predict the future. Today, we predict business meetings, when a department store will open to the public, the start of a college lecture, periods of high traffic on the highways, and the start of our favorite television shows by using time. The better we are able to measure time, the better we will be able to predict when certain types of events will occur (e.g., the start of spring so we can begin planting).

To measure time, we need some predictable, periodic, event. Since ancient times, there have been three celestial events that suit this purpose: the solar *day*, the lunar *month*, and the solar *year*. The solar day (or *tropical day*) consists of one complete rotation of the Earth on its axis. The lunar month consists of one complete set of moon phases. The solar year is one complete orbit of the Earth around the Sun. Since these periodic events are easy to measure (crudely, at least), they have become the primary basis by which we measure time.

Since these three celestial events were obvious even in prehistoric times, it should come as no surprise that one society would base their measurement of time on one cyclic standard such as the lunar month while another social group would base their time unit on a different cycle such as the solar year. Clearly, such fundamentally different time keeping schemes would complicate business transactions between the two societies effectively erecting an artificial barrier between them. Nevertheless, until about the year 46 BC (by our modern calendar), most countries used their own system for time keeping.

One major problem with reconciling the different calendars is that the celestial cycles are not integral. That is, there are not an even number of solar days in a lunar month, there are not an integral number of solar days in a solar year, and there are not an integral number of lunar months in a solar year. Indeed, there are approximately 365.2422 days in a solar year and approximately 29.5 days in a lunar month. Twelve lunar months are 354 days, a little over a week short of a full year. Therefore, it is very difficult to reconcile these three periodic events if you want to use two of them or all three of them in your calendar.

In 46 BC (or BCE, for *Before Common Era*, as it is more modernly written) Julius Caesar introduced the calendar upon which our modern calendar is based. He decreed that each year would be exactly $365 \frac{1}{4}$ days long by having three successive years having 365 days each and every fourth year having 366 days. He also abolished reliance upon the lunar cycle from the calendar. However, $365 \frac{1}{4}$ is just a little bit more than 365.2422, so Julius Caesar's calendar lost a day every 128 years or so.

Around 700 AD (or CE, for *Common Era*, as it is more modernly written) it was common to use the birth of Jesus Christ as the *Epoch* year. Unfortunately, the equinox kept losing a full day every 128 years and by the year 1500 the equinoxes occurred on March 12th, and September 12th. This was of increasing concern to the Church since it was using the Calendar to predict Easter, the most important Christian holiday³. In 1582 CE, Pope Gregory XIII dropped ten days from the Calendar so that the equinoxes would fall on March 21st and September 21st, as before, and as advised by Christoph Clavius, he dropped three leap years every 400 years. From that point forward, century years were leap years only if divisible by 400. Hence 1700, 1800, 1900 are *not* leap years, but 2000 *is* a leap year. This new calendar is known as the Gregorian Calendar (named after Pope Gregory XIII) and with the exception of the change from BC/AD to BCE/CE is, essentially, the calendar in common use today⁴.

The Gregorian Calendar wasn't accepted universally until well into the twentieth century. Largely Roman Catholic countries (e.g., Spain and France) adopted the Gregorian Calendar the same year as Rome. Other countries followed later. For example, portions of Germany did not adopt the Gregorian Calendar until the year 1700 AD while England held out until 1750. For this reason, many of the American founding fathers have *two* birthdates listed. The first date is the date in force at the time of their birth, the second date is their birthdate using the Gregorian Calendar. For example, George Washington was actually born on Feb-

3. Easter is especially important since the Church computed all other holidays relative to Easter. If the date of Easter was off, then all holidays would be off.

4. One can appreciate that non-Christian cultures might be offended at by the abbreviations BC (Before Christ) and AD (Anno Domini [day of our Lord]).

ruary 11th by the English Calendar, but after England adopted the Gregorian Calendar, this date changed to February 22nd. Note that George Washington's birthday didn't actually change, only the calendar used to measure dates at the time changed.

The Gregorian Calendar still isn't correct, though the error is very small. After approximately 3323 years it will be off by a day. Although there has been some proposals thrown around to adjust for this in the year 4000, that is such a long time off that it's hardly worth contemporary concern (with any luck, mankind will be a spacefaring race by then and the concept of a year, month, or day, may be a quaint anachronism).

There is one final problem with the calendar- the length of the solar day is constantly changing. Ocean tidal forces, meteors burning up in our atmosphere, and other effects are slowing down the Earth's rotation resulting in longer days. The effect is small, but compared to the length of a day, but it amounts to a loss of one to three milliseconds (that is, about 1/500th of a second) every 100 years since the defining Epoch (Jan 1, 1900). That means that Jan 1, 2000 is about two seconds longer than Jan 1, 1900. Since there are 86,400 seconds in a day, it will probably take on the order of 100,000 years before we lose a day due to the Earth's rotation slowing down. However, those who want to measure especially small time intervals have a problem: hours and seconds have been defined as submultiples of a single day. If the length of a day is constantly changing, that means that the definition of a second is constantly changing as well. In other words, two very precise measurements of equivalent events taken 10 years apart may show measurable differences.

To solve this problem scientists have developed the *Cesium-133 Atomic Clock*, the most accurate timing device ever invented. The Cesium atom, under special conditions, vibrates at exactly 9,192,631,770 cycles per second, for the year 1900. Because the clock is so accurate, it has to be adjusted periodically (about every 500 days, currently) so that its time (known as Universal Coordinated Time or UTC) matches that of the Earth (UT1). A high-quality Cesium Clock (like the one at the National Institute of Standards and Technology in Boulder, Colorado, USA) is very large (about the size of a large truck) and can keep accurate time to about one second in a million and a half years. Commercial units (about the size of a large suitcase) are available and they keep time accurate to about one second every 5-10,000 years.

The wall calendar you purchase each year is a device that is very similar to the Cesium Atomic Clock- it lets you measure time. The Cesium clock, clearly, lets time two discrete events that are very close to one another, but either device will probably let you predict that you start two week's vacation in Mexico starting next Monday (and the wall calendar does it for a whole lot less money). Most people don't think of a calendar as a time keeping device, but the only difference between it and a watch is the *granularity*, that is, the finest amount of time one can measure with the device. With a typical electronic watch, you can probably measure (accurately) to as little as 1/100 seconds. With a calendar, the minimum interval you can measure is one day. While the watch is appropriate for measuring the 100 meter dash, it is inappropriate for measuring the duration of the Second World War; the calendar, however, is perfect for this latter task.

Time measurement devices, be they a Cesium Clock, a wristwatch, or a Calendar, do not measure time in an absolute sense. Instead, these devices measure time between two events. For the Gregorian Calendar, the (intended) Epoch event that marks year one was the birth of Christ. Unfortunately in 1582, the use of negative numbers was not widespread and even the use of zero was not common. Therefore, 1 AD was (supposed to be) the first year of Christ's life. The year prior to that point was considered 1BC. This unfortunate choice created some mathematical problems that tend to bother people 2,000 years later. For example, the first decade was the first 10 years of Christ's life, that is, 1 AD through 10 AD. Likewise, the first century was considered the first 100 years after Christ's birth, that is, 1 AD through 100 AD. Likewise, the first millennium was the first 1,000 years after Christ's birth, specifically 1 AD through 1000 AD. Similarly, the second millennium is the next 1,000 years, specifically 1001 AD through 2000 AD. The third, millennium, contrary to popular belief, began on January 1, 2001 (Hence the title of Clark's book: "2001: A Space Odyssey"). It is an unfortunately accident of human psychology that people attach special significance to round numbers; there were many people mistakenly celebrating the turn of the millennium on December 31st, 1999 when, in fact, the actual date was still a year away.

Now you're probably wondering what this has to do with computers and the representation of dates in the computer... The reason for taking a close look at the history of the Calendar is so that you don't misuse the date and time representations found in the HLA Standard Library. In particular, note that the HLA date format is based on the Gregorian Calendar. Since the Gregorian Calendar was "born" in October of 1582, it makes absolutely no sense to represent any date earlier than about Jan 1, 1583 using the HLA date format. Granted, the data type can represent earlier dates numerically, but any date computations would be severely

off if one or both of the dates in the computation are pre-1583 (remember, Pope Gregory dropped 10 days from the calendar; right off the bat your “days between two dates” computation would be off by 10 real days if the two dates crossed the date that Rome adopted the Gregorian Calendar).

In fact, you should be wary of any dates prior to about January 1, 1800. Prior to this point there were a couple of different (though similar) calendars in use in various countries. Unless you’re a historian and have the appropriate tables to convert between these dates, you should not use dates prior to this point in calculations. Fortunately, by the year 1800, most countries that had a calendar based on Juilus Caesar’s calendar fell into line and adopted the Gregorian Calendar. Some other calendars (most notably, the Chinese Calendar) were in common use into the middle of the 20th century. However, it is unlikely you would ever confuse a Chinese date with a Gregorian date.

6.4 HLA Date Functions

HLA provides a wide array of date functions you can use to manipulate date objects. The following subsections describe many of these functions and how you use them.

6.4.1 `date.IsValid` and `date.validate`

When storing data directly into the fields of a `date.daterec` object, you must be careful to ensure that the resulting date is correct. The HLA date procedures will raise an *ex.InvalidDate* exception if the date values are out of range. The `date.IsValid` and `date.validate` procedures provide some handy code to check the validity of a date object. These two routines use either of the following calling sequences:

```
date.IsValid( dateVar ); // dateVar is type date.daterec
date.IsValid( m, d, y ); // m, d, y are uns8, uns8, uns16, respectively

date.validate( dateVar ); // See comments above.
date.validate( m, d, y );
```

The `date.IsValid` procedure checks the date to see if it is a valid date. This procedure returns true or false in the AL register to indicate whether the date is valid. The `date.validate` procedure also checks the validity of the date; however, it raises the *ex.InvalidDate* exception if the date is invalid. The following sample program demonstrates the use of these two routines:

```
program DateTimeDemo;
#include( "stdlib.hhf" );

static
    m:          uns8;
    d:          uns8;
    y:          uns16;

    theDate:date.daterec;

begin DateTimeDemo;

    try

        stdout.put( "Enter the month (1-12):" );
        stdin.get( m );

        stdin.flushInput();
        stdout.put( "Enter the day (1-31):" );
```

```

stdin.get( d );

stdin.flushInput();
stdout.put( "Enter the year (1583-9999): " );
stdin.get( y );

if( date.isValid( m, d, y ) ) then
    stdout.put( m, "/", d, "/", y, " is a valid date." nl );

endif;

// Assign the fields to a date variable.

mov( m, al );
mov( al, theDate.month );
mov( d, al );
mov( al, theDate.day );
mov( y, ax );
mov( ax, theDate.year );

// Force an exception if the date is illegal.

date.validate( theDate );

exception( ex.ConversionError )

    stdout.put
    (
        "One of the input values contained illegal characters" nl
    );

exception( ex.ValueOutOfRange )

    stdout.put
    (
        "One of the input values was too large" nl
    );

exception( ex.InvalidDate )

    stdout.put
    (
        "The input date (", m, "/", d, "/", y, ") was invalid" nl
    );

endtry;

end DateTimeDemo;

```

Program 6.1 **Date Validation Example**

6.4.2 Checking for Leap Years

Determining whether a given year is a leap year is somewhat complex. The exact algorithm is “any year that is evenly divisible by four and is not evenly divisible by 100 or is evenly divisible by 400 is a leap

year⁵.” The HLA “datetime.hhf” module provides a convenient function, *date.IsLeapYear*, that efficiently determines whether a given year is a leap year. There are two different ways you can call this function; either of the following will work:

```
date.IsLeapYear( dateVar );    // dateVar is a date.dateRec variable.
date.IsLeapYear( y );         // y is a word value.
```

The following code demonstrates the use of this routine.

```
program DemoIsLeapYear;
#include( "stdlib.hhf" );

static
    m:          uns8;
    d:          uns8;
    y:          uns16;

    theDate:date.daterec;

begin DemoIsLeapYear;

    try

        stdout.put( "Enter the month (1-12):" );
        stdin.get( m );

        stdin.flushInput();
        stdout.put( "Enter the day (1-31):" );
        stdin.get( d );

        stdin.flushInput();
        stdout.put( "Enter the year (1583-9999): " );
        stdin.get( y );

        // Assign the fields to a date variable.

        mov( m, al );
        mov( al, theDate.month );
        mov( d, al );
        mov( al, theDate.day );
        mov( y, ax );
        mov( ax, theDate.year );

        // Force an exception if the date is illegal.

        date.validate( theDate );

        // Okay, report whether this is a leap year:

        if( date.isLeapYear( theDate ) ) then
```

5. The Gregorian Calendar does not account for the fact that sometime between the years 3,000 and 4,000 we will have to add an extra leap day to keep the Calendar in sync with the Earth’s rotation around the Sun. The HLA *date.IsLeapYear* does not handle this situation either. Keep this in mind if you are doing date calculations that involve dates after the year 3,000. This is a defect in the current definition of the Gregorian Calendar, which HLA’s routines faithfully reproduce.

```
        stdout.put( "The year ", y, " is a leap year." nl );
    else
        stdout.put( "The year ", y, " is not a leap year." nl );
    endif;

    // Technically, the leap day is Feb 25, but most people don't
    // realize this, so use the following output to keep them happy:
    if( date.isLeapYear( y ) ) then
        if( m = 2 ) then
            if( d = 29 ) then
                stdout.put( m, "/", d, "/", y, " is the leap day." nl );
            endif;
        endif;
    endif;

    exception( ex.ConversionError )
        stdout.put
        (
            "One of the input values contained illegal characters" nl
        );
    exception( ex.ValueOutOfRange )
        stdout.put
        (
            "One of the input values was too large" nl
        );
    exception( ex.InvalidDate )
        stdout.put
        (
            "The input date (", m, "/", d, "/", y, ") was invalid" nl
        );
endtry;

end DemoIsLeapYear;
```

Program 6.2 Calling the date.IsLeapYear Function

6.4.3 Obtaining the System Date

The *date.today* function returns the current system date in the *date.daterec* variable you pass as a parameter. The following program demonstrates how to call this routine:

```

program DemoToday;
#include( "stdlib.hhf" );

static
    TodaysDate:date.daterec;

begin DemoToday;

    date.today( TodaysDate );

    stdout.put
    (
        "Today is ",
        (type uns8 TodaysDate.month), "/",
        (type uns8 TodaysDate.day), "/",
        (type uns16 TodaysDate.year),
        nl
    );

    // Okay, report whether this is a leap year:

    if( date.isLeapYear( TodaysDate )) then

        stdout.put( "This is a leap year." nl );

    else

        stdout.put( "This is not a leap year." nl );

    endif;

end DemoToday;

```

Program 6.3 Reading the System Date

6.4.4 Date to String Conversions and Date Output

The HLA date module provides a set of routines that will convert a *date.daterec* object to the string representation of that date. HLA provides a mechanism that lets you select from one of several different conversion formats when translating dates to strings. The date package defines an enumerated data type, *date.OutputFormat*, that specifies the different conversion mechanisms. The possible conversions are (these examples assume you are converting the date January 2, 2033):

| | |
|--------------------|-----------------------------|
| <i>date.mdyy</i> | - Outputs date as 1/2/33. |
| <i>date.mdyyyy</i> | - Outputs date as 1/2/2033. |
| <i>date.mmddyy</i> | - Outputs date as 01/02/33. |

```

date.mmddyyyy    - Outputs date as 01/02/2033.
date.yyymd      - Outputs date as 33/1/2.
date.yyyymd     - Outputs date as 2033/1/2.
date.yymmdd     - Outputs date as 33/01/02.
date.yyyymmdd   - Outputs date as 2033/01/02.
date.MONdyyyy   - Outputs date as Jan 1, 2033.
date.MONTHdyyyy - Outputs date as January 1, 2033.

```

To set the conversion format, you must call the *date.SetFormat* procedure and pass one of the above values as the single parameter⁶. For all but the last two formats above, the default month/day/year separator is the slash (“/”) character. You can call the *date.SetSeparator* procedure, passing it a single character parameter, to change the separator character.

The *date.toString* and *date.a_toString* procedures convert a date to string data. Like the other string routines this chapter discusses, the difference between the *date.toString* and *date.a_toString* procedures is that *date.a_toString* automatically allocates storage for the string whereas you must supply a string with sufficient storage to the *date.toString* procedure. Note that a string containing 20 characters is sufficient for all the different date formats. The *date.toString* and *date.a_toString* procedures use the following calling sequences:

```

date.toString( m, d, y, s );
date.toString( dateVar, s );

date.a_toString( m, d, y );
date.a_toString( dateVar );

```

Note that *m* and *d* are byte values, *y* is a word value, *dateVar* is a *date.dateRec* value, and *s* is a string variable that must point at a string that holds at least 20 characters.

The *date.Print* procedure uses the *date.toString* function to print a date to the standard output device. This is a convenient function to use to display a date after some date calculation.

The following program demonstrates the use of the procedures this section discusses:

```

program DemoStrConv;
#include( "stdlib.hhf" );

static
  TodaysDate:date.daterec;
  s:          string;

begin DemoStrConv;

  date.today( TodaysDate );
  stdout.put( "Today's date is " );
  date.print( TodaysDate );
  stdout.newln();

  // Convert the date using various formats
  // and display the results:

  date.setFormat( date.mdyy );
  date.a_toString( TodaysDate );
  mov( eax, s );
  stdout.put( "Date in mdyy format: ", s, "" nl );

```

6. the *date.SetFormat* routine raises the *ex.InvalidDateFormat* exception if the parameter is not one of these values.

```

strfree( s );

date.setFormat( date.mmddyy );
date.a_toString( TodaysDate );
mov( eax, s );
stdout.put( "Date in mmddyy format: ", s, "" nl );
strfree( s );

date.setFormat( date.mdyyyy );
date.a_toString( TodaysDate );
mov( eax, s );
stdout.put( "Date in mdyyyy format: ", s, "" nl );
strfree( s );

date.setFormat( date.mmddyyyy );
date.a_toString( TodaysDate );
mov( eax, s );
stdout.put( "Date in mmddyyyy format: ", s, "" nl );
strfree( s );

date.setFormat( date.MONdyyyy );
date.a_toString( TodaysDate );
mov( eax, s );
stdout.put( "Date in MONdyyyy format: ", s, "" nl );
strfree( s );

date.setFormat( date.MONTHdyyyy );
date.a_toString( TodaysDate );
mov( eax, s );
stdout.put( "Date in MONTHdyyyy format: ", s, "" nl );
strfree( s );

end DemoStrConv;

```

Program 6.4 Date <-> String Conversion and Date Output Routines

6.4.5 date.unpack and data.pack

The `date.pack` and `date.unpack` functions pack and unpack date data. The calling syntax for these functions is the following:

```

date.pack( y, m, d, dr );
date.unpack( dr, y, m, d );

```

Note: `y`, `m`, `d` must be `uns32` or `dword` variables; `dr` must be a `date.daterec` object.

The `date.pack` function takes the `y`, `m`, and `d` values and packs them into a `date.daterec` format and stores the result into `dr`. The `date.unpack` function does just the opposite. Neither of these routines check their parameters for proper range. It is the caller's responsibility to ensure that `d`'s value is in the range 1..31 (as appropriate for the month and year), `m`'s value is in the range 1..12, and `y`'s value is in the range 1583..9999.

6.4.6 `date.Julian`, `date.fromJulian`

These two functions convert a Gregorian date to and from a Julian day number⁷. Julian day numbers specify January 1, 4713 BCE as day zero and number the days consecutively from that point⁸. One nice thing about Julian day numbers is that date calculations are very easy. You can compute the number of days between two dates by simply subtracting them, you can compute new dates by adding an integer number of days to a Julian day number, etc. The biggest problem with Julian day numbers is converting them to and from the Gregorian Calendar with which we're familiar. Fortunately, these two functions handle that chore. The syntax for calling these two functions is:

```
date.fromJulian( julian, dateRecVar );
date.Julian( m, d, y );
date.Julian( dateRecVar );
```

The first call above converts the Julian day number that you pass in the first parameter to a Gregorian date and stores the result into the `date.daterec` variable you pass as the second parameter. Keep in mind that Julian day numbers that correspond to dates before Jan 1, 1582, will not produce accurate calendar dates since the Gregorian calendar did not exist prior to that point.

The second two calls above compute the Julian day number and return the value in the EAX register. They differ only in the types of parameters they expect. The first call to `date.Julian` above expects three parameters, `m` and `b` being byte values and `y` being a word value. The second call expects a `date.daterec` parameter; it extracts those three fields and converts them to the Julian day number.

6.4.7 `date.datePlusDays`, `date.datePlusMonths`, and `date.daysBetween`

These two functions provide some simple date arithmetic operations. The compute a new date by adding some number of days or months to an existing date. The calling syntax for these functions is

```
date.datePlusDays( numDays, dateRecVar );
date.datePlusMonths( numMonths, dateRecVar );
```

Note: `numDays` and `numMonths` are `uns32` values, `dateRecVar` must be a `date.daterec` variable.

The `date.datePlusDays` function computes a new date that is `numDays` days beyond the date that `dateRecVar` specifies. This function leaves the resulting date in `dateRecVar`. This function automatically compensates for the differing number of days in each month as well as the differing number of days in leap years. The `date.datePlusMonths` function does a similar calculation except it adds `numMonths` months, rather than days to `dateRecVar`.

The `date.datePlusDays` function is not particularly efficient if the `numDays` parameter is large. There is a more efficient way to calculate a new date if `numDays` exceeds 1,000: convert the date to a Julian Day Number, add the `numDays` value directly to the Julian Number, and then convert the result back to a date.

The `date.daysBetween` function computes the number of days between two dates. Like `date.datePlusDays`, this function is not particularly efficient if the two dates are more than about three years apart; it is more efficient to compute the Julian day numbers of the two dates and subtract those values. For spans of less than three years, this function is probably more efficient. The calling sequence for this function is the following:

```
date.daysBetween( m1, d1, y1, m2, d2, y2 );
date.daysBetween( m1, d1, y1, dateRecVar2 );
date.daysBetween( dateRecVar1, m2, d2, y2 );
date.daysBetween( dateRecVar1, dateRecVar2 );
```

7. Note that a Julian date and a Julian day number are not the same thing. Julian dates are based on the Julian Calendar, commissioned by Julius Caesar, which is very similar to the Gregorian Calendar; Julian day numbers were invented in the 1800's and are primarily used by astronomers.

8. Jan 1, 4713 BCE was chosen as a date that predates recorded history.

The four different calls allow you to specify either date as a *m/d/y* value or as a *date.daterec* value. The *m* and *d* parameters in these calls must be *byte* values and the *y* parameter must be a *word* value. The *dateRecVar1* and *dateRecVar2* parameters must, obviously, be *date.daterec* values. These functions return the number of days between the two dates in the EAX register. Note that the dates must be valid, but there is no requirement that the first date be less than the second date.

6.4.8 `date.dayNumber`, `date.daysLeft`, and `date.dayOfWeek`

The *date.dayNumber* function computes the day number into the current year (with Jan 1 being day number one) and returns this value in EAX. This value is always in the range 1..365 (or 1..366 for leap years). A call to this function uses the following syntax:

```
date.dayNumber( m, d, y );
date.dayNumber( dateRecVar );
```

The two forms differ only in the way you pass the date. The first call above expects two byte values (*m* and *d*) and a word value (*y*). The second form above expects a *date.daterec* value.

The *date.daysLeft* function computes the number of days left in a year. This function returns the number of days left in a year *counting the date you pass as a parameter*. Therefore, this function returns one for Dec 31st. Like *date.dayNumber*, this function always returns a value in the range 1..365/366 (regular/leap year). The calling syntax for this function is similar to *date.dayNumber*, it is

```
date.daysLeft( m, d, y );
date.daysLeft( dateRecVar );
```

The parameters have the same meaning as for *date.dayNumber*.

The *date.dayOfWeek* function accepts a date and returns a day of week value in the EAX register. A call to this function uses the following syntax:

```
date.dayOfWeek( m, d, y );
date.dayOfWeek( dateRecVar );
```

The parameters have their usual meanings.

These function calls return a value in the range 0..7 (in EAX) as follows:

| | |
|----|-----------|
| 0: | Sunday |
| 1: | Monday |
| 2: | Tuesday |
| 3: | Wednesday |
| 4: | Thursday |
| 5: | Friday |
| 6: | Saturday |

6.5 Times

The HLA Standard Library provides a simple time module that lets you manipulate times in an HHMMSS (hours/minutes/seconds) format. The *time* namespace in the *date/time* module defines the time data type as follows:

```
type
    timerec:
        record
```

```
secs:uns8;
mins:uns8;
hours:uns16;
endrecord;
```

This format easily handles 60 seconds per minute and 60 minutes per hour. It also handles up to 65,535 hours (just over 2730 days or about 7- $\frac{1}{2}$ years).

The advantages to this time format parallel the advantages of the date format: it is easy to convert the time format to/from external representation (i.e., HH:MM:SS) and the storage format lets you compare times by treating them as *uns32* objects. Another advantage to this format is that it supports more than 24 hours, so you can use it to maintain timings for events that are not calendar based (up to seven years).

There are a couple of disadvantages to this format. The primary disadvantage is that the minimum granularity is one second; if you want to work with fractions of a second then you will need to use a different format and you will have to write the functions for that format. Another disadvantage is that time calculations are somewhat inconvenient. It is difficult to add *n* seconds to a time variable.

Before discussing the HLA Standard Library Time functions, a quick discussion of other possible time formats is probably wise. The only reasonable alternative to the HH:MM:SS format that the HLA Standard Library Time module uses is to use an integer value to represent some number of time units. The only question is “what time units do you want to use?” Whatever time format you use, you should be able to represent at least 86,400 seconds (24 hours) with the format. Furthermore, the granularity should be one second or less. This effectively means you will need at least 32 bits since 16 bits only provides for 65,536 seconds at one second granularity (okay, 24 bits would work, but it’s much easier to work with four-byte objects than three-byte objects).

With 32-bits, we can easily represent more than 24 hours’ worth of milliseconds (in fact, you can represent almost 50 days before the format rolls over). We could represent five days with a $\frac{1}{10,000}$ second granularity, but this is not a common timing to use (most people want microseconds if they need better than millisecond granularity), so millisecond granularity is probably the best choice for a 32-bit format. If you need better than millisecond granularity, you should use a combine date/time 64-bit format that measures microseconds since Julian Day Number zero (Jan 1, 4713 BCE). That’s good for about a half million years. If you need finer granularity than microseconds, well, you’re own your own! You’ll have to carefully weigh the issues of granularity vs. years covered vs. the size of your data.

6.5.1 time.curTime

This function returns the current time as read from the system’s time of day clock. The calling syntax for this function is the following:

```
time.curTime( timeRecVar );
```

This function call stores the current system time in the *time.timerec* variable you pass as a parameter.

6.5.2 time.hmsToSecs and time.secstoHMS

These two functions convert between the HLA internal time format and a pure seconds format. Generally, when doing time arithmetic (e.g., time plus seconds, minutes, or hours), it’s easiest to convert your times to seconds, do the calculations with seconds, and then translate the time back to the HLA internal format. This lets you avoid the headaches of modulo-60 arithmetic.

The calling sequences for the *time.hmsToSecs* function are

```
time.hmsToSecs( timeRecValue );
time.hmsToSecs( h, m, s );
```

Both functions return the number of seconds in the EAX register. They differ only in the type of parameters they expect. The first form above expects an HLA *time.timerec* value. The second call above lets you

directly specify the hours, minutes, and seconds as separate parameters. The *h* parameter must be a word value, the *m* and *s* parameters must be byte values.

The *time.secsToHMS* function uses the following calling sequence:

```
time.secsToHMS( seconds, timeRecVar );
```

The first parameter must be an `uns32` value specifying some number of seconds less than 235,939,600 seconds (which corresponds to 65,536 hours). The second parameter in this call must be a *time.timerec* variable. This function converts the seconds parameter to the HLA internal time format and stores the value into the *timeRecVar* variable.

6.5.3 Time Input/Output

The HLA Standard Library doesn't provide any specific I/O routines for time data. However, reading and writing time data in ASCII form is a fairly trivial process. This section will provide some examples of time I/O using the HLA Standard Input and Standard Output modules.

To output time in a standard HH:MM:SS format, just use the `stdout.putisize` routines with a width value of two and a fill character of '0' for the three fields of the HLA *time.timerec* data type. The following code demonstrates this:

```
static
    t:time.timerec;
    .
    .
    .
    stdout.putisize( t.h, 2, '0' );
    stdout.put( ':' );
    stdout.putisize( t.m, 2, '0' );
    stdout.put( ':' );
    stdout.putisize( t.s, 2, '0' );
```

If this seems like too much typing, well fear not; in the next chapter you will learn how to create your own functions and you can put this code into a function that will print the time with a single function call.

Time input is a little more complicated. As it turns out, HLA accepts the colon (":") character as a delimiter when reading numbers from the user. Therefore, reading a time value is no more difficult than reading any other three integer values; you can do it with a single call like the following:

```
stdin.get( t.hours, t.mins, t.secs );
```

There is one remaining problem with the time input code: it does not validate the input. To do this, you must manually check the seconds and minutes fields to ensure they are values in the range 0..59. If you wish to enforce a limit on the hours field, you should check that value as well. The following code offers one possible solution:

```
stdin.get( t.hours, t.mins, t.secs );
if( t.m >= 60 ) then

    raise( ex.ValueOutOfRange );

endif;
if( t.s >= 60 ) then

    raise( ex.ValueOutOfRange );

endif;
```

6.6 Putting It All Together

Date and time data types do not get anywhere near the consideration they deserve in modern programs. To help ensure that you calculate dates properly in your HLA programs, the HLA Standard Library provides a set of date and time functions that ease the use of dates and times in your programs.

7.1 Chapter Overview

In this chapter you will learn about the *file* persistent data type. In most assembly languages, file I/O is a major headache. Not so in HLA with the HLA Standard Library. File I/O is no more difficult than writing data to the standard output device or reading data from the standard input device. In this chapter you will learn how to create and manipulate sequential and random-access files.

7.2 File Organization

A file is a collection of data that the system maintains in persistent storage. Persistent means that the storage is non-volatile – that is, the system maintains the data even after the program terminates; indeed, even if you shut off system power. For this reason, plus the fact that different programs can access the data in a file, applications typically use files to maintain data across executions of the application and to share data with other applications.

Windows typically saves file data on a disk drive or some other form of secondary storage device. As you may recall from the chapter on the memory hierarchy (see “The Memory Hierarchy” on page 293), secondary storage (disk drives) is much slower than main memory. Therefore, you generally do not store data that a programming commonly accesses in files during program execution unless that data is far too large to fit into main memory (e.g., a large database).

Under Windows, a standard file is simply a stream of bytes that the operating system does not interpret in any way. It is the responsibility of the application to interpret this information, much the same as it is your application’s responsibility to interpret data in memory. The stream of bytes in a file could be a sequence of ASCII characters (e.g., a text file) or they could be pixel values that form a 24-bit color photograph.

Files generally take one of two different forms: *sequential files* or *random access files*. Sequential files are great for data you read or write all at once; random access files work best for data you read and write in pieces (or rewrite, as the case may be). For example, a typical text file (like an HLA source file) is a good example of a sequential file. Usually your text editor will read or write the entire file at once. Similarly, the HLA compiler will read the data from the file in a sequential fashion without skipping around in the file. A database file, on the other hand, requires random access since the application can read data from anywhere in the file in response to a query.

7.2.1 Files as Lists of Records

A good view of a file is as a list of records. That is, the file is broken down into a sequential string of records that share a common structure. A list is simply an open-ended single dimensional array of items, so we can view a file as an array of records. As such, we can index into the file and select record number zero, record number one, record number two, etc. Using common file access operations, it is quite possible to skip around to different records in a file. Under Windows, the principle difference between a sequential file and a random access file is the organization of the records and how easy it is to locate a specific record within the file. In this section we’ll take a look at the issues that differentiate these two types of files.

The easiest file organization to understand is the random access file. A random access file is a list of records whose lengths are all identical (i.e., random access files require fixed length records). If the record length is n bytes, then the first record appears at byte offset zero in the file, the second record appears at byte offset n in the file, the third record appears at byte offset $n*2$ in the file, etc. This organization is virtually identical to that of an array of records in main memory; you use the same computation to locate an “element” of this list in the file as you would use to locate an element of an array in memory; the only difference is that a file doesn’t have a “base address” in memory, you simply compute the zero-based offset of the

record in the file. This calculation is quite simple, and using some file I/O functions you learn about a little later, you can quickly locate and manipulate any record in a random access file.

Sequential files also consist of a list of records. However, these records do not all have to be the same length¹. If a sequential file does not use fixed length records then we say that the file uses variable-length records. If a sequential file uses variable-length records, then the file must contain some kind of marker or other mechanism to separate the records in the file. Typical sequential files use one of two mechanisms: a length prefix or some special terminating value. These two schemes should sound quite familiar to those who have read the chapter on strings. Character strings use a similar scheme to determine the bounds of a string in memory.

A text file is the best example of a sequential file that uses variable-length records. Text files use a special marker at the end of each record to delineate the records. In a text file, a record corresponds to a single line of text. Under Windows, the carriage return/line feed character sequence marks the end of each record. Other operating systems may use a different sequence; e.g., Linux uses a single line feed character while the Mac OS uses a single carriage return. Since we're working with Windows here, we'll adopt the carriage return/line feed convention.

Accessing records in a file containing variable-length records is problematic. Unless you have an array of offsets to each record in a variable-length file, the only practical way to locate record n in a file is to read the first $n-1$ records. This is why variable-length files are sequential-access – you have to read the file sequentially from the start in order to locate a specific record in the file. This will be much slower than accessing the file in a random access fashion. Generally, you would not use a variable-length record organization for files you need to access in a random fashion.

At first blush it would seem that fixed-length random access files offer all the advantages here. After all, you can access records in a file with fixed-length records much more rapidly than files using the variable-length record organization. However, there is a cost to this: your fixed-length records have to be large enough to hold the largest possible data object you want to store in a record. To store a sequence of lines in a text file, for example, your record sizes would have to be large enough to hold the longest possible input line. This could be quite large (for example, HLA allows lines up to 256 characters). Each record in the file will consume this many bytes even if the record uses substantially less data. For example, an empty line only requires two bytes (for the carriage return/line feed sequence). If your record size is 256 bytes, then you're wasting 254 bytes for that blank line in your file. If the average line length is around 60 characters, then each line wastes an average of about 200 characters. This problem, known as *internal fragmentation*, can waste a tremendous amount of space on your disk as your files get larger or you create lots of files. File organizations that use variable-length records generally don't suffer from this problem.

7.2.2 Binary vs. Text Files

Another important thing to realize about files is that they don't all contain human readable text. OBJ and EXE files are good examples of files that contain binary information rather than text. A text file is a very special kind of variable-length sequential file that uses special end of line markers (carriage returns/line feeds) at the end of each record (line) in the file. Binary files are everything else.

Binary files are often more compact than text files and they are usually more efficient to access. Consider a text file that contains the following set of two-byte integer values:

```
1234
543
3645
32000
1
87
0
```

1. There is nothing preventing a sequential file from using fixed length records. However, they don't require fixed length records.

As a text file, this file consumes at least 34 bytes (assuming a two-byte end of line marker on each line). However, were we to store the data in a fixed-record length binary file, with two bytes per integer value, this file would only consume 14 bytes – less than half the space. Furthermore, since the file now uses fixed-length records (two bytes per record) we can efficiently access it in a random fashion. Finally, there is one additional, though hidden, efficiency aspect to the binary format: when a program reads and writes binary data it doesn't have to convert between the binary and string formats. This is an expensive process (with respect to computer time). If a human being isn't going to read this file with a separate program (like a text editor) then converting to and from text format on every I/O operation is a wasted effort.

Consider the following HLA record type:

```
type
  person:
    record
      name:string;
      age:int16;
      ssn:char[11];
      salary:real64;
    endrecord;
```

If we were to write this record as text to a text file, a typical record would take the following form (<nl> indicates the end of line marker, a carriage return/line feed pair):

```
Hyde, Randall<nl>
45<nl>
555-55-5555<nl>
123456.78<nl>
```

Presumably, the next *person* record in the file would begin with the next line of text in the text file.

The binary version of this file (using a fixed length record, reserving 64 bytes for the *name* string) would look, schematically, like the following:

Figure 4.1 Fixed-lengthFormat for Person Record

Don't get the impression that binary files must use fixed length record sizes. We could create a variable-length version of this record by using a zero byte to terminate the string, as follows:

Figure 4.2 Variable-length Format for Person Record

In this particular record format the *age* field starts at offset 14 in the record (since the name field and the “end of field” marker [the zero byte] consume 14 bytes). If a different name were chosen, then the *age* field would begin at a different offset in the record. In order to locate the age, ssn, and salary fields of this record, the program would have to scan past the name and find the zero terminating byte. The remaining fields would follow at fixed offsets from the zero terminating byte. As you can see, it’s a bit more work to process this variable-length record than the fixed-length record. Once again, this demonstrates the performance difference between random access (fixed-length) and sequential access (variable length, in this case) files.

Although binary files are often more compact and more efficient to access, they do have their drawbacks. In particular, only applications that are aware of the binary file’s record format can easily access the file. If you’re handed an arbitrary binary file and asked to decipher its contents, this could be very difficult. Text files, on the other hand, can be read by just about any text editor or filter program out there. Hence, your data files will be more interchangeable with other programs if you use text files. Furthermore, it is easier to debug the output of your programs if they produce text files since you can load a text file into the same editor you use to edit your source files.

7.3 Sequential Files

Sequential files are perfect for three types of persistent data: ASCII text files, “memory dumps”, and stream data. Since you’re probably familiar with ASCII text files, we’ll skip their discussion. The other two methods of writing sequential files deserve more explanation.

A “memory dump” is a file that consists of data you transfer from data structures in memory directly to a file. Although the term “memory dump” suggests that you sequentially transfer data from consecutive memory locations to the file, this isn’t necessarily the case. Memory access can, an often does, occur in a random access fashion. However, once the application constructs a record to write to the file, it writes that record in a sequential fashion (i.e., each record is written in order to the file). A “memory dump” is what most applications do when you request that they save the program’s current data to a file or read data from a file into application memory. When writing, they gather all the important data from memory and write it to the file in a sequential fashion; when reading (loading) data from a file, they read the data from the file in a sequential fashion and store the data into appropriate memory-based data structures. Generally, when loading or saving file data in this manner, the program opens a file, reads/writes data from/to the file, and then it closes the file. Very little processing takes place during the data transfer and the application does not leave the file open for any length of time beyond what is necessary to read or write the file’s data.

Stream data on input is like data coming from a keyboard. The program reads the data at various points in the application where it needs new input to continue. Similarly, stream data on output is like a write to the console device. The application writes data to the file at various points in the program after important computations have taken place and the program wishes to report the results of the calculation. Note that when reading data from a sequential file, once the program reads a particular piece of data, that data is no longer available in future reads (unless, of course, the program closes and reopens the file). When writing data to a sequential file, once data is written, it becomes a permanent part of the output file. When processing this kind of data the program typically opens a file and then continues execution. As program execution contin-

ues, the application can read or write data in the file. At some point, typically towards the end of the application's execution, the program closes the file and commits the data to disk.

Although disk drives are generally thought of as random access devices, the truth is that they are only pseudo-random access; in fact, they perform much better when writing data sequentially on the disk surface. Therefore, sequential access files tend to provide the highest performance (for sequential data) since they match the highest performance access mode of the disk drive.

Working with sequential files in HLA is very easy. In fact, you already know most of the functions you need in order to read or write sequential files. All that's left to learn is how to open and close files and perform some simple tests (like "have we reached the end of a file when reading data from the file?").

The file I/O functions are nearly identical to the *stdin* and *stdout* functions. Indeed, *stdin* and *stdout* are really nothing more than special file I/O functions that read data from the standard input device (a file) or write data to the standard output device (which is also a file). You use the file I/O functions in a manner analogous to *stdin* and *stdout* except you use the *fileio* prefix rather than *stdin* or *stdout*. For example, to write a string to an output file, you could use the *fileio.puts* function almost the same way you use the *stdout.puts* routine. Similarly, if you wanted to read a string from a file, you would use *fileio.gets*. The only real difference between these function calls and their *stdin* and *stdout* counterparts is that you must supply an extra parameter to tell the function what file to use for the transfer. This is a double word value known as the *file handle*. You'll see how to initialize this file handle in a moment, but assuming you have a *dword* variable that holds a file handle value, you can use calls like the following to read and write data to sequential files:

```
fileio.get( inputHandle, i, j, k ); // Reads i, j, k, from file inputHandle.
fileio.put( outputHandle, "I = ", i, "J = ", j, " K = ", k, nl );
```

Although this example only demonstrates the use of *get* and *put*, be aware that almost all of the *stdin* and *stdout* functions are available as *fileio* functions, as well (in fact, most of the *stdin* and *stdout* functions simply call the appropriate *fileio* function to do the real work).

There is, of course, the issue of this file handle variable. You're probably wondering what a file handle is and how you tell the *fileio* routines to work with data in a specific file on your disk. Well, the definition of the file handle object is the easiest to explain – it's just a *dword* variable that Windows initializes and uses to keep track of your file. To declare a file handle, you'd just create a *dword* variable, e.g.,

```
static
    myFileHandle:dword;
```

You should never explicitly manipulate the value of a file handle variable. Windows will initialize this variable for you (via some calls you'll see in a moment) and Windows expects you to leave this value alone as long as your working with the file Windows associates with that handle. If you're curious, Windows stores small integer values into the handle variable. Internally, Windows uses this value as an index into an array that contains pertinent information about open files. If you mess with the file handle's value, you will confuse Windows' greatly the next time you attempt to access the file. Moral of the story – leave this value alone while the file is open.

Before you can read or write a file you must open that file and associate a filename with it. The HLA Standard Library provides a couple of functions that provide this service: *fileio.open* and *fileio.openNew*. The *fileio.open* function opens an existing file for reading, writing, or both. Generally, you open sequential files for reading or writing, but not both (though there are some special cases where you can open a sequential file for reading and writing). The syntax for the call to this function is

```
fileio.open( "filename", access );
```

The first parameter is a string value that specifies the Windows filename of the file to open. This can be a string constant, a register that contains the address of a string value, or a string variable. The second parameter is a constant that specifies how you want to open the file. You may use any of the three predefined constants for the second parameter:

```
fileio.r
fileio.w
fileio.rw
```

`fileio.r` obviously specifies that you want to open an existing file in order to read the data from that file; likewise, `fileio.w` says that you want to open an existing file and overwrite the data in that file. The `fileio.rw` option lets you open a file for both reading and writing.

The `fileio.open` routine, if successful, returns a Windows *file handle* in the EAX register. Generally, you will want to save the return value into a double word variable for use by the other HLA *fileio* routines (i.e., the `MyFileHandle` variable in the earlier example).

If Windows cannot open the file, `fileio.open` will raise an *ex.FileOpenFailure* exception. This usually means that it could not find the specified file on the disk.

The `fileio.open` routine requires that the file exist on the disk or it will raise an exception. If you want to create a new file, that might not already exist, the `fileio.openNew` function will do the job for you. This function uses the following syntax:

```
fileio.openNew( "filename" );
```

Note that this call has only a single parameter, a string specifying the filename. When you open a file with `fileio.openNew`, the file is always opened for writing. If a file by the specified filename already exists, then this function will delete the existing file and the new data will be written over the top of the old file.

Like `fileio.open`, `fileio.openNew` returns a file handle in the EAX register if it successfully opens the file. You should save this value in a file handle variable. This function raises the *ex.FileOpenFailure* exception if it cannot open the file.

Once you open a sequential file with `fileio.open` or `fileio.openNew` and you save the file handle value away, you can begin reading data from an input file (`fileio.r`) or writing data to an output file (`fileio.w`). To do this, you would use functions like `fileio.put` as noted above.

When the file I/O is complete, you must close the file to commit the file data to the disk. You should always close all files you open as soon as you are through with them so that the program doesn't consume excess system resources. The syntax for `fileio.close` is very simple, it takes a single parameter, the file handle value returned by `fileio.open` or `fileio.openNew`:

```
fileio.close( file_handle );
```

If there is an error closing the file, `fileio.close` will raise the *ex.FileCloseError* exception. Note that Windows automatically closes all open files when an application terminates; however, it is very bad programming style to depend on this feature. If the system crashes (or the user turns off the power) before the application terminates, file data may be lost. So you should always close your files as soon as you are done accessing the data in that file.

The last function of interest to us right now is the `fileio.eof` function. This function returns true (1) or false (0) in the AL register depending on whether the current file pointer is at the end of the file. Generally you would use this function when reading data from an input file to determine if there is more data to read from the file. You would not normally call this function for output files; it always returns true unless the disk is full. Since the `fileio` routines will raise an exception if the disk is full, there is no need to waste time checking for end of file (EOF) when writing data to a file. The syntax for `fileio.eof` is

```
fileio.eof( file_handle );
```

The following program example demonstrates a complete program that opens and writes a simple text file:

```
program SimpleFileOutput;
#include( "stdlib.hhf" )

static
    outputHandle:dword;

begin SimpleFileOutput;

    fileio.openNew( "myfile.txt" );
```

```

mov( eax, outputHandle );

for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

    fileio.put( outputHandle, (type uns32 ebx ), nl );

endfor;
fileio.close( outputHandle );

end SimpleFileOutput;

```

Program 7.1 A Simple File Output Program

The following sample program reads the data that Program 7.1 produces and writes the data to the standard output device:

```

program SimpleFileInput;
#include( "stdlib.hhf" )

static
    inputHandle:dword;
    u:uns32;

begin SimpleFileInput;

    fileio.open( "myfile.txt", win.GENERIC_READ );
    mov( eax, inputHandle );

    for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

        fileio.get( inputHandle, u );
        stdout.put( "ebx=", ebx, " u=", u, nl );

    endfor;
    fileio.close( inputHandle );

end SimpleFileInput;

```

Program 7.2 A Sample File Input Program

There are a couple of interesting functions that you can use when working with sequential files. They are the following:

```

fileio.rewind( fileHandle );
fileio.append( fileHandle );

```

The *fileio.rewind* function resets the “file pointer” (the cursor into the file where the next read or write will take place) back to the beginning of the file. This name is a carry-over from the days of files on tape drives when the system would rewind the tape on the tape drive to move the read/write head back to the beginning of the file.

If you’ve opened a file for reading, then *fileio.rewind* lets you begin reading the file from the start (i.e., make a second pass over the data). If you’ve opened the file for writing, then *fileio.rewind* will cause future

writes to overwrite the data you've previously written; you won't normally use this function with files you've opened only for writing. If you've opened the file for reading and writing (using the "fileio.rw" option) then you can write the data after you've first opened the file and then rewind the file and read the data you've written. The following is a modification to Program 7.2 that reads the data file twice. This program also demonstrates the use of *fileio.eof* to test for the end of the file (rather than just counting the records).

```

program SimpleFileInput2;
#include( "stdlib.hhf" )

static
    inputHandle:dword;
    u:uns32;

begin SimpleFileInput2;

    fileio.open( "myfile.txt", win.GENERIC_READ );
    mov( eax, inputHandle );

    for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

        fileio.get( inputHandle, u );
        stdout.put( "ebx=", ebx, " u=", u, nl );

    endfor;
    stdout.newln();

    // Rewind the file and reread the data from the beginning.
    // This time, use fileio.eof() to determine when we've
    // reached the end of the file.

    fileio.rewind( inputHandle );
    while( fileio.eof( inputHandle ) = false ) do

        // Read and display the next item from the file:

        fileio.get( inputHandle, u );
        stdout.put( "u=", u, nl );

        // Note: after we read the last numeric value, there is still
        // a newline sequence left in the file, if we don't read the
        // newline sequence after each number then EOF will be false
        // at the start of the loop and we'll get an EOF exception
        // when we try to read the next value. Calling fileio.ReadLn
        // "eats" the newline after each number and solves this problem.

        fileio.readLn( inputHandle );

    endwhile;
    fileio.close( inputHandle );

end SimpleFileInput2;

```

Program 7.3 Another Sample File Input Program

The *fileio.append* function moves the file pointer to the end of the file. This function is really only useful for files you've opened for writing (or reading and writing). After executing *fileio.append*, all data you write to the file will be written after the data that already exists in the file (i.e., you use this call to append data to the end of a file you've opened). The following program demonstrates how to use this program to append data to the file created by Program 7.1:

```

program AppendDemo;
#include( "stdlib.hhf" )

static
    fileHandle:dword;
    u:uns32;

begin AppendDemo;

    fileio.open( "myfile.txt", win.GENERIC_READ | win.GENERIC_WRITE );
    mov( eax, fileHandle );
    fileio.append( eax );

    for( mov( 10, ecx ); ecx < 20; inc( ecx )) do

        fileio.put( fileHandle, (type uns32 ecx), nl );

    endfor;

    // Okay, let's rewind to the beginning of the file and
    // display all the data from the file, including the
    // new data we just wrote to it:

    fileio.rewind( fileHandle );
    while( !fileio.eof( fileHandle )) do

        // Read and display the next item from the file:

        fileio.get( fileHandle, u );
        stdout.put( "u=", u, nl );
        fileio.readLine( fileHandle );

    endwhile;
    fileio.close( fileHandle );

end AppendDemo;

```

Program 7.4 Demonstration of the fileio.Append Routine

Another function, similar to *fileio.eof*, that will prove useful when reading data from a file is the *fileio.eoln* function. This function returns true if the next characters to be read from the file are carriage return, linefeed, or the sequence of these two characters. This function returns true or false in the EAX register if it detects an end of line sequence. The calling sequence for this function is

```
fileio.eoln( fileHandle );
```

If *fileio.eoln* detects an end of line sequence, it will read those characters from the file (so the next read from the file will not read the end of line characters). If *fileio.eoln* does not detect the end of line sequence, it does not modify the file pointer position. The following sample program demonstrates the use of

fileio.eoln in the AppendDemo program, replacing the call to *fileio.readLn* (since *fileio.eoln* reads the end of line sequence, there is no need for the call to *fileio.readLn*):

```

program EolnDemo;
#include( "stdlib.hhf" )

static
    fileHandle:dword;
    u:uns32;

begin EolnDemo;

    fileio.open( "myfile.txt", win.GENERIC_READ | win.GENERIC_WRITE );
    mov( eax, fileHandle );
    fileio.append( eax );

    for( mov( 10, ecx ); ecx < 20; inc( ecx ) ) do

        fileio.put( fileHandle, (type uns32 ecx), nl );

    endfor;

    // Okay, let's rewind to the beginning of the file and
    // display all the data from the file, including the
    // new data we just wrote to it:

    fileio.rewind( fileHandle );
    while( !fileio.eof( fileHandle ) ) do

        // Read and display the next item from the file:

        fileio.get( fileHandle, u );
        stdout.put( "u=", u, nl );
        if( !fileio.eoln( fileHandle ) ) then

            stdout.put( "Hmmm, expected the end of the line", nl );

        endif;

    endwhile;
    fileio.close( fileHandle );

end EolnDemo;

```

7.4 Random Access Files

The problem with sequential files is that they are, well, sequential. They are great for dumping and retrieving large blocks of data all at once, but they are not suitable for applications that need to read, write, and rewrite the same data in a file multiple times. In those situations random access files provide the only reasonable alternative.

Windows doesn't differentiate sequential and random access files anymore than the CPU differentiates byte and character values in memory; it's up to your application to treat the files as sequential or random

access. As such, you use many of the same functions to manipulate random access files as you use to manipulate sequential access files; you just use them differently is all.

You still open files with *fileio.open* and *fileio.openNew*. Random access files are generally opened for reading or reading and writing. You rarely open a random access file as write-only since a program typically needs to read data if it's jumping around in the file.

You still close the files with *fileio.close*.

You can read and write the files with *fileio.get* and *fileio.put*, although you would not normally use these functions for random access file I/O because each record you read or write has to be exactly the same length and these functions aren't particularly suited for fixed-length record I/O. Most of the time you will use one of the following functions to read and write fixed-length data:

```
fileio.write( fileHandle, buffer, count );
fileio.read( fileHandle, buffer, count );
```

The *fileHandle* parameter is the usual Windows file handle value (a *dword* variable). The *count* parameter is an *uns32* object that specifies how many bytes to read or write. The *buffer* parameter must be a *byte* array variable (or a variable you coerce to type *byte*). This parameter supplies the address of the first byte in memory where the I/O transfer will take place. These functions return the number of bytes read or written in the EAX register. For *fileio.read*, if the return value in EAX does not equal *count's* value, then you've reached the end of the file. For *fileio.write*, if EAX does not equal *count* then the disk is full.

Here is a typical call to the *fileio.read* function that will read a record from a file:

```
fileio.read( myHandle, myRecord, @size( myRecord ) );
```

If the return value in EAX does not equal `@size(myRecord)` and it does not equal zero (indicating end of file) then there is something seriously wrong with the file since the file should contain an integral number of records.

Writing data to a file with *fileio.write* uses a similar syntax to *fileio.read*.

You can use *fileio.read* and *fileio.write* to read and write data from/to a sequential file, just as you can use routines like *fileio.get* and *fileio.put* to read/write data from/to a random access file. You'd typically use these routines to read and write data from/to a binary sequential file.

The functions we've discussed to this point don't let you randomly access records in a file. If you call *fileio.read* several times in a row, the program will write those records sequentially to the text file. To do true random access I/O we need the ability to jump around in the file. Fortunately, the HLA Standard Library's file module provides several functions you can use to accomplish this.

The *fileio.position* function returns the current offset into the file in the EAX register. If you call this function immediately before reading or writing a record to a file, then this function will tell you the exact position of that record. You can use this value to quickly locate that record for a future access. The calling sequence for this function is

```
fileio.position( fileHandle ); // Returns current file position in EAX.
```

The *fileio.seek* function repositions the file pointer to the offset you specify as a parameter. The following is the calling sequence for this function:

```
fileio.seek( fileHandle, offset ); // Repositions file to specified offset.
```

The function call above will reposition the file pointer to the byte offset specified by the *offset* parameter. If you feed this function the value returned by *fileio.position*, then the next read or write operation will access the record written (or read) immediately after the *fileio.position* call.

You can pass any arbitrary offset value as a parameter to the *fileio.seek* routine; this value does not have to be one that the *fileio.position* function returns. For random access file I/O you would normally compute this offset file by specifying the index of the record you wish to access multiplied by the size of the record. For example, the following code computes the byte offset of record *index* in the file, repositions the file pointer to that record, and then reads the record:

```
intmul( @size( myRecord ), index, ebx );
fileio.seek( fileHandle, ebx );
```

```
fileio.read( fileHandle, (type byte myRecord), @size( myRecord ) );
```

You can use essentially this same code sequence to select a specific record in the file for writing.

Note that it is not an error to seek beyond the current end of file and then write data. If you do this, Windows will automatically fill in the intervening records with uninitialized data. Generally, this isn't a great way to create files, but it is perfectly legal. On the other hand, be aware that if you do this by accident, you may wind up with garbage in the file and no error to indicate that this has happened.

The fileio module provides another routine for repositioning the file pointer: *fileio.rSeek*. This function's calling sequence is very similar to *fileio.seek*, it is

```
fileio.rSeek( fileHandle, offset );
```

The difference between this function and the regular *fileio.seek* function is that this function repositions the file pointer offset bytes from the end of the file (rather than offset bytes from the start of the file). The "r" in "rSeek" stands for "reverse" seek.

Repositioning the file pointer, especially if you reposition it a fair distance from its current location, can be a time-consuming process. If you reposition the file pointer and then attempt to read a record from the file, the system may need to reposition a disk arm (a very slow process) and wait for the data to rotate underneath the disk read/write head. This is why random access I/O is much less efficient than sequential I/O.

The following program demonstrates random access I/O by writing and reading a file of records:

```
program RandomAccessDemo;
#include( "stdlib.hhf" )

type
  fileRec:
    record
      x:int16;
      y:int16;
      magnitude:uns8;
    endrecord;

const

  // Some arbitrary data we can use to initialize the file:

  fileData:=
    [
      fileRec:[ 2000, 1, 1 ],
      fileRec:[ 1000, 10, 2 ],
      fileRec:[ 750, 100, 3 ],
      fileRec:[ 500, 500, 4 ],
      fileRec:[ 100, 1000, 5 ],
      fileRec:[ 62, 2000, 6 ],
      fileRec:[ 32, 2500, 7 ],
      fileRec:[ 10, 3000, 8 ]
    ];

static
  fileHandle:dword;
  RecordFromFile:fileRec;
  InitialFileData:fileRec[ 8 ] := fileData;

begin RandomAccessDemo;
```

```

fileio.openNew( "fileRec.bin" );
mov( eax, fileHandle );

// Okay, write the initial data to the file in a sequential fashion:

for( mov( 0, ebx ); ebx < 8; inc( ebx ) ) do

    intmul( @size( fileRec ), ebx, ecx );// Compute index into fileData
    fileio.write
    (
        fileHandle,
        (type byte InitialFileData[ecx]),
        @size( fileRec )
    );

endfor;

// Okay, now let's demonstrate a random access of this file
// by reading the records from the file backwards.

stdout.put( "Reading the records, backwards:" nl );
for( mov( 7, ebx ); (type int32 ebx) >= 0; dec( ebx ) ) do

    intmul( @size( fileRec ), ebx, ecx );// Compute file offset
    fileio.seek( fileHandle, ecx );
    fileio.read
    (
        fileHandle,
        (type byte RecordFromFile),
        @size( fileRec )
    );
    if( eax = @size( fileRec ) ) then

        stdout.put
        (
            "Read record #",
            (type uns32 ebx),
            ", values:" nl
            " x: ", RecordFromFile.x, nl
            " y: ", RecordFromFile.y, nl
            " magnitude: ", RecordFromFile.magnitude, nl nl
        );

    else

        stdout.put( "Error reading record number ", (type uns32 ebx), nl );

    endif;

endfor;
fileio.close( fileHandle );

end RandomAccessDemo;

```

Program 7.6 Random Access File I/O Example

7.5 ISAM (Indexed Sequential Access Method) Files

ISAM is a trick that attempts to allow random access to variable-length records in a sequential file. This is a technique employed by IBM on their mainframe data bases in the 1960's and 1970's. Back then, disk space was very precious (remember why we wound up with the Y2K problem?) and IBM's engineers did everything they could to save space. At that time disks held about five megabytes, or so, were the size of washing machines, and cost tens of thousands of dollars. You can appreciate why they wanted to make every byte count. Today, data base designers have disk drives with hundreds of gigabytes per drive and RAID² devices with dozens of these drives installed. They don't bother trying to conserve space at all ("Heck, I don't know how big the person's name can get, so I'll allocate 256 bytes for it!"). Nevertheless, even with large disk arrays, saving space is often a wise idea. Not everyone has a terabyte (1,000 gigabytes) at their disposal and a user of your application may not appreciate your decision to waste their disk space. Therefore, techniques like ISAM that can reduce disk storage requirements are still important today.

ISAM is actually a very simple concept. Somewhere, the program saves the offset to the start of every record in a file. Since offsets are four bytes long, an array of *dwords* will work quite nicely³. Generally, as you construct the file you fill in the list (array) of offsets and keep track of the number of records in the file. For example, if you were creating a text file and you wanted to be able to quickly locate any line in the file, you would save the offset into the file of each line you wrote to the file. The following code fragment shows how you could do this:

```
static
    outputLine: string;
    ISAMarray: dword[ 128*1024 ]; // allow up to 128K records.
    .
    .
    .
    mov( 0, ecx );           // Keep record count here.
    forever

        << create a line of text in "outputLine" >>

        fileio.position( fileHandle );
        mov( eax, ISAMarray[ecx*4] ); // Save away current record offset.
        fileio.put( fileHandle, outputLine, nl ); // Write the record.
        inc( ecx ); // Advance to next element of ISAMarray.

        << determine if we're done and BREAK if we are >>

    endfor;

    << At this point, ECX contains the number of records and >>
    << ISAMarray[0]..ISAMarray[ecx-1] contain the offsets to >>
    << each of the records in the file. >>
```

After building the file using the code above, you can quickly jump to an arbitrary line of text by fetching the index for that line from the *ISAMarray* list. The following code demonstrates how you could read line *recordNumber* from the file:

```
mov( recordNumber, ebx );
fileio.seek( fileHandle, ISAMarray[ ebx*4 ] );
fileio.a_gets( fileHandle, inputString );
```

As long as you've precalculated the *ISAMarray* list, accessing an arbitrary line in this text file is a trivial matter.

2. Redundant array of inexpensive disks. RAID is a mechanism for combining lots of cheap disk drives together to form the equivalent of a really large disk drive.

3. This assumes, of course, that your files have a maximum size of four gigabytes.

Of course, back in the days when IBM programmers were trying to squeeze every byte from their databases as possible so they would fit on a five megabyte disk drive, they didn't have 512 kilobytes of RAM to hold 128K entries in the *ISAMarray* list. Although a half a megabyte is no big deal today, there are a couple of reasons why keeping the *ISAMarray* list in a memory-based array might not be such a good idea. First, databases are much larger these days. Some databases have hundreds of millions of entries. While setting aside a half a megabyte for an ISAM table might not be a bad thing, few people are willing to set aside a half a gigabyte for this purpose. Even if your database isn't amazingly big, there is another reason why you might not want to keep your *ISAMarray* in main memory – it's the same reason you don't keep the file in memory – memory is volatile and the data is lost whenever the application quits or the user removes power from the system. The solution is exactly the same as for the file data: you store the *ISAMarray* data in its own file. A program that builds the ISAM table while writing the file is a simple modification to the previous ISAM generation program. The trick is to open two files concurrently and write the ISAM data to one file while you're writing the text to the other file:

```
static
    fileHandle: dword;    // file handle for the text file.
    outputLine: string;   // file handle for the ISAM file.
    CurrentOffset: dword; // Holds the current offset into the text file.
    .
    .
    .
forever

    << create a line of text in "outputLine" >>

    // Get the offset of the next record in the text file
    // and write this offset (sequentially) to the ISAM file.

    fileio.position( fileHandle );
    mov( eax, CurrentOffset );
    fileio.write( isamHandle, (type byte CurrentOffset), 4 );

    // Okay, write the actual text data to the text file:

    fileio.put( fileHandle, outputLine, nl ); // Write the record.

    << determine if we're done and BREAK if we are >>

endfor;
```

If necessary, you can count the number of records as before. You might write this value to the first record of the ISAM file (since you know the first record of the text file is always at offset zero, you can use the first element of the ISAM list to hold the count of ISAM/text file records).

Since the ISAM file is just a sequence of four-byte integers, each record in the file (i.e., an integer) has the same length. Therefore, we can easily access any value in the ISAM file using the random access file I/O mechanism. In order to read a particular line of text from the text file, the first task is to read the offset from the ISAM file and then use that offset to read the desired line from the text file. The code to accomplish this is as follows:

```
// Assume we want to read the line specified by the "lineNumber" variable.

if( lineNumber <> 0 ) then

    // If not record number zero, then fetch the offset to the desired
    // line from the ISAM file:

    intmul( 4, lineNumber, eax ); // Compute the index into the ISAM file.
    fileio.seek( isamHandle, eax );
    fileio.read( isamHandle, (type byte CurrentOffset), 4 ); // Read offset
```

```

else

    mov( 0, eax ); // Special case for record zero because the file
                  // contains the record count in this position.

endif;
fileio.seek( fileHandle, CurrentOffset ); // Set text file position.
fileio.a_gets( fileHandle, inputLine ); // Read the line of text.

```

This operation runs at about half the speed of having the ISAM array in memory (since it takes four file accesses rather than two to read the line of text from the file), but the data is non-volatile and is not limited by the amount of available RAM.

If you decide to use a memory-based array for your ISAM table, it's still a good idea to keep that data in a file somewhere so you don't have to recompute it (by reading the entire file) every time your application starts. If the data is present in a file, all you've got to do is read that file data into your *ISAMarray* list. Assuming you've stored the number of records in element number zero of the ISAM array, you could use the following code to read your ISAM data into the *ISAMarray* variable:

```

static
    isamSize: uns32;
    isamHandle: dword;
    fileHandle: dword;
    ISAMarray: dword[ 128*1024 ];
    .
    .
    .
// Read the first record of the ISAM file into the isamSize variable:

fileio.read( isamHandle, (type byte isamSize), 4 );

// Now read the remaining data from the ISAM file into the ISAMarray
// variable:

if( isamSize >= 128*1024 ) then

    raise( ex.ValueOutOfRange );

endif;
intmul( 4, isamSize, ecx ); // #records * 4 is number of bytes to read.
fileio.read( isamHandle, (type byte ISAMarray), ecx );

// At this point, ISAMarray[0]..ISAMarray[isamSize-1] contain the indexes
// into the text file for each line of text.

```

7.6 Truncating a File

If you open an existing file (using *fileio.open*) for output and write data to that file, it overwrites the existing data from the start of the file. However, if the new data you write to the file is shorter than the data originally appearing in the file, the excess data from the original file, beyond the end of the new data you've written, will still appear at the end of the new data. Sometimes this might be desirable, but most of the time you'll want to delete the old data after writing the new data.

One way to delete the old data is to use the *fileio.openNew* function to open the file. The *fileio.openNew* function automatically deletes any existing file so only the data you write to the file will be present in the file. However, there may be times when you may want to read the old data first, rewind the file, and then overwrite the data. In this situation, you'll need a function that will *truncate* the old data at the end of the file

after you've written the new data. The *fileio.truncate* function accomplishes this task. This function uses the following calling syntax:

```
fileio.truncate( fileHandle );
```

Note that this function does not close the file. You still have to call *fileio.close* to commit the data to the disk.

The following sample program demonstrates the use of the *fileio.truncate* function:

```

program TruncateDemo;
#include( "stdlib.hhf" )

static
    fileHandle:dword;
    u:uns32;

begin TruncateDemo;

    fileio.openNew( "myfile.txt" );
    mov( eax, fileHandle );
    for( mov( 0, ecx ); ecx < 20; inc( ecx ) ) do

        fileio.put( fileHandle, (type uns32 ecx), nl );

    endfor;

    // Okay, let's rewind to the beginning of the file and
    // rewrite the first ten lines and then truncate the
    // file at that point.

    fileio.rewind( fileHandle );
    for( mov( 0, ecx ); ecx < 10; inc( ecx ) ) do

        fileio.put( fileHandle, (type uns32 ecx), nl );

    endfor;
    fileio.truncate( fileHandle );

    // Rewind and display the file contents to ensure that
    // the file truncation has worked.

    fileio.rewind( fileHandle );
    while( !fileio.eof( fileHandle ) ) do

        // Read and display the next item from the file:

        fileio.get( fileHandle, u );
        stdout.put( "u=", u, nl );
        fileio.readLine( fileHandle );

    endwhile;
    fileio.close( fileHandle );

end TruncateDemo;

```

7.7 File Utility Routines

The following subsections describe *fileio* functions that manipulate files or return meta-information about files (e.g., the file size and attributes).

7.7.1 Copying, Moving, and Renaming Files

Some very useful file utilities are copying, moving, and renaming files. For example, you might want to copy a file an application has created in order to make a backup copy. Moving files from one subdirectory to another, or even from one disk to another is another common operation. Likewise, the need to change the name of a file arises all the time. In this section we'll take a look at the HLA Standard Library routines that accomplish these operations.

Copying a file is a nearly trivial process. All you've got to do is open a source file, open a destination file, then read the bytes from the source file and write them to the destination file until you hit end of file. Unfortunately, this simple approach to copying a file can suffer from performance problems. Windows provides an internal function to copy files using a high performance algorithm. The HLA Standard Library *fileio.copy* function provides an interface to this copy operation. The copy a file using the *fileio.copy* procedure, you'd use the following call sequence:

```
fileio.copy( sourcefileName, destFileName, failIfExists );
```

The *sourceFileName* and *destFileName* parameters are strings that specify the pathnames of the source and destination files. These can be string constants or variables. The last parameter is a boolean variable that specifies what should happen if the destination file exists. If this parameter contains true and the file already exists, then the function will fail; if *failIfExists* is false, the *fileio.copy* routine will replace the existing destination file with a copy of the source file. In either case, of course, the source file must exist or this function will fail. This function returns a boolean success/failure result in the EAX register. It returns true if the function returns TRUE in EAX.

Program 7.8 demonstrates the use of this function to copy a file:

```
program CopyDemo;
#include( "stdlib.hhf" )

begin CopyDemo;

    // Make a copy of myfile.txt to itself to demonstrate
    // a true "failsIfExists" parameter.

    if( !fileio.copy( "myfile.txt", "myfile.txt", true ) ) then

        stdout.put( "Did not copy 'myfile.txt' over itself" nl );

    else

        stdout.put( "Whoa! The failsIfExists parameter didn't work." nl );

    endif;

    // Okay, make a copy of the file to a different file, to verify
    // that this works properly:

    if( fileio.copy( "myfile.txt", "copyOfMyFile.txt", false ) ) then

        stdout.put( "Successfully copied the file" nl );

    endif;
end CopyDemo;
```

```

else
    stdout.put( "Failed to copy the file (maybe it doesn't exist?)" nl );
endif;
end CopyDemo;

```

Program 7.8 Demonstration of a fileio.copy Operation

To move a file from one location to another might seem like another trivial task – all you’ve got to do is copy the file to the destination and then delete the original file. However, this scheme is quite inefficient in most situations. Copying the file can be an expensive process if the file is large; Worse, the move operation may fail if you’re moving the file to a new location on the same disk and there is insufficient space for a second copy of the file. A much better solution is to simply move the file’s *directory entry* from one location to another on the disk. Windows’ disk directory entries are quite small, so moving a file to a different location on the same disk by simply moving its directory entry is very fast and efficient. Unfortunately, if you move a file from one file system (disk) to another, you will have to first copy the file and then delete the original file. Once again, you don’t have to bother with the complexities of this operation because Windows has a built-in function that automatically moves files for you. The HLA Standard Library’s *fileio.move* procedure provides a direct interface to this function. The calling sequence is

```
fileio.move( source, dest );
```

The two parameters are strings providing the source and destination filenames. This function returns true or false in EAX to denote the success or failure of the operation.

Not only can the *fileio.move* procedure move a file around on the disk, it can also move subdirectories around. The only catch is that you cannot move a subdirectory from one volume (file system/disk) to another.

If both the destination and source filenames are simple filenames, not a pathnames, then the *fileio.move* function moves the source file from the current directory back to the current directory. Although this seems rather weird, this is a very common operation; this is how you rename a file. The HLA Standard Library does not have a separate “fileio.rename” function. Instead, you use the fileio.move function to rename files by moving them to the same directory but with a different filename. Program 7.9 demonstrates how to use *fileio.move* in this capacity.

```

program FileMoveDemo;
#include( "stdlib.hhf" )

begin FileMoveDemo;

    // Rename the "myfile.txt" file to the name "renamed.txt".

    if( !fileio.move( "myfile.txt", "renamed.txt" ) ) then

        stdout.put
        (
            "Could not rename 'myfile.txt' (maybe it doesn't exist?)" nl
        );

    else

        stdout.put( "Successfully renamed the file" nl );
    end if;
end FileMoveDemo;

```

```

endif;

end FileMoveDemo;

```

Program 7.9 Using fileio.move to Rename a File

7.7.2 Computing the File Size

Another useful function to have is one that computes the size of an existing file on the disk. The *fileio.size* function provides this capability. The calling sequences for this function are

```

fileio.size( filenameString );
fileio.size( fileHandle );

```

The first form above expects you to pass the filename as a string parameter. The second form expects a handle to a file you've opened with *fileio.open* or *fileio.openNew*. These two calls return the size of the file in EAX. If an error occurs, these functions return -1 (\$FFFF_FFFF) in EAX. Note that the files must be less than four gigabytes in length when using this function (if you need to check the size of larger files, you will have to call the appropriate Windows function rather than these functions; however, since files larger than four gigabytes are rather rare, you probably won't have to worry about this problem).

One interesting use for this function is to determine the number of records in a fixed-length-record random access file. By getting the size of the file and dividing by the size of a record, you can determine the number of records in the file.

Another use for this function is to allow you to determine the size of a (smaller) file, allocate sufficient storage to hold the entire file in memory (by using *malloc*), and then read the entire file into memory using the *fileio.read* function. This is generally the fastest way to read data from a file into memory.

Program 7.10 demonstrates the use of the two forms of the *fileio.size* function by displaying the size of the "myfile.txt" file created by other sample programs in this chapter.

```

program FileSizeDemo;
#include( "stdlib.hhf" )

static
  handle:dword;

begin FileSizeDemo;

  // Display the size of the "myfile.txt" file:

  fileio.size( "myfile.txt" );
  if( eax <> -1 ) then

    stdout.put( "Size of file: ", (type uns32 eax), nl );

  else

    stdout.put( "Error calculating file size" nl );

  endif;

  // Same thing, using the file handle as a parameter:

```

```

fileio.open( "myfile.txt", win.GENERIC_READ );
mov( eax, handle );
fileio.size( handle );
if( eax <> -1 ) then

    stdout.put( "Size of file(2): ", (type uns32 eax), nl );

else

    stdout.put( "Error calculating file size" nl );

endif;
fileio.close( handle );

end FileSizeDemo;

```

Program 7.10 Sample Program That Demonstrates the fileio.size Function

7.7.3 Deleting Files

Another useful file utility function is the fileio.delete function. As its name suggests, this function deletes a file that you specify as the function's parameter. The calling sequence for this function is

```
fileio.delete( filenameToDelete );
```

The single parameter is a string containing the pathname of the file you wish to delete. This function returns true/false in the EAX register to denote success/failure.

Program 7.11 provides an example of the use of the *fileio.delete* function.

```

program DeleteFileDemo;
#include( "stdlib.hhf" )

static
    handle:dword;

begin DeleteFileDemo;

    // Delete the "myfile.txt" file:

    fileio.delete( "xyz" );
    if( eax ) then

        stdout.put( "Deleted the file", nl );

    else

        stdout.put( "Error deleting the file" nl );

    endif;

end DeleteFileDemo;

```

Program 7.11 Example Usage of the `fileio.delete` Procedure

7.8 Directory Operations

In addition to manipulating files, you can also manipulate directories with some of the *fileio* functions. You've already seen how to use the *fileio.move* function to move or rename a directory. The HLA Standard Library also includes several functions that let you create and use subdirectories. These functions are *fileio.cd* (change directory), *fileio.gwd* (get working directory), and *fileio.mkdir* (make directory). Their calling sequences are

```
fileio.cd( pathnameString );
fileio.gwd( stringToHoldPathname );
fileio.mkdir( newDirectoryName );
```

The *fileio.cd* and *fileio.mkdir* functions return success or failure (true or false, respectively) in the EAX register. For the *fileio.gwd* function, the string parameter is a destination string where the system will store the pathname to the current directory. You must allocate sufficient storage for the string prior to passing the string to this function (260 characters⁴ is a good default amount if you're unsure how long the pathname could be). If the actual pathname is too long to fit in the destination string you supply as a parameter, the *fileio.gwd* function will raise the *ex.StringOverflow* exception.

The *fileio.cd* function sets the current working directory to the pathname you specify. After calling this function, Windows will assume that all future "unadorned" file references (those without any "\ " characters in the pathname) will default to the directory you specify as the *fileio.cd* parameter. Proper use of this function can help make your program much more convenient to use by your program's users since they won't have to enter full pathnames for every file they manipulate.

The *fileio.gwd* function lets you query the system to determine the current working directory. After a call to *fileio.cd*, the string that *fileio.gwd* returns should be the same as *fileio.cd*'s parameter. Typically, you would use this function to keep track of the default directory when your program first starts running. Your program will exhibit good manners by switching back to this default directory when your program terminates.

The *fileio.mkdir* function lets your program create a new subdirectory. If your program creates data files and stores them in a default directory somewhere, it's good etiquette to let the user specify the subdirectory where your program should put these files. If you do this, you should give your users the option to create a new directory (in case they want the data placed in a brand-new directory). You can use *fileio.mkdir* for this purpose.

7.9 Putting It All Together

This chapter began with a discussion of the basic file operations. That section was rather short because you've already learned most of what you need to know about file I/O when learning the *stdout* and *stdin* functions. So the introductory material concentrated on a file general file concepts (like the differences between sequential and random access files and the differences between binary and text files). After teaching you the few extra routines you need in order to open and close files, the remainder of this chapter simply concentrated on providing a few examples (like ISAM) of file access and a discussion of the *fileio* routines available in the HLA Standard Library.

4. This is the default MAX_PATH value in Windows.

While this chapter demonstrates the mechanics of file I/O, how you efficiently use files is well beyond the scope of this chapter. In future volumes you will see how to search for data in files, sort data in files, and even create databases. So keep on reading if you're interested in more information about file operations.

The HLA Standard Library actually provides two file I/O modules. This chapter discusses the procedure-oriented functions. The Standard Library also provides a set of object-oriented file I/O classes and methods. Unfortunately, a discussion of those functions will have to wait until you've read the chapter on classes and object-oriented programming in a later volume. Until then, the functions this chapter describes are just fine (in fact, who's to say they're not better than the object-oriented file I/O functions?).

Introduction to Procedures

Chapter Eight

8.1 Chapter Overview

In a procedural programming language the basic unit of code is the *procedure*. A procedure is a set of instructions that compute some value or take some action (such as printing or reading a character value). The definition of a procedure is very similar to the definition of an *algorithm*. A procedure is a set of rules to follow which, if they conclude, produce some result. An algorithm is also such a sequence, but an algorithm is guaranteed to terminate whereas a procedure offers no such guarantee.

This chapter discusses how HLA implements procedures. This is actually the first of three chapters on this subject in this text. This chapter presents HLA procedures from a high level language perspective. A later chapter, Intermediate Procedures, discusses procedures at the machine language level. A whole volume in this sequence, Advanced Procedures, covers advanced programming topics of interest to the very serious assembly language programmer. This chapter, however, provides the foundation for all that follows.

8.2 Procedures

Most procedural programming languages implement procedures using the call/return mechanism. That is, some code calls a procedure, the procedure does its thing, and then the procedure returns to the caller. The call and return instructions provide the 80x86's *procedure invocation mechanism*. The calling code calls a procedure with the CALL instruction, the procedure returns to the caller with the RET instruction. For example, the following 80x86 instruction calls the HLA Standard Library *stdout.newln* routine¹:

```
call stdout.newln;
```

The *stdout.newln* procedure prints a carriage return/line feed sequence to the video display and returns control to the instruction immediately following the “call stdout.newln;” instruction.

Alas, the HLA Standard Library does not supply all the routines you will need. Most of the time you'll have to write your own procedures. To do this, you will use HLA's procedure declaration facilities. A basic HLA procedure declaration takes the following form:

```
procedure ProcName;
  << Local declarations >>
begin ProcName;
  << procedure statements >>
end ProcName;
```

Procedure declarations appear in the declaration section of your program. That is, anywhere you can put a STATIC, CONST, TYPE, or other declaration section, you may place a procedure declaration. In the syntax example above, *ProcName* represents the name of the procedure you wish to define. This can be any valid HLA identifier. Whatever identifier follows the PROCEDURE reserved word must also follow the BEGIN and END reserved words in the procedure. As you've probably noticed, a procedure declaration looks a whole lot like an HLA program. In fact, the only difference (so far) is the use of the PROCEDURE reserved word rather than the PROGRAM reserved word.

Here is a concrete example of an HLA procedure declaration. This procedure stores zeros into the 256 double word objects that EBX points at upon entry into the procedure:

```
procedure zeroBytes;
begin zeroBytes;

    mov( 0, eax );
    mov( 256, ecx );
```

1. Normally you would call newln using the “newln();” statement, but the CALL instruction works as well.

```

repeat
    mov( eax, [ebx] );
    add( 4, ebx );
    dec( ecx );

until( ecx = 0 );

end zeroBytes;

```

You can use the 80x86 CALL instruction to call this procedure. When, during program execution, the code falls into the “end zeroBytes;” statement, the procedure returns to whomever called it and begins executing the first instruction beyond the CALL instruction. The following program provides an example of a call to the *zeroBytes* routine:

```

program zeroBytesDemo;
#include( "stdlib.hhf" );

procedure zeroBytes;
begin zeroBytes;

    mov( 0, eax );
    mov( 256, ecx );
    repeat

        mov( eax, [ebx] );// Zero out current dword.
        add( 4, ebx );// Point ebx at next dword.
        dec( ecx );// Count off 256 dwords.

    until( ecx = 0 );// Repeat for 256 dwords.

end zeroBytes;

static
    dwArray: dword[256];

begin zeroBytesDemo;

    lea( ebx, dwArray );
    call zeroBytes;

end zeroBytesDemo;

```

Program 8.1 Example of a Simple Procedure

As you may have noticed when calling HLA Standard Library procedures, you don’t always need to use the CALL instruction to call HLA procedures. There is nothing special about the HLA Standard Library procedures versus your own procedures. Although the formal 80x86 mechanism for calling procedures is to use the CALL instruction, HLA provides a HLL extension that lets you call a procedure by simply specifying that procedure’s name followed by an empty set of parentheses². For example, either of the following statements will call the HLA Standard Library *stdout.newln* procedure:

```

call stdout.newln;
stdout.newln();

```

2. This assumes that the procedure does not have any parameters.

Likewise, either of the following statements will call the *zeroBytes* procedure in Program 8.1:

```
call zeroBytes;
zeroBytes();
```

The choice of calling mechanism is strictly up to you. Most people, however, find the HLL syntax easier to read.

8.3 Saving the State of the Machine

Take a look at the following program:

```
program nonWorkingProgram;
#include( "stdlib.hhf" );

procedure PrintSpaces;
begin PrintSpaces;

    mov( 40, ecx );
    repeat

        stdout.put( ' ' );// Print 1 of 40 spaces.
        dec( ecx );// Count off 40 spaces.

    until( ecx = 0 );

end PrintSpaces;

begin nonWorkingProgram;

    mov( 20, ecx );
    repeat

        PrintSpaces();
        stdout.put( '*', nl );
        dec( ecx );

    until( ecx = 0 );

end nonWorkingProgram;
```

Program 8.2 Program with an Unintended Infinite Loop

This section of code attempts to print 20 lines of 40 spaces and an asterisk. Unfortunately, there is a subtle bug that causes it to print 40 spaces per line and an asterisk in an infinite loop. The main program uses the REPEAT..UNTIL loop to call *PrintSpaces* 20 times. *PrintSpaces* uses ECX to count off the 40 spaces it prints. *PrintSpaces* returns with ECX containing zero. The main program then prints an asterisk, a newline, decrements ECX, and then repeats because ECX isn't zero (it will always contain \$FFFF_FFFF at this point).

The problem here is that the *PrintSpaces* subroutine doesn't preserve the ECX register. Preserving a register means you save it upon entry into the subroutine and restore it before leaving. Had the *PrintSpaces* subroutine preserved the contents of the ECX register, the program above would have functioned properly.

Use the 80x86's PUSH and POP instructions to preserve register values while you need to use them for something else. Consider the following code for *PrintSpaces*:

```

procedure PrintSpaces;
begin PrintSpaces;

    push( eax );
    push( ecx );
    mov( 40, ecx );
    repeat

        stdout.put( ' ' ); // Print 1 of 40 spaces.
        dec( ecx );        // Count off 40 spaces.

    until( ecx = 0 );
    pop( ecx );
    pop( eax );

end PrintSpaces;

```

Note that *PrintSpaces* saves and restores EAX and ECX (since this procedure modifies these registers). Also, note that this code pops the registers off the stack in the reverse order that it pushed them. The operation of the stack imposes this ordering.

Either the caller (the code containing the CALL instruction) or the callee (the subroutine) can take responsibility for preserving the registers. In the example above, the callee preserved the registers. The following example shows what this code might look like if the caller preserves the registers:

```

program callerPreservation;
#include( "stdlib.hhf" );

procedure PrintSpaces;
begin PrintSpaces;

    mov( 40, ecx );
    repeat

        stdout.put( ' ' );// Print 1 of 40 spaces.
        dec( ecx );// Count off 40 spaces.

    until( ecx = 0 );

end PrintSpaces;

begin callerPreservation;

    mov( 20, ecx );
    repeat

        push( eax );
        push( ecx );
        PrintSpaces();
        pop( ecx );
        pop( eax );
        stdout.put( '\n', nl );
        dec( ecx );

    until( ecx = 0 );

```

```
end callerPreservation;
```

Program 8.3 Demonstration of Caller Register Preservation

There are two advantages to callee preservation: space and maintainability. If the callee preserves all affected registers, then there is only one copy of the PUSH and POP instructions, those the procedure contains. If the caller saves the values in the registers, the program needs a set of PUSH and POP instructions around every call. Not only does this make your programs longer, it also makes them harder to maintain. Remembering which registers to push and pop on each procedure call is not something easily done.

On the other hand, a subroutine may unnecessarily preserve some registers if it preserves all the registers it modifies. In the examples above, the code needn't save EAX. Although *PrintSpaces* changes AL, this won't affect the program's operation. If the caller is preserving the registers, it doesn't have to save registers it doesn't care about:

```
program callerPreservation2;
#include( "stdlib.hhf" );

procedure PrintSpaces;
begin PrintSpaces;

    mov( 40, ecx );
    repeat

        stdout.put( ' ' );// Print 1 of 40 spaces.
        dec( ecx );// Count off 40 spaces.

    until( ecx = 0 );

end PrintSpaces;

begin callerPreservation2;

    mov( 10, ecx );
    repeat

        push( ecx );
        PrintSpaces();
        pop( ecx );
        stdout.put( '*', nl );
        dec( ecx );

    until( ecx = 0 );

    mov( 5, ebx );
    while( ebx > 0 ) do

        PrintSpaces();

        stdout.put( ebx, nl );
        dec( ebx );

    endwhile;
```

```

mov( 110, ecx );
for( mov( 0, eax );  eax < 7; inc( eax ) ) do

    PrintSpaces();

    stdout.put( eax, " ", ecx, nl );
    dec( ecx );

endfor;

end callerPreservation2;

```

Program 8.4 Demonstrating that Caller Preservation Need not Save All Registers

This example provides three different cases. The first loop (REPEAT..UNTIL) only preserves the ECX register. Modifying the AL register won't affect the operation of this loop. Immediately after the first loop, this code calls *PrintSpaces* again in the WHILE loop. However, this code doesn't save EAX or ECX because it doesn't care if *PrintSpaces* changes them. Since the final loop (FOR) uses EAX and ECX, it saves them both.

One big problem with having the caller preserve registers is that your program may change. You may modify the calling code or the procedure so that they use additional registers. Such changes, of course, may change the set of registers that you must preserve. Worse still, if the modification is in the subroutine itself, you will need to locate *every* call to the routine and verify that the subroutine does not change any registers the calling code uses.

Preserving registers isn't all there is to preserving the environment. You can also push and pop variables and other values that a subroutine might change. Since the 80x86 allows you to push and pop memory locations, you can easily preserve these values as well.

8.4 Prematurely Returning from a Procedure

The HLA EXIT and EXITIF statements let you return from a procedure without having to fall into the corresponding END statement in the procedure. These statements behave a whole lot like the BREAK and BREAKIF statements for loops, except they transfer control to the bottom of the procedure rather than out of the current loop. These statements are quite useful in many cases.

The syntax for these two statements is the following:

```

exit procedurename;
exitif( boolean_expression ) procedurename;

```

The *procedurename* operand is the name of the procedure you wish to exit. If you specify the name of your main program, the EXIT and EXITIF statements will terminate program execution (even if you're currently inside a procedure rather than the body of the main program).

The EXIT statement immediately transfers control out of the specified procedure or program. The conditional exit, EXITIF, statement first tests the boolean expression and exits if the result is true. It is semantically equivalent to the following:

```

if( boolean_expression ) then

    exit procedurename;

endif;

```

Although the EXIT and EXITIF statements are invaluable in many cases, you should try to avoid using them without careful consideration. If a simple IF statement will let you skip the rest of the code in your

procedure, by all means use the IF statement. Procedures that contain lots of EXIT and EXITIF statements will be harder to read, understand, and maintain than procedures without these statements (after all, the EXIT and EXITIF statements are really nothing more than GOTO statements and you've probably heard already about the problems with GOTOs). EXIT and EXITIF are convenient when you got to return from a procedure inside a sequence of nested control structures and slapping an IF.ENDIF around the remaining code in the procedure is not possible.

8.5 Local Variables

HLA procedures, like procedures and functions in most high level languages, let you declare *local variables*. Local variables are generally accessible only within the procedure, they are not accessible by the code that calls the procedure. Local variable declarations are identical to variable declarations in your main program except, of course, you declare the variables in the procedure's declaration section rather than the main program's declaration section. Actually, you may declare anything in the procedure's declaration section that is legal in the main program's declaration section, including constants, types, and even other procedures³. In this section, however, we'll concentrate on local variables.

Local variables have two important attributes that differentiate them from the variables in your main program (i.e., *global* variables): *lexical scope* and *lifetime*. Lexical scope, or just *scope*, determines when an identifier is usable in your program. Lifetime determines when a variable has memory associated with it and is capable of storing data. Since these two concepts differentiate local and global variables, it is wise to spend some time discussing these two attributes.

Perhaps the best place to start when discussing the scope and lifetimes of local variables is with the scope of lifetimes of global variables -- those variables you declare in your main program. Until now, the only rule you've had to follow concerning the declaration of your variables has been "you must declare all variables that you use in your programs." The position of the HLA declaration section with respect to the program statements automatically enforces the other major rule which is "you must declare all variables before their first use." With the introduction of procedures, it is now possible to violate this rule since (1) procedures may access global variables, and (2) procedure declarations may appear anywhere in a declaration section including before some variable declarations. The following program demonstrates this source code organization:

```

program demoGlobalScope;
#include( "stdlib.hhf" );

static
    AccessibleInProc: char;

    procedure aProc;
    begin aProc;

        mov( 'a', AccessibleInProc );

    end aProc;

static
    InaccessibleInProc: char;

begin demoGlobalScope;

```

3. The chapter on Advanced Procedures discusses the concept of local procedures in greater detail.

```

mov( 'b', InaccessibleInProc );
aProc();
stdout.put
(
  "AccessibleInProc = '", AccessibleInProc, "' n\l
  "InaccessibleInProc = '", InaccessibleInProc, "' n\l
);

end demoGlobalScope;

```

Program 8.5 Demonstration of Global Scope

This example demonstrates that a procedure can access global variables in the main program as long as you declare those global variables before the procedure. In this example, the *aProc* procedure cannot access the *InaccessibleInProc* variable because its declaration appears after the procedure declaration. However, *aProc* may reference *AccessibleInProc* since its declaration appears before the *aProc* procedure in the source code.

A procedure can access any `STATIC`, `STORAGE`, `READONLY`, or `DATA` object exactly the same way the main program accesses such variables -- by simply referencing the name. Although a procedure may access global `VAR` objects, a different syntax is necessary and you need to learn a little more before you will understand the purpose of the additional syntax. Therefore, we'll defer the discussion of accessing `VAR` objects until the chapter on Advanced Procedures.

Accessing global objects is convenient and easy. Unfortunately, as you've probably learned when studying high level language programming, accessing global objects makes your programs harder to read, understand, and maintain. Like most introductory programming texts, this text will discourage the use of global variables within procedures. Accessing global variables within a procedure is sometimes the best solution to a given problem. However, such (legitimate) access typically occurs only in advanced programs involving multiple threads of execution or in other complex systems. Since it is unlikely you would be writing such code at this point, it is equally unlikely that you will absolutely need to access global variables in your procedures so you should carefully consider your options before accessing global variables within your procedures⁴.

Declaring local variables in your procedures is very easy, you use the same declaration sections as the main program: `STATIC`, `READONLY`, `STORAGE`, and `VAR`. The same rules and syntax for the declaration sections and the access of variables you declare in these sections applies in your procedure. The following example code demonstrates the declaration of a local variable.

```

program demoLocalVars;
#include( "stdlib.hhf" );

// Simple procedure that displays 0..9 using
// a local variable as a loop control variable.

procedure CntTo10;
var
  i: int32;

begin CntTo10;

  for( mov( 0, i ); i < 10; inc( i ) ) do

```

4. Note that this argument against accessing global variables does not apply to other global symbols. It is perfectly reasonable to access global constants, types, procedures, and other objects in your programs.

```

        stdout.put( "i=", i, nl );
    endfor;
end CntTo10;

begin demoLocalVars;

    CntTo10();

end demoLocalVars;

```

Program 8.6 Example of a Local Variable in a Procedure

Local variables you declare in a procedure are accessible only within that procedure⁵. Therefore, the variable *i* in procedure *CntTo10* in Program 8.6 is not accessible in the main program.

HLA relaxes, somewhat, the rule that identifiers must be unique in a program for local variables. In an HLA program, all identifiers must be unique within a given *scope*. Therefore, all global names must be unique with respect to one another. Similarly, all local variables within a given procedure must have unique names *but only with respect to other local symbols in that procedure*. In particular, a local name may be the same as a global name. When this occurs, HLA creates two separate variables for the two objects. Within the scope of the procedure any reference to the common name accesses the local variable; outside that procedure, any reference to the common name references the global identifier. Although the quality of the resultant code is questionable, it is perfectly legal to have a global identifier named *MyVar* with the same local name in two or more different procedures. The procedures each have their own local variant of the object which is independent of *MyVar* in the main program. Program 8.7 provides an example of an HLA program that demonstrates this feature.

```

program demoLocalVars2;
#include( "stdlib.hhf" );

static
    i: uns32 := 10;
    j: uns32 := 20;

    // The following procedure declares "i" and "j"
    // as local variables, so it does not have access
    // to the global variables by the same name.

    procedure First;
    var
        i: int32;
        j: uns32;

    begin First;

        mov( 10, j );
        for( mov( 0, i ); i < 10; inc( i ) ) do

            stdout.put( "i=", i, " j=", j, nl );
            dec( j );

```

5. Strictly speaking, this is not true. The chapter on Advanced Procedures will present an exception.

```

        endfor;

    end First;

    // This procedure declares only an "i" variable.
    // It cannot access the value of the global "i"
    // variable but it can access the value of the
    // global "j" object since it does not provide
    // a local variant of "j".

    procedure Second;
    var
        i:uns32;

    begin Second;

        mov( 10, j );
        for( mov( 0, i ); i < 10; inc( i ) ) do

            stdout.put( "i=", i, " j=", j, nl );
            dec( j );

        endfor;

    end Second;

begin demoLocalVars2;

    First();
    Second();

    // Since the calls to First and Second have not
    // modified variable "i", the following statement
    // should print "i=10". However, since the Second
    // procedure manipulated global variable "j", this
    // code will print "j=0" rather than "j=20".

    stdout.put( "i=", i, " j=", j, nl );

end demoLocalVars2;

```

Program 8.7 Local Variables Need Not Have Globally Unique Names

There are good and bad points to be made about reusing global names within a procedure. On the one hand, there is the potential for confusion. If you use a name like *ProfitsThisYear* as a global symbol and you reuse that name within a procedure, someone reading the procedure might think that the procedure refers to the global symbol rather than the local symbol. On the other hand, simple names like *i*, *j*, and *k* are nearly meaningless (almost everyone expects the program to use them as loop control variables or for other local uses), so reusing these names as local objects is probably a good idea. From a software engineering perspective, it is probably a good idea to keep all variables names that have a very specific meaning (like *ProfitsThisYear*) unique throughout your program. General names, that have a nebulous meaning (like *index*, *counter*, and names like *i*, *j*, or *k*) will probably be okay to reuse as global variables

There is one last point to make about the scope of identifiers in an HLA program: variables in separate procedures (that is, two procedures where one procedure is not declared in the declaration section of the second procedure) are separate, even if they have the same name. The *First* and *Second* procedures in Program

8.7, for example, share the same name (*i*) for a local variable. However, the *i* in *First* is a completely different variable than the *i* in *Second*.

The second major attribute that differentiates (certain) local variables from global variables is *lifetime*. The lifetime of a variable spans from the point the program first allocates storage for a variable to the point the program deallocates the storage for that variable. Note that lifetime is a dynamic attribute (controlled at run time) whereas scope is a static attribute (controlled at compile time). In particular, a variable can actually have several lifetimes if the program repeatedly allocates and then deallocates the storage for that variable.

Global variables always have a single lifetime that spans from the moment the main program first begins execution to the point the main program terminates. Likewise, all static objects have a single lifetime that spans the execution of the program (remember, static objects are those you declare in the `STATIC`, `READ-ONLY`, or `STORAGE` sections). This is true even for procedures. So there is no difference between the lifetime of a local static object and the lifetime of a global static object. Variables you declare in the `VAR` section, however, are a different matter. `VAR` objects use *automatic storage allocation*. Automatic storage allocation means that the procedure automatically allocates storage for a local variable upon entry into a procedure. Similarly, the program deallocates storage for automatic objects when the procedure returns to its caller. Therefore, the lifetime of an automatic object is from the point the procedure is first called to the point it returns to its caller.

Perhaps the most important thing to note about automatic variables is that you cannot expect them to maintain their values between calls to the procedure. Once the procedure returns to its caller, the storage for the automatic variable is lost and, therefore, the value is lost as well. Therefore, *you must always assume that a local VAR object is uninitialized upon entry into a procedure*; even if you know you've called the procedure before and the previous procedure invocation initialized that variable. Whatever value the last call stored into the variable was lost when the procedure returned to its caller. If you need to maintain the value of a variable between calls to a procedure, you should use one of the static variable declaration types.

Given that automatic variables cannot maintain their values across procedure calls, you might wonder why you would want to use them at all. However, there are several benefits to automatic variables that static variables do not have. The biggest disadvantage to static variables is that they consume memory even when the (only) procedure that references them is not running. Automatic variables, on the other hand, only consume storage while their associated procedure is executing. Upon return, the procedure returns any automatic storage it allocated back to the system for reuse by other procedures. You'll see some additional advantages to automatic variables later in this chapter.

8.6 Other Local and Global Symbol Types

As mentioned in the previous section, HLA lets you declare constants, values, types, and anything else legal in the main program's declaration section within a procedure's declaration section. The same rules for scope apply to these identifiers. Therefore, you can reuse constant names, procedure names, type names, etc. in local declarations (although this is almost always a bad idea).

Referencing global constants, values, and types, does not present the same software engineering problems that occur when you reference global variables. The problem with referencing global variables is that a procedure can change the value of a global variable in a non-obvious way. This makes programs more difficult to read, understand, and maintain since you can't often tell that a procedure is modifying memory by looking only at the call to that procedure. Constants, values, types, and other non-variable objects, don't suffer from this problem because you cannot change them at run-time. Therefore, the pressure to avoid global objects at nearly all costs doesn't apply to non-variable objects.

Having said that it's okay to access global constants, types, etc., it's also worth pointing out that you should declare these objects locally within a procedure if the only place your program references such objects is within that procedure. Doing so will make your programs a little easier to read since the person reading your code won't have to search all over the place for the symbol's definition.

8.7 Parameters

Although there is a large class of procedures that are totally self-contained, most procedures require some input data and return some data to the caller. Parameters are values that you pass to and from a procedure. In straight assembly language, passing parameters can be a real chore. Fortunately, HLA provides a HLL-like syntax for procedure declarations and for procedure calls involving parameters. This chapter will present HLA's HLL parameter syntax. Later chapters on Intermediate Procedures and Advanced Procedures will deal with the low-level mechanisms for passing parameters in pure assembly code.

The first thing to consider when discussing parameters is *how* we pass them to a procedure. If you are familiar with Pascal or C/C++ you've probably seen two ways to pass parameters: pass by value and pass by reference. HLA certainly supports these two parameter passing mechanisms. However, HLA also supports pass by value/result, pass by result, pass by name, and pass by lazy evaluation. Of course, HLA is assembly language so it is possible to pass parameters in HLA using any scheme you can dream up (at least, any scheme that is possible at all on the CPU). However, HLA provides special HLL syntax for pass by value, reference, value/result, result, name, and lazy evaluation.

Because pass by value/result, result, name, and lazy evaluation are somewhat advanced, this chapter will not deal with those parameter passing mechanisms. If you're interested in learning more about these parameter passing schemes, see the chapters on Intermediate and Advanced Procedures.

Another concern you will face when dealing with parameters is *where* you pass them. There are lots of different places to pass parameters; the chapter on Intermediate Procedures will consider these places in greater detail. In this chapter, since we're using HLA's HLL syntax for declaring and calling procedures, we'll wind up passing procedure parameters on the stack. You don't really need to concern yourself with the details since HLA abstracts them away for you; however, do keep in mind that procedure calls and procedure parameters make use of the stack. Therefore, something you push on the stack immediately before a procedure call is not going to be immediately on the top of the stack upon entry into the procedure.

8.7.1 Pass by Value

A parameter passed by value is just that – the caller passes a value to the procedure. Pass by value parameters are input only parameters. That is, you can pass them to a procedure but the procedure cannot return them. In HLA the idea of a pass by value parameter being an input only parameter makes a lot of sense. Given the HLA procedure call:

```
CallProc(I);
```

If you pass *I* by value, then *CallProc* does not change the value of *I*, regardless of what happens to the parameter inside *CallProc*.

Since you must pass a copy of the data to the procedure, you should only use this method for passing small objects like bytes, words, and double words. Passing arrays and records by value is very inefficient (since you must create and pass a copy of the object to the procedure).

HLA, like Pascal and C/C++, passes parameters by value unless you specify otherwise. Here's what a typical function looks like with a single pass by value parameter:

```
procedure PrintNSpaces( N:uns32 );
begin PrintNSpaces;

    push( ecx );
    mov( N, ecx );
    repeat

        stdout.put( ' ' ); // Print 1 of N spaces.
        dec( ecx );       // Count off N spaces.

    until( ecx = 0 );
    pop( ecx );
```

```
end PrintNSpaces;
```

The parameter *N* in *PrintNSpaces* is known as a formal parameter. Anywhere the name *N* appears in the body of the procedure the program references the value passed through *N* by the caller.

The calling sequence for *PrintNSpaces* can be any of the following:

```
PrintNSpaces( constant );
PrintNSpaces( reg32 );
PrintNSpaces( uns32_variable );
```

Here are some concrete examples of calls to *PrintNSpaces*:

```
PrintNSpaces( 40 );
PrintNSpaces( EAX );
PrintNSpaces( SpacesToPrint );
```

The parameter in the calls to *PrintNSpaces* is known as an *actual parameter*. In the examples above, 40, EAX, and *SpacesToPrint* are the actual parameters.

Note that pass by value parameters behave exactly like local variables you declare in the VAR section with the single exception that the procedure's caller initializes these local variables before it passes control to the procedure.

HLA uses positional parameter notation just like most high level languages. Therefore, if you need to pass more than one parameter, HLA will associate the actual parameters with the formal parameters by their position in the parameter list. The following *PrintNChars* procedure demonstrates a simple procedure that has two parameters.

```
procedure PrintNChars( N:uns32; c:char );
begin PrintNChars;

    push( ecx );
    mov( N, ecx );
    repeat

        stdout.put( c );    // Print 1 of N characters.
        dec( ecx );        // Count off N characters.

    until( ecx = 0 );
    pop( ecx );

end PrintNChars;
```

The following is an invocation of the *PrintNChars* procedure that will print 20 asterisk characters:

```
PrintNChars( 20, '*' );
```

Note that HLA uses semicolons to separate the formal parameters in the procedure declaration and it uses commas to separate the actual parameters in the procedure invocation (Pascal programmers should be comfortable with this notation). Also note that each HLA formal parameter declaration takes the following form:

parameter_identifier : *type_identifier*

In particular, note that the parameter type has to be an identifier. None of the following are legal parameter declarations because the data type is not a single identifier:

```
PtrVar: pointer to uns32
ArrayVar: uns32[10]
recordVar: record i:int32; u:uns32; endrecord
DynArray: array.dArray( uns32, 2 )
```

However, don't get the impression that you cannot pass pointer, array, record, or dynamic array variables as parameters. The trick is to declare a data type for each of these types in the TYPE section. Then you can use a single identifier as the type in the parameter declaration. The following code fragment demonstrates how to do this with the four data types above:

```
type
  uPtr:      pointer to uns32;
  uArray10:  uns32[10];
  recType:   record i:int32; u:uns32; endrecord
  dType:     array.dArray( uns32, 2 );

procedure FancyParms
(
  PtrVar: uPtr;
  ArrayVar:uArray10;
  recordVar:recType;
  DynArray: dtype
);
begin FancyParms;
.
.
.
end FancyParms;
```

By default, HLA assumes that you intend to pass a parameter by value. HLA also lets you explicitly state that a parameter is a value parameter by prefacing the formal parameter declaration with the VAL keyword. The following is a version of the PrintNSpaces procedure that explicitly states that *N* is a pass by value parameter:

```
procedure PrintNSpaces( val N:uns32 );
begin PrintNSpaces;

  push( ecx );
  mov( N, ecx );
  repeat

    stdout.put( ' ' ); // Print 1 of N spaces.
    dec( ecx );       // Count off N spaces.

  until( ecx = 0 );
  pop( ecx );

end PrintNSpaces;
```

Explicitly stating that a parameter is a pass by value parameter is a good idea if you have multiple parameters in the same procedure declaration that use different passing mechanisms.

When you pass a parameter by value and call the procedure using the HLA high level language syntax, HLA will automatically generate code that will make a copy of the actual parameter's value and copy this data into the local storage for that parameter (i.e., the formal parameter). For small objects pass by value is probably the most efficient way to pass a parameter. For large objects, however, HLA must generate code that copies each and every byte of the actual parameter into the formal parameter. For large arrays and records this can be a very expensive operation⁶. Unless you have specific semantic concerns that require you to pass an array or record by value, you should use pass by reference or some other parameter passing mechanism for arrays and records.

6. Note to C/C++ programmers: HLA does not automatically pass arrays by reference. If you specify an array type as a formal parameter, HLA will emit code that makes a copy of each and every byte of that array when you call the associated procedure.

When passing parameters to a procedure, HLA checks the type of each actual parameter and compares this type to the corresponding formal parameter. If the types do not agree, HLA then checks to see if either the actual or formal parameter is a byte, word, or dword object and the other parameter is one, two, or four bytes in length (respectively). If the actual parameter does not satisfy either of these conditions, HLA reports a parameter type mismatch error. If, for some reason, you need to pass a parameter to a procedure using a different type than the procedure calls for, you can always use the HLA type coercion operator to override the type of the actual parameter.

8.7.2 Pass by Reference

To pass a parameter by reference, you must pass the address of a variable rather than its value. In other words, you must pass a pointer to the data. The procedure must dereference this pointer to access the data. Passing parameters by reference is useful when you must modify the actual parameter or when you pass large data structures between procedures.

To declare a pass by reference parameter you must preface the formal parameter declaration with the VAR keyword. The following code fragment demonstrates this:

```
procedure UsePassByReference( var PBRvar: int32 );
begin UsePassByReference;
    .
    .
    .
end UsePassByReference;
```

Calling a procedure with a pass by reference parameter uses the same syntax as pass by value except that the parameter has to be a memory location; it cannot be a constant or a register. Furthermore, the type of the memory location must exactly match the type of the formal parameter. The following are legal calls to the procedure above (assuming *i32* is an *int32* variable):

```
UsePassByReference( i32 );
UsePassByReference( (type int32 [ebx] ) );
```

The following are all illegal *UsePassbyReference* invocations (assumption: *charVar* is of type *char*):

```
UsePassByReference( 40 );           // Constants are illegal.
UsePassByReference( EAX );         // Bare registers are illegal.
UsePassByReference( charVar );     // Actual parameter type must match
// the formal parameter type.
```

Unlike the high level languages Pascal and C++, HLA does not completely hide the fact that you are passing a pointer rather than a value. In a procedure invocation, HLA will automatically compute the address of a variable and pass that address to the procedure. Within the procedure itself, however, you cannot treat the variable like a value parameter (as you could in most HLLs). Instead, you treat the parameter as a *dword* variable containing a pointer to the specified data. You must explicitly dereference this pointer when accessing the parameter's value. The following example provides a simple demonstration of this:

```
program PassByRefDemo;
#include( "stdlib.hhf" );

var
    i: int32;
    j: int32;

procedure pbr( var a:int32; var b:int32 );
const
    aa: text := "(type int32 [ebx])";
    bb: text := "(type int32 [ebx])";
```

```

begin pbr;

    push( eax );
    push( ebx );// Need to use EBX to dereference a and b.

    // a = -1;

    mov( a, ebx );// Get ptr to the "a" variable.
    mov( -1, aa );// Store -1 into the "a" parameter.

    // b = -2;

    mov( b, ebx );// Get ptr to the "b" variable.
    mov( -2, bb );// Store -2 into the "b" parameter.

    // Print the sum of a+b.
    // Note that ebx currently contains a pointer to "b".

    mov( bb, eax );
    mov( a, ebx );// Get ptr to "a" variable.
    add( aa, eax );
    stdout.put( "a+b=", (type int32 eax), nl );

end pbr;

begin PassByRefDemo;

    // Give i and j some initial values so
    // we can see that pass by reference will
    // overwrite these values.

    mov( 50, i );
    mov( 25, j );

    // Call pbr passing i and j by reference

    pbr( i, j );

    // Display the results returned by pbr.

    stdout.put
    (
        "i= ", i, nl,
        "j= ", j, nl
    );

end PassByRefDemo;

```

Program 8.8 Accessing Pass by Reference Parameters

Passing parameters by reference can produce some peculiar results in some rare circumstances. Consider the *pbr* procedure in Program 8.8. Were you to modify the call in the main program to be “*pbr(i,i)*” rather than “*pbr(i,j)*,” the program would produce the following non-intuitive output:

```

a+b=-4
i= -2;
j= 25;

```

The reason this code displays “a+b=-4” rather than the expected “a+b=-3” is because the “pbr(i,i);” call passes the same actual parameter for *a* and *b*. As a result, the *a* and *b* reference parameters both contain a pointer to the same memory location- that of the variable *i*. In this case, *a* and *b* are *aliases* of one another. Therefore, when the code stores -2 at the location pointed at by *b*, it overwrites the -1 stored earlier at the location pointed at by *a*. When the program fetches the value pointed at by *a* and *b* to compute their sum, both *a* and *b* point at the same value, which is -2. Summing -2 + -2 produces the -4 result that the program displays. This non-intuitive behavior is possible anytime you encounter aliases in a program. Passing the same variable as two different parameters probably isn’t very common. But you could also create an alias if a procedure references a global variable and you pass that same global variable by reference to the procedure (this is a good example of yet one more reason why you should avoid referencing global variables in a procedure).

Pass by reference is usually less efficient than pass by value. You must dereference all pass by reference parameters on each access; this is slower than simply using a value since it typically requires at least two instructions. However, when passing a large data structure, pass by reference is faster because you do not have to copy a large data structure before calling the procedure. Of course, you’d probably need to access elements of that large data structure (e.g., an array) using a pointer, so very little efficiency is lost when you pass large arrays by reference.

8.8 Functions and Function Results

Functions are procedures that return a result. In assembly language, there are very few syntactical differences between a procedure and a function which is why HLA doesn’t provide a specific declaration for a function. Nevertheless, although there is very little *syntactical* difference between assembly procedures and functions, there are considerable *semantic* differences. That is, although you can declare them the same way in HLA, you use them differently.

Procedures are a sequence of machine instructions that fulfill some activity. The end result of the execution of a procedure is the accomplishment of that activity. Functions, on the other hand, execute a sequence of machine instructions specifically to compute some value to return to the caller. Of course, a function can perform some activity as well and procedures can undoubtedly compute some values, but the main difference is that the purpose of a function is to return some computed result; procedures don’t have this requirement.

A good example of a procedure is the *stdout.puti32* procedure. This procedure requires a single *int32* parameter. The purpose of this procedure is to print the decimal conversion of this integer value to the standard output device. Note that *stdout.puti32* doesn’t return any kind of value that is usable by the calling program.

A good example of a function is the *cs.member* function. This function expects two parameters: the first is a character value and the second is a character set value. This function returns true (1) in EAX if the character is a member of the specified character set. It returns false if the character parameter is not a member of the character set.

Logically, the fact that *cs.member* returns a usable value to the calling code (in EAX) while *stdout.puti32* does not is a good example of the main difference between a function and a procedure. So, in general, a procedure becomes a function by virtue of the fact that you explicitly decide to return a value somewhere upon procedure return. No special syntax is needed to declare and use a function. You still write the code as a procedure.

8.8.1 Returning Function Results

The 80x86’s registers are the most popular place to return function results. The *cs.member* routine in the HLA Standard Library is a good example of a function that returns a value in one of the CPU’s registers. It returns true (1) or false (0) in the EAX register. By convention, programmers try to return eight, sixteen, and thirty-two bit (non-real) results in the AL, AX, and EAX registers, respectively⁷. For example, this is where most high level languages return these types of results.

Of course, there is nothing particularly sacred about the AL/AX/EAX register. You could return function results in any register if it is more convenient to do so. However, if you don't have a good reason for not using AL/AX/EAX, then you should follow the convention. Doing so will help others understand your code better since they will generally assume that your functions return small results in the AL/AX/EAX register set.

If you need to return a function result that is larger than 32 bits, you obviously must return it somewhere besides in EAX (which can hold values 32 bits or less). For values slightly larger than 32 bits (e.g., 64 bits or maybe even as many as 128 bits) you can split the result into pieces and return those parts in two or more registers. For example, it is very common to see programs returning 64-bit values in the EDX:EAX register pair. For example, the HLA Standard Library *stdin.geti64* function returns a 64-bit integer in the EDX:EAX register pair.

If you need to return a really large object as a function result, say an array of 1,000 elements, you obviously are not going to be able to return the function result in the registers. There are two common ways to deal with really large function return results: either pass the return value as a reference parameter or allocate storage on the heap (using *malloc*) for the object and return a pointer to it in a 32-bit register. Of course, if you return a pointer to storage you've allocated on the heap, the calling program must free this storage when it is done with it.

8.8.2 Instruction Composition in HLA

Several HLA Standard Library functions allow you to call them as operands of other instructions. For example, consider the following code fragment:

```
if( cs.member( al, {'a'..'z'}) ) then
  .
  .
  .
endif;
```

As your high level language experience (and HLA experience) should suggest, this code calls the *cs.member* function to check to see if the character in AL is a lower case alphabetic character. If the *cs.member* function returns true then this code fragment executes the then section of the IF statement; however, if *cs.member* returns false, this code fragment skips the IF.THEN body. There is nothing spectacular here except for the fact that HLA doesn't support function calls as boolean expressions in the IF statement (look back at Chapter Two in Volume One to see the complete set of allowable expressions). How then, does this program compile and run producing the intuitive results?

The very next section will describe how you can tell HLA that you want to use a function call in a boolean expression. However, to understand how this works, you need to first learn about *instruction composition* in HLA.

Instruction composition lets you use one instruction as the operand of another. For example, consider the MOV instruction. It has two operands, a source operand and a destination operand. Instruction composition lets you substitute a valid 80x86 machine instruction for either (or both) operands. The following is a simple example:

```
mov( mov( 0, eax ), ebx );
```

Of course the immediate question is "what does this mean?" To understand what is going on, you must first realize that most instructions "return" a value to the compiler while they are being compiled. For most instructions, the value they "return" is their destination operand. Therefore, "mov(0, eax);" returns the string "eax" to the compiler during compilation since EAX is the destination operand. Most of the time, specifically when an instruction appears on a line by itself, the compiler ignores the string result the instruction returns. However, HLA uses this string result whenever you supply an instruction in place of some

7. In the next chapter you'll see where most programmers return real results.

operand. Specifically, HLA uses that string in place of the instruction as the operand. Therefore, the MOV instruction above is equivalent to the following two instruction sequence:

```
mov( 0, eax );    // HLA compiles interior instructions first.
mov( eax, ebx );
```

When processing composed instructions (that is, instruction sequences that have other instructions as operands), HLA always works in an “left-to-right then depth-first (inside-out)” manner. To make sense of this, consider the following instructions:

```
add( sub( mov( i, eax ), mov( j, ebx ) ), mov( k, ecx ) );
```

To interpret what is happening here, begin with the source operand. It consists of the following:

```
sub( mov( i, eax ), mov( j, ebx ) )
```

The source operand for this instruction is “mov(i, eax)” and this instruction does not have any composition, so HLA emits this instruction and returns its destination operand (EAX) for use as the source to the SUB instruction. This effectively gives us the following:

```
sub( eax, mov( j, ebx ) )
```

Now HLA compiles the instruction that appears as the destination operand (“mov(j, ebx)”) and returns its destination operand (EBX) to substitute for this MOV in the SUB instruction. This yields the following:

```
sub( eax, ebx )
```

This is a complete instruction, without composition, that HLA can compile. So it compiles this instruction and returns its destination operand (EBX) as the string result to substitute for the SUB in the original ADD instruction. So the original ADD instruction now becomes:

```
add( ebx, mov( i, ecx ) );
```

HLA next compiles the MOV instruction appearing in the destination operand. It returns its destination operand as a string that HLA substitutes for the MOV, finally yielding the simple instruction:

```
add( ebx, ecx );
```

The compilation of the original ADD instruction, therefore, yields the following instruction sequence:

```
mov( i, eax );
mov( j, ebx );
sub( eax, ebx );
mov( k, ecx );
add( ebx, ecx );
```

Whew! It’s rather difficult to look at the original instruction and easily see that this sequence is the result. As you can easily see in this example, *overzealous use of instruction composition can produce nearly unreadable programs*. You should be very careful about using instruction composition in your programs. With only a few exceptions, writing a composed instruction sequence makes your program harder to read.

Note that the excessive use of instruction composition may make errors in your program difficult to decipher. Consider the following HLA statement:

```
add( mov( eax, i ), mov( ebx, j ) );
```

This instruction composition yields the 80x86 instruction sequence:

```
mov( eax, i );
mov( ebx, j );
add( i, j );
```

Of course, the compiler will complain that you’re attempting to add one memory location to another. However, the instruction composition effectively masks this fact and makes it difficult to comprehend the cause of the error message. Moral of the story: avoid using instruction composition unless it really makes your

program easier to read. The few examples in this section demonstrate how *not* to use instruction composition.

There are two main areas where using instruction composition can help make your programs more readable. The first is in HLA's high level language control structures. The other is in procedure parameters. Although instruction composition is useful in these two cases (and probably a few others as well), this doesn't give you a license to use extremely convoluted instructions like the ADD instruction in this example. Instead, most of the time you will use a single instruction or a function call in place of a single operand in a high level language boolean expression or in a procedure/function parameter.

While we're on the subject, exactly what does a procedure call return as the string that HLA substitutes for the call in an instruction composition? For that matter, what do statements like IF.ENDIF return? How about instructions that don't have a destination operand? Well, function return results are the subject of the very next section so you'll read about that in a few moments. As for all the other statements and instructions, you should check out the HLA reference manual. It lists each instruction and its "RETURNS" value. The "RETURNS" value is the string that HLA will substitute for the instruction when it appears as the operand to another instruction. Note that many HLA statements and instructions return the empty string as their "RETURNS" value (by default, so do procedure calls). If an instruction returns the empty string as its composition value, then HLA will report an error if you attempt to use it as the operand of another instruction. For example, the IF.ENDIF statement returns the empty string as its "RETURNS" value, so you may not bury an IF.ENDIF inside another instruction.

8.8.3 The HLA RETURNS Option in Procedures

HLA procedure declarations allow a special option that specifies the string to use when a procedure invocation appears as the operand of another instruction: the RETURNS option. The syntax for a procedure declaration with the RETURNS option is as follows:

```
procedure ProcName ( optional parameters ); RETURNS( string_constant );
  << Local declarations >>
begin ProcName;
  << procedure statements >>
end ProcName;
```

If the RETURNS option is not present, HLA associates the empty string with the RETURNS value for the procedure. This effectively makes it illegal to use that procedure invocation as the operand to another instruction.

The RETURNS option requires a single string parameter surrounded by parentheses. This must be a string constant⁸. HLA will substitute this string constant for the procedure call if it ever appears as the operand of another instruction. Typically this string constant is a register name; however, any text that would be legal as an instruction operand is okay here. For example, you could specify memory address or constants. For purposes of clarity, you should always specify the location of a function's return value in the RETURNS parameter.

As an example, consider the following boolean function that returns true or false in the EAX register if the single character parameter is an alphabetic character⁹:

8. Do note, however, that it doesn't have to be a string literal constant. A CONST string identifier or even a constant string expression is legal here.

9. Before you run off and actually use this function in your own programs, note that the HLA Standard Library provides the *char.isAlpha* function that provides this test. See the HLA documentation for more details.

```

procedure IsAlphabeticChar( c:char ); RETURNS( "EAX" );
begin IsAlphabeticChar;

    // Note that cs.member returns true/false in EAX

    cs.member( c, { 'a'..'z', 'A'..'Z' } );

end IsAlphabeticChar;

```

Once you tack the RETURNS option on the end of this procedure declaration you can legally use a call to *IsAlphabeticChar* as an operand to other HLA statements and instructions:

```

mov( IsAlphabeticChar( al ), EBX );
.
.
.
if( IsAlphabeticChar( ch ) ) then
.
.
.
endif;

```

The last example above demonstrates that, via the RETURNS option, you can embed calls to your own functions in the boolean expression field of various HLA statements. Note that the code above is equivalent to

```

IsAlphabeticChar( ch );
if( EAX ) then
.
.
.
endif;

```

Not all HLA high level language statements expand composed instructions before the statement. For example, consider the following WHILE statement:

```

while( IsAlphabeticChar( ch ) ) do
.
.
.
endwhile;

```

This code does not expand to the following:

```

IsAlphabeticChar( ch );
while( EAX ) do
.
.
.
endwhile;

```

Instead, the call to *IsAlphabeticChar* expands inside the WHILE's boolean expression so that the program calls this function on each iteration of the loop.

You should exercise caution when entering the RETURNS parameter. HLA does not check the syntax of the string parameter when it is compiling the procedure declaration (other than to verify that it is a string constant). Instead, HLA checks the syntax when it replaces the function call with the RETURNS string. So if you had specified "EAZ" instead of "EAX" as the RETURNS parameter for *IsAlphabeticChar* in the previous examples, HLA would not have reported an error until you actually used *IsAlphabeticChar* as an operand. Then of course, HLA complains about the illegal operand and it's not at all clear what the problem is by looking at the *IsAlphabeticChar* invocation. So take special care not to introduce typographical errors in the RETURNS string; figuring out such errors later can be very difficult.

8.9 Side Effects

A *side effect* is any computation or operation by a procedure that isn't the primary purpose of that procedure. For example, if you elect not to preserve all affected registers within a procedure, the modification of those registers is a side effect of that procedure. Side effect programming, that is, the practice of using a procedure's side effects, is very dangerous. All too often a programmer will rely on a side effect of a procedure. Later modifications may change the side effect, invalidating all code relying on that side effect. This can make your programs hard to debug and maintain. Therefore, you should avoid side effect programming.

Perhaps some examples of side effect programming will help enlighten you to the difficulties you may encounter. The following procedure zeros out an array. For efficiency reasons, it makes the caller responsible for preserving necessary registers. As a result, one side effect of this procedure is that the EBX and ECX registers are modified. In particular, the ECX register contains zero upon return.

```
procedure ClrArray;
begin ClrArray;

    lea( ebx, array );
    mov( 32, ecx );
    while( ecx > 0 ) do

        mov( 0, (type dword [ebx]));
        add( 4, ebx );
        dec( ecx );

    endwhile;

end ClrArray;
```

If your code expects ECX to contain zero after the execution of this subroutine, you would be relying on a side effect of the *ClrArray* procedure. The main purpose behind this code is zeroing out an array, not setting the ECX register to zero. Later, if you modify the *ClrArray* procedure to the following, your code that depends upon ECX containing zero would no longer work properly:

```
procedure ClrArray;
begin ClrArray;

    mov( 0, ebx );
    while( ebx < 32 ) do

        mov( 0, array[ebx*4] );
        inc( ebx );

    endwhile;

end ClrArray;
```

So how can you avoid the pitfalls of side effect programming in your procedures? By carefully structuring your code and paying close attention to exactly how your calling code and the subservient procedures interface with one another. These rules can help you avoid problems with side effect programming:

- Always properly document the input and output conditions of a procedure. Never rely on any other entry or exit conditions other than these documented operations.
- Partition your procedures so that they compute a single value or execute a single operation. Subroutines that do two or more tasks are, by definition, producing side effects unless every invocation of that subroutine requires all the computations and operations.
- When updating the code in a procedure, make sure that it still obeys the entry and exit conditions. If not, either modify the program so that it does or update the documentation for that procedure to reflect the new entry and exit conditions.

- Avoid passing information between routines in the CPU's flag register. Passing an error status in the carry flag is about as far as you should ever go. Too many instructions affect the flags and it's too easy to foul up a return sequence so that an important flag is modified on return.
- Always save and restore all registers a procedure modifies.
- Avoid passing parameters and function results in global variables.
- Avoid passing parameters by reference (with the intent of modifying them for use by the calling code).

These rules, like all other rules, were meant to be broken. Good programming practices are often sacrificed on the altar of efficiency. There is nothing wrong with breaking these rules as often as you feel necessary. However, your code will be difficult to debug and maintain if you violate these rules often. But such is the price of efficiency¹⁰. Until you gain enough experience to make a judicious choice about the use of side effects in your programs, you should avoid them. More often than not, the use of a side effect will cause more problems than it solves.

8.10 Recursion

Recursion occurs when a procedure calls itself. The following, for example, is a recursive procedure:

```
procedure Recursive;
begin Recursive;

    Recursive();

end Recursive;
```

Of course, the CPU will never return from this procedure. Upon entry into *Recursive*, this procedure will immediately call itself again and control will never pass to the end of the procedure. In this particular case, run away recursion results in an infinite loop.

Like a looping structure, recursion requires a termination condition in order to stop infinite recursion. *Recursive* could be rewritten with a termination condition as follows:

```
procedure Recursive;
begin Recursive;

    dec( eax );
    if( @nz ) then

        Recursive();

    endif;

end Recursive;
```

This modification to the routine causes *Recursive* to call itself the number of times appearing in the EAX register. On each call, *Recursive* decrements the EAX register by one and calls itself again. Eventually, *Recursive* decrements EAX to zero and returns. Once this happens, each successive call returns back to *Recursive* until control returns to the original call to *Recursive*.

So far, however, there hasn't been a real need for recursion. After all, you could efficiently code this procedure as follows:

```
procedure Recursive;
begin Recursive;
```

10. This is not just a snide remark. Expert programmers who have to wring the last bit of performance out of a section of code often resort to poor programming practices in order to achieve their goals. They are prepared, however, to deal with the problems that are often encountered in such situations and they are a lot more careful when dealing with such code.

```

repeat
    dec( eax );

until( @z );

end Recursive;

```

Both examples would repeat the body of the procedure the number of times passed in the EAX register¹¹. As it turns out, there are only a few recursive algorithms that you cannot implement in an iterative fashion. However, many recursively implemented algorithms are more efficient than their iterative counterparts and most of the time the recursive form of the algorithm is much easier to understand.

The quicksort algorithm is probably the most famous algorithm that almost always appears in recursive form. An HLA implementation of this algorithm follows:

```

program QSDemo;
#include( "stdlib.hhf" );

type
    ArrayType:uns32[ 10 ];

static
    theArray:ArrayType := [1,10,2,9,3,8,4,7,5,6];

procedure quicksort( var a:ArrayType; Low:int32; High: int32 );
const
    i:    text := "(type int32 edi)";
    j:    text := "(type int32 esi)";
    Middle:text := "(type uns32 edx)";
    ary:text := "[ebx]";

begin quicksort;

    push( eax );
    push( ebx );
    push( ecx );
    push( edx );
    push( esi );
    push( edi );

    mov( a, ebx );// Load BASE address of "a" into EBX

    mov( Low, edi);// i := Low;
    mov( High, esi );// j := High;

    // Compute a pivotal element by selecting the
    // physical middle element of the array.

    mov( i, eax );
    add( j, eax );
    shr( 1, eax );
    mov( ary[eax*4], Middle );// Put middle value in EDX

    // Repeat until the EDI and ESI indicies cross one
    // another (EDI works from the start towards the end

```

11. Although the latter version will do it considerably faster since it doesn't have the overhead of the CALL/RET instructions.

```

// of the array, ESI works from the end towards the
// start of the array).

repeat

    // Scan from the start of the array forward
    // looking for the first element greater or equal
    // to the middle element).

    while( Middle > ary[i*4] ) do

        inc( i );

    endwhile;

    // Scan from the end of the array backwards looking
    // for the first element that is less than or equal
    // to the middle element.

    while( Middle < ary[j*4] ) do

        dec( j );

    endwhile;

    // If we've stopped before the two pointers have
    // passed over one another, then we've got two
    // elements that are out of order with respect
    // to the middle element. So swap these two elements.

    if( i <= j ) then

        mov( ary[i*4], eax );
        mov( ary[j*4], ecx );
        mov( eax, ary[j*4] );
        mov( ecx, ary[i*4] );
        inc( i );
        dec( j );

    endif;

until( i > j );

// We have just placed all elements in the array in
// their correct positions with respect to the middle
// element of the array. So all elements at indicies
// greater than the middle element are also numerically
// greater than this element. Likewise, elements at
// indicies less than the middle (pivotal) element are
// now less than that element. Unfortunately, the
// two halves of the array on either side of the pivotal
// element are not yet sorted. Call quicksort recursively
// to sort these two halves if they have more than one
// element in them (if they have zero or one elements, then
// they are already sorted).

if( Low < j ) then

    quicksort( a, Low, j );

endif;

```

```

    if( i < High ) then
        quicksort( a, i, High );
    endif;

    pop( edi );
    pop( esi );
    pop( edx );
    pop( ecx );
    pop( ebx );
    pop( eax );

end quicksort;

begin QSDemo;

stdout.put( "Data before sorting: " nl );
for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

    stdout.put( theArray[ebx*4]:5 );

endfor;
stdout.newln();

quicksort( theArray, 0, 9 );

stdout.put( "Data after sorting: " nl );
for( mov( 0, ebx ); ebx < 10; inc( ebx ) ) do

    stdout.put( theArray[ebx*4]:5 );

endfor;
stdout.newln();

end QSDemo;

```

Program 8.9 Recursive Quicksort Program

Note that this quicksort procedure uses registers for all non-parameter local variables. Also note how Quicksort uses TEXT constant definitions to provide more readable names for the registers. This technique can often make an algorithm easier to read; however, one must take care when using this trick not to forget that those registers are being used.

8.11 Forward Procedures

As a general rule HLA requires that you declare all symbols before their first use in a program¹². Therefore, you must define all procedures before their first call. There are two reasons this isn't always practical: mutual recursion and source code organization. Fortunately, HLA lets you use a *forward procedure definition* to declare a procedure *prototype*. Forward declarations let you define a procedure before you actually supply the code for that procedure.

12. There are a few minor exceptions to this rule, but it is certainly true for procedure calls.

A forward procedure declaration is a familiar procedure declaration that uses the reserved word `FORWARD` in place of the procedure's declaration section and body. The following is a forward declaration for the quicksort procedure appearing in the last section:

```
procedure quicksort( var a:ArrayType; Low:int32; High: int32 ); forward;
```

A forward declaration in an HLA program is a promise to the compiler that the actual procedure declaration will appear, exactly as stated in the forward declaration, at a later point in the source code. "Exactly as stated" means exactly that. The forward declaration must have the same parameters, they must be passed the same way, and they must all have the same type as the actual parameters in the procedure¹³.

Routines that are mutually recursive (that is, procedure A calls procedure B and procedure B calls procedure A) require at least one forward declaration since only one of procedure A or B can be declared before the other. In practice, however, mutual recursion (direct or indirect) doesn't occur very frequently, so the need for forward declarations is not that great.

In the absence of mutual recursion, it is always possible to organize your source code so that each procedure declaration appears before its first invocation. What's possible and what's desired are two different things, however. You might want to group a related set of procedures at the beginning of your source code and a different set of procedures towards the end of your source code. This logical grouping, by function rather than by invocation, may make your programs much easier to read and understand. However, this organization may also yield code that attempts to call a procedure before its declaration. No sweat. Just use a forward procedure definition to resolve the problem.

One major difference between the forward definition and the actual procedure declaration has to do with the procedure options. Some options, like `RETURNS` may appear only in the forward declaration. Other options may only appear in the actual procedure declaration (we haven't covered any of the other procedure options yet, so don't worry about them just yet). If your procedure requires a `RETURNS` option, the `RETURNS` option must appear before the `FORWARD` reserved word. E.g.,

```
procedure IsItReady( valueToTest: dword ); returns( "EAX" ); forward;
```

The `RETURNS` option must not also appear in the actual procedure declaration.

8.12 Putting It All Together

This chapter has filled in one of the critical elements missing from your assembly language knowledge: how to create user-defined procedures in an HLA program. This chapter discussed HLA's high level procedure declaration and calling syntax. It also described how to pass parameters by value and by reference as well as the use of local variables in HLA procedures. This chapter also provided information about instruction composition and the `RETURNS` option for procedures. Finally, this chapter explained recursion and the use of forward procedure declarations (prototypes).

The one thing this chapter did not discuss was how procedures are written in "pure" assembly language. This chapter presents just enough information to let you start using procedures in your HLA programs. The "real stuff" will have to wait for a few chapters. Fear not, however; later chapters will teach you far more than you probably care to know about procedures in assembly language programs.

13. Actually, "exactly" is too strong a word. You will see some exceptions in a moment.

Managing Large Programs

Chapter Nine

9.1 Chapter Overview

When writing larger HLA programs you do not typically write the whole program as a single source file. This chapter discusses how to break up a large project into smaller pieces and assemble the pieces separately. This radically reduces development time on large projects.

9.2 Managing Large Programs

Most assembly language programs are not totally stand alone programs. In general, you will call various standard library or other routines which are not defined in your main program. For example, you've probably noticed by now that the 80x86 doesn't provide any machine instructions like "read", "write", or "printf" for doing I/O operations. Of course, you can write your own procedures to accomplish this. Unfortunately, writing such routines is a complex task, and beginning assembly language programmers are not ready for such tasks. That's where the HLA Standard Library comes in. This is a package of procedures you can call to perform simple I/O operations like *stdout.put*.

The HLA Standard Library contains tens of thousands of lines of source code. Imagine how difficult programming would be if you had to merge these thousands of lines of code into your simple programs. Fortunately, you don't have to.

For small programs, working with a single source file is fine. For large programs this gets very cumbersome (consider the example above of having to include the entire HLA Standard Library into each of your programs). Furthermore, once you've debugged and tested a large section of your code, continuing to assemble that same code when you make a small change to some other part of your program is a waste of time. The HLA Standard Library, for example, takes several minutes to assemble, even on a fast machine. Imagine having to wait five or ten minutes on a fast Pentium machine to assemble a program to which you've made a one line change!

As with high level languages, the solution is *separate compilation*. First, you break up your large source files into manageable chunks. Then you compile the separate files into object code modules. Finally, you link the object modules together to form a complete program. If you need to make a small change to one of the modules, you only need to reassemble that one module, you do not need to reassemble the entire program.

The HLA Standard Library works in precisely this way. The Standard Library is already compiled and ready to use. You simply call routines in the Standard Library and link your code with the Standard Library using a *linker* program. This saves a tremendous amount of time when developing a program that uses the Standard Library code. Of course, you can easily create your own object modules and link them together with your code. You could even add new routines to the Standard Library so they will be available for use in future programs you write.

"Programming in the large" is a term software engineers have coined to describe the processes, methodologies, and tools for handling the development of large software projects. While everyone has their own idea of what "large" is, separate compilation, and some conventions for using separate compilation, are one of the big techniques for "programming in the large." The following sections describe the tools HLA provides for separate compilation and how to effectively employ these tools in your programs.

9.3 The #INCLUDE Directive

The #INCLUDE directive, when encountered in a source file, switches program input from the current file to the file specified in the parameter list of the include directive. This allows you to construct text files

containing common constants, types, source code, and other HLA items, and include such a file into the assembly of several separate programs. The syntax for the include directive is

```
#include( "filename" )
```

Filename must be a valid Windows filename. HLA merges the specified file into the compilation at the point of the #INCLUDE directive. Note that you can nest #INCLUDE statements inside files you include. That is, a file being included into another file during assembly may itself include a third file. In fact, the “stdlib.hhf” header file you see in most example programs in this text is really nothing more than the following¹:

```
#include( "hla.hhf" )
#include( "win32.hhf" ) // This statement depends on the OS.
#include( "x86.hhf" )
#include( "misctypes.hhf" )
#include( "hll.hhf" )

#include( "excepts.hhf" )
#include( "memory.hhf" )

#include( "args.hhf" )
#include( "conv.hhf" )
#include( "strings.hhf" )
#include( "cset.hhf" )
#include( "patterns.hhf" )
#include( "tables.hhf" )
#include( "arrays.hhf" )
#include( "chars.hhf" )

#include( "math.hhf" )
#include( "rand.hhf" )

#include( "stdio.hhf" )
#include( "console.hhf" )
```

Program 9.1 The stdlib.hhf Header File, as of 01/01/2000

By including “stdlib.hhf” in your source code, you automatically include all the HLA library modules. It’s often more efficient (in terms of compile time and size of code generated) to provide only those #INCLUDE statements for the modules you actually need in your program. However, including “stdlib.hhf” is extremely convenient and takes up less space in this text, which is why most programs appearing in this text use “stdlib.hhf”.

Note that the #INCLUDE directive does not need to end with a semicolon. If you put a semicolon after the #INCLUDE, that semicolon becomes part of the source file and is the first character following the included file during compilation. HLA generally allows spare semicolons in various parts of the program, so you will often see a #INCLUDE statement ending with a semicolon that produces no harm. In general, though, you should not get in the habit of putting semicolons after #INCLUDE statements because there is the slight possibility this could create a syntax error in certain circumstances.

Using the #include directive by itself does not provide separate compilation. You *could* use the include directive to break up a large source file into separate modules and join these modules together when you assemble your file. The following example would include the PRINTF.HLA and PUTC.HLA files during the assembly of your program:

1. Note that this file changes over time as new library modules appear in the HLA Standard Library, so this file is probably not up to date.

```
#include( "printf.hla" )
#include( "putc.hla" )
```

Now your program *will* benefit from the modularity gained by this approach. Alas, you will not save any development time. The `#INCLUDE` directive inserts the source file at the point of the `#INCLUDE` during compilation, exactly as though you had typed that code in yourself. HLA still has to compile the code and that takes time. Were you to include all the files for the Standard Library routines in this manner, your assemblies would take *forever*.

In general, you should *not* use the include directive to include source code as shown above². Instead, you should use the `#INCLUDE` directive to insert a common set of constants, types, external procedure declarations, and other such items into a program. Typically an assembly language include file does *not* contain any machine code (outside of a macro, see the chapter on Macros and the Compile-Time Language for details). The purpose of using `#INCLUDE` files in this manner will become clearer after you see how the external declarations work.

9.4 Ignoring Duplicate Include Operations

As you begin to develop sophisticated modules and libraries, you eventually discover a big program: some header files will need to include other header files (e.g., the `stdlib.hhf` header file includes all the other Standard Library Header files). Well, this isn't actually a big problem, but a problem will occur when one header file includes another, and that second header file includes another, and that third header file includes another, and ..., and that last header file includes the first header file. Now *this* is a big problem.

There are two problems with a header file indirectly including itself. First, this creates an infinite loop in the compiler. The compiler will happily go on about its business including all these files over and over again until it runs out of memory or some other error occurs. Clearly this is not a good thing. The second problem that occurs (usually before the problem above) is that the second time HLA includes a header file, it starts complaining bitterly about duplicate symbol definitions. After all, the first time it reads the header file it processes all the declarations in that file, the second time around it views all those symbols as duplicate symbols.

HLA provides a special include directive that eliminates this problem: `#INCLUDEONCE`. You use this directive exactly like you use the `#include` directive, e.g.,

```
#includeonce( "myHeaderFile.hhf" )
```

If `myHeaderFile.hhf` directly or indirectly includes itself (with a `#INCLUDEONCE` directive), then HLA will ignore the new request to include the file. Note, however, that if you use the `#INCLUDE` directive, rather than `#INCLUDEONCE`, HLA will include the file a second name. This was done in case you really do need to include a header file twice, for some reason (though it is hard to imagine needing to do this).

The bottom line is this: you should always use the `#INCLUDEONCE` directive to include header files you've created. In fact, you should get in the habit of always using `#INCLUDEONCE`, even for header files created by others (the HLA Standard Library already has provisions to prevent recursive includes, so you don't have to worry about using `#INCLUDEONCE` with the Standard Library header files).

There is another technique you can use to prevent recursive includes – using conditional compilation. For details on this technique, see the chapter on the HLA Compile-Time Language in a later volume.

9.5 UNITS and the EXTERNAL Directive

Technically, the `#INCLUDE` directive provides you with all the facilities you need to create modular programs. You can create several modules, each containing some specific routine, and include those modules, as necessary, in your assembly language programs using `#INCLUDE`. However, HLA provides a better way: external and public symbols.

2. There is nothing wrong with this, other than the fact that it does not take advantage of separate compilation.

One major problem with the include mechanism is that once you've debugged a routine, including it into a compilation wastes a lot of time since HLA must recompile bug-free code every time you assemble the main program. A much better solution would be to preassemble the debugged modules and link the object code modules together rather than reassembling the entire program every time you change a single module. This is what the EXTERNAL directive allows you to do.

To use the external facilities, you must create at least two source files. One file contains a set of variables and procedures used by the second. The second file uses those variables and procedures without knowing how they're implemented. The only problem is that if you create two separate HLA programs, the linker will get confused when you try to combine them. This is because both HLA programs have their own main program. Which main program does Windows run when it loads the program into memory? To resolve this problem, HLA uses a different type of compilation module, the UNIT, to compile programs without a main program. The syntax for an HLA UNIT is actually simpler than that for an HLA program, it takes the following form:

```
unit unitname;

    << declarations >>

end unitname;
```

With one exception, anything that can go in the declaration section of an HLA program can go into the declaration section of an HLA unit. Notice that a unit does not have a BEGIN clause and there are no program statements in the unit³; a unit only contains declarations.

In addition to the fact that a unit does not contain any executable statements, there is one other difference between units and programs. Units cannot have a VAR section. This is because the VAR section declares variables that are local to the main program's source code. Since there is no source code associated with a unit, VAR sections are illegal⁴.

To demonstrate, consider the following two modules:

```
unit Number1;

static
    Var1:uns32;
    Var2:uns32;

    procedure Add1and2;
    begin Add1and2;

        push( eax );
        mov( Var2, eax );
        add( eax, Var1 );

    end Add1and2;

end Number1;
```

Program 9.2 Example of a Simple HLA Unit

3. Of course, units may contain procedures and those procedures may have statements, but the unit itself does not have any executable instructions associated with it.

4. Of course, procedures in the unit may have their own VAR sections, but the procedure's declaration section is separate from the unit's declaration section.

```

program main;
#include( "stdlib.hhf" );

begin main;

    mov( 2, Var2 );
    mov( 3, Var1 );
    Add1and2();
    stdout.put( "Var1=", Var1, nl );

end main;

```

Program 9.3 Main Program that References External Objects

The main program references `Var1`, `Var2`, and `Add1and2`, yet these symbols are external to this program (they appear in unit *Number1*). If you attempt to compile the main program as it stands, HLA will complain that these three symbols are undefined.

Therefore, you must declare them external with the `EXTERNAL` option. An external procedure declaration looks just like a forward declaration except you use the reserved word `EXTERNAL` rather than `FORWARD`. To declare external static variables, simply follow those variables' declarations with the reserved word `EXTERNAL`. The following is a modification to the previous main program that includes the external declarations:

```

program main;
#include( "stdlib.hhf" );

    procedure Add1and2; external;

static
    Var1: uns32; external;
    Var2: uns32; external;

begin main;

    mov( 2, Var2 );
    mov( 3, Var1 );
    Add1and2();
    stdout.put( "Var1=", Var1, nl );

end main;

```

Program 9.4 Modified Main Program with EXTERNAL Declarations

If you attempt to compile this second version of *main*, using the typical HLA compilation command "HLA main2.hla" you will be somewhat disappointed. This program will actually compile without error. However, when HLA attempts to link this code it will report that the symbols *Var1*, *Var2*, and *Add1and2* are undefined. This happens because you haven't compiled and linked in the associated unit with this main program. Before you try that, and discover that it still doesn't work, you should know that all symbols in a unit, by default, are *private* to that unit. This means that those symbols are inaccessible in code outside that unit unless you explicitly declare those symbols as *public* symbols. To declare symbols as public, you simply put

external declarations for those symbols in the unit before the actual symbol declarations. If an external declaration appears in the same source file as the actual declaration of a symbol, HLA assumes that the name is needed externally and makes that symbol a public (rather than private) symbol. The following is a correction to the *Number1* unit that properly declares the external objects:

```

unit Number1;

static
    Var1:uns32; external;
    Var2:uns32; external;

    procedure Add1and2; external;

static
    Var1:uns32;
    Var2:uns32;

    procedure Add1and2;
    begin Add1and2;

        push( eax );
        mov( Var2, eax );
        add( eax, Var1 );

    end Add1and2;

end Number1;

```

Program 9.5 Correct Number1 Unit with External Declarations

It may seem redundant declaring these symbols twice as occurs in Program 9.5, but you'll soon see that you don't normally write the code this way.

If you attempt to compile the *main* program or the *Number1* unit using the typical HLA statement, i.e.,

```

HLA main2.hla
HLA unit2.hla

```

You'll quickly discover that the linker still returns errors. It returns an error on the compilation of *main2.hla* because you still haven't told HLA to link in the object code associated with *unit2.hla*. Likewise, the linker complains if you attempt to compile *unit2.hla* by itself because it can't find a main program. The simple solution is to compile both of these modules together with the following single command:

```

HLA main2.hla unit2.hla

```

This command will properly compile both modules and link together their object code.

Unfortunately, the command above defeats one of the major benefits of separate compilation. When you issue this command it will compile both *main2* and *unit2* prior to linking them together. Remember, a major reason for separate compilation is to reduce compilation time on large projects. While the above command is convenient, it doesn't achieve this goal.

To separately compile the two modules you must run HLA separately on them. Of course, we saw earlier that attempting to compile these modules separately produced linker errors. To get around this problem, you need to compile the modules without linking them. The "-c" (compile-only) HLA command line option achieves this. To compile the two source files without running the linker, you would use the following commands:

```
HLA -c main2.hla
HLA -c unit2.hla
```

This produces two object code files, `main2.obj` and `unit2.obj`, that you can link together to produce a single executable. You could run the Microsoft linker program directly, but an easier way is to use the HLA compiler to link the object modules together for you:

```
HLA main2.obj unit2.obj
```

This command produces an executable file named `main2.exe`⁵. You could also type the following command to compile the main program and link it with a previously compiled unit2 object module:

```
HLA main2.hla unit2.obj
```

In general, HLA looks at the suffixes of the filenames following the HLA commands. If the filename doesn't have a suffix, HLA assumes it to be ".HLA". If the filename has a suffix, then HLA will do the following with the file:

- If the suffix is ".HLA", HLA will compile the file with the HLA compiler.
- If the suffix is ".ASM", HLA will assemble the file with MASM.
- If the suffix is ".OBJ" or ".LIB" then HLA will link that module with the rest of the compilation.

9.5.1 Behavior of the EXTERNAL Directive

Whenever you declare a symbol EXTERNAL using the external directive, keep in mind several limitations of EXTERNAL objects:

- Only one EXTERNAL declaration of an object may appear in a given source file. That is, you cannot define the same symbol twice as an EXTERNAL object.
- Only PROCEDURE, STATIC, READONLY, and STORAGE variable objects can be external. VAR and parameter objects cannot be external.
- External objects must be at the global declaration level. You cannot declare EXTERNAL objects within a procedure or other nested structure.
- EXTERNAL objects publish their name globally. Therefore, you must carefully choose the names of your EXTERNAL objects so they do not conflict with other symbols.

This last point is especially important to keep in mind. As this text is being written, the HLA compiler translates your HLA source code into assembly code. HLA assembles the output by using MASM (the Microsoft Macro Assembler). Finally, HLA links your modules using the Microsoft Linker. At each step in this process, your choice of external names could create problems for you.

Consider the following HLA external/public declaration:

```
static
    extObj:      uns32; external;
    extObj:      uns32;
    localObject: uns32;
```

When you compile a program containing these declarations, HLA automatically generates a "munged" name for the `localObject` variable that probably isn't ever going to have any conflicts with system-global external symbols⁶. Whenever you declare an external symbol, however, HLA uses the object's name as the default external name. This can create some problems if you inadvertently use some global name as your variable name. Worse still, MASM will not be able to properly assemble the HLA output if you happen to choose an identifier that is legal in HLA but is a MASM reserved word. For example, if you attempt to com-

5. If you want to explicitly specify the name of the output file, HLA provides a command-line option to achieve this. You can get a menu of all legal command line options by entering the command "HLA -?".

6. Typically, HLA creates a name like `?001A_localObject` out of `localObject`. This is a legal MASM identifier but it is not likely it will conflict with any other global symbols when HLA compiles the program with MASM.

pile the following code fragment as part of an HLA program, it will compile properly but MASM will not be able to assemble the code:

```
static
  c: char; external;
  c: char;
```

The reason MASM will have trouble with this is because HLA will write the identifier “c” to the assembly language output file and it turns out that “c” is a MASM reserved word (MASM uses it to denote C-language linkage).

To get around the problem of conflicting external names, HLA supports an additional syntax for the EXTERNAL option that lets you explicitly specify the external name. The following example demonstrates this extended syntax:

```
static
  c: char; external( "var_c" );
  c: char;
```

If you follow the EXTERNAL keyword with a string constant enclosed by parentheses, HLA will continue to use the declared name (*c* in this example) as the identifier within your HLA source code. Externally (i.e., in the MASM assembly code) HLA will substitute the name *var_c* whenever you reference *c*. This feature helps you avoid problems with the misuse of MASM reserved words, or other global symbols, in your HLA programs.

You should also note that this feature of the EXTERNAL option lets you create *aliases*. For example, you may want to refer to an object by the name *StudentCount* in one module while refer to the object as *PersonCount* in another module (you might do this because you have a general library module that deals with counting people and you want to use the object in a program that deals only with students). Using a declaration like the following lets you do this:

```
static
  StudentCount: uns32; external( "PersonCount" );
```

Of course, you’ve already seen some of the problems you might encounter when you start creating aliases. So you should use this capability sparingly in your programs. Perhaps a more reasonable use of this feature is to simplify certain OS APIs. For example, Win32 uses some really long names for certain procedure calls. You can use the EXTERNAL directive to provide a more meaningful name than the standard one supplied by Windows.

9.5.2 Header Files in HLA

HLA’s technique of using the same EXTERNAL declaration to define public as well as external symbols may seem somewhat counter-intuitive. Why not use a PUBLIC reserved word for public symbols and the EXTERNAL keyword for external definitions? Well, as counter-intuitive as HLA’s external declarations may seem, they are founded on decades of solid experience with the C/C++ programming language that uses a similar approach to public and external symbols⁷. Combined with a *header file*, HLA’s external declarations make large program maintenance a breeze.

An important benefit of the EXTERNAL directive (versus separate PUBLIC and EXTERNAL directives) is that it lets you minimize duplication of effort in your source files. Suppose, for example, you want to create a module with a bunch of support routines and variables for use in several different programs (e.g., the HLA Standard Library). In addition to sharing some routines and some variables, suppose you want to share constants, types, and other items as well.

7. Actually, C/C++ is a little different. All global symbols in a module are assumed to be public unless explicitly declared private. HLA’s approach (forcing the declaration of public items via EXTERNAL) is a little safer.

The #INCLUDE file mechanism provides a perfect way to handle this. You simply create a #INCLUDE file containing the constants, macros, and external definitions and include this file in the module that implements your routines and in the modules that use those routines (see Figure 9.1).

Figure 9.1 Using Header Files in HLA Programs

A typical header file contains only CONST, VAL, TYPE, STATIC, READONLY, STORAGE, and procedure objects (plus a few others we haven't look at yet, like macros). Objects in the STATIC, READONLY, and STORAGE sections, as well as all procedure declarations, are always EXTERNAL objects. In particular, you generally should not put any VAR objects in a header file, nor should you put any non-external variables or procedure bodies in a header file. If you do, HLA will make duplicate copies of these objects in the different source files that include the header file. Not only will this make your programs larger, but it will cause them to fail under certain circumstances. For example, you generally put a variable in a header file so you can share the value of that variable amongst several different modules. However, if you fail to declare that symbol as external in the header file and just put a standard variable declaration there, each module that includes the source file will get its own separate variable - the modules will not share a common variable.

If you create a standard header file, containing CONST, VAL, and TYPE declarations, and external objects, you should always be sure to include that file in the declaration section of all modules that need the definitions in the header file. Generally, HLA programs include all their header files in the first few statements after the PROGRAM or UNIT header.

This text adopts the HLA Standard Library convention of using an ".hhf" suffix for HLA header files ("HHF" stands for HLA Header File).

9.6 Make Files

Although using separate compilation reduces assembly time and promotes code reuse and modularity, it is not without its own drawbacks. Suppose you have a program that consists of two modules: pgma.hla and pgmb.hla. Also suppose that you've already compiled both modules so that the files pgma.obj and pgmb.obj exist. Finally, you make changes to pgma.hla and pgmb.hla and compile the pgma.hla file *but forget to compile the pgmb.hla file*. Therefore, the pgmb.obj file will be *out of date* since this object file does not reflect the changes made to the pgmb.hla file. If you link the program's modules together, the resulting .exe file will only contain the changes to the pgma.hla file, it will not have the updated object code associated with pgmb.hla. As projects get larger they tend to have more modules associated with them, and as more programmers begin working on the project, it gets very difficult to keep track of which object modules are up to date.

This complexity would normally cause someone to recompile *all* modules in a project, even if many of the .obj files are up to date, simply because it might seem too difficult to keep track of which modules are up to date and which are not. Doing so, of course, would eliminate many of the benefits that separate compilation offers. Fortunately, there is a tool that can help you manage large projects: *nmake*. The nmake program, with a little help from you, can figure out which files need to be reassemble and which files have up to date

.obj files. With a properly defined *make file*, you can easily assemble only those modules that absolutely must be assembled to generate a consistent program.

A make file is a text file that lists compile-time dependencies between files. An .exe file, for example, is *dependent* on the source code whose assembly produce the executable. If you make any changes to the source code you will (probably) need to reassemble or recompile the source code to produce a new .exe file⁸.

Typical dependencies include the following:

- An executable file (.exe) generally depends only on the set of object files (.obj) that the linker combines to form the executable.
- A given object code file (.obj) depends on the assembly language source files that were assembled to produce that object file. This includes the assembly language source files (.hla) and any files included during that assembly (generally .hhf files).
- The source files and include files generally don't depend on anything.

A make file generally consists of a dependency statement followed by a set of commands to handle that dependency. A dependency statement takes the following form:

```
dependent-file : list of files
```

Example:

```
pgm.exe: pgma.obj pgmb.obj
```

This statement says that “pgm.exe” is dependent upon pgma.obj and pgmb.obj. Any changes that occur to pgma.obj or pgmb.obj will require the generation of a new pgm.exe file.

The nmake program uses a *time/date stamp* to determine if a dependent file is out of date with respect to the files it depends upon. Any time you make a change to a file, Windows will update a *modification time and date* associated with the file. The nmake program compares the modification date/time stamp of the dependent file against the modification date/time stamp of the files it depends upon. If the dependent file's modification date/time is earlier than one or more of the files it depends upon, or one of the files it depends upon is not present, then nmake assumes that some operation must be necessary to update the dependent file.

When an update is necessary, nmake executes the set of commands following the dependency statement. Presumably, these commands would do whatever is necessary to produce the updated file.

The dependency statement *must* begin in column one. Any commands that must execute to resolve the dependency must start on the line immediately following the dependency statement and each command must be indented one tabstop. The pgm.exe statement above would probably look something like the following:

```
pgm.exe: pgma.obj pgmb.obj
    hla -opgm.exe pgma.obj pgmb.obj
```

(The “-opgm.exe” option tells HLA to name the executable file “pgm.exe.”)

If you need to execute more than one command to resolve the dependencies, you can place several commands after the dependency statement in the appropriate order. Note that you must indent all commands one tab stop. The nmake program ignores any blank lines in a make file. Therefore, you can add blank lines, as appropriate, to make the file easier to read and understand.

There can be more than a single dependency statement in a make file. In the example above, for example, pgm.exe depends upon the pgma.obj and pgmb.obj files. Obviously, the .obj files depend upon the source files that generated them. Therefore, before attempting to resolve the dependencies for pgm.exe, nmake will first check out the rest of the make file to see if pgma.obj or pgmb.obj depends on anything. If they do, nmake will resolve those dependencies first. Consider the following make file:

```
pgm.exe: pgma.obj pgmb.obj
    hla -opgm.exe pgma.obj pgmb.obj

pgma.obj: pgma.hla
    hla -c pgma.hla
```

8. Obviously, if you only change comments or other statements in the source file that do not affect the executable file, a recompile or reassembly will not be necessary. To be safe, though, we will assume *any* change to the source file will require a reassembly.

```
pgmb.obj: pgmb.hla
        hla -c pgmb.hla
```

The nmake program will process the first dependency line it finds in the file. However, the files pgm.exe depends upon themselves have dependency lines. Therefore, nmake will first ensure that pgma.obj and pgmb.obj are up to date before attempting to execute HLA to link these files together. Therefore, if the only change you've made has been to pgmb.hla, nmake takes the following steps (assuming pgma.obj exists and is up to date).

1. The nmake program processes the first dependency statement. It notices that dependency lines for pgma.obj and pgmb.obj (the files on which pgm.exe depends) exist. So it processes those statements first.
2. the nmake program processes the pgma.obj dependency line. It notices that the pgma.obj file is newer than the pgma.hla file, so it does *not* execute the command following this dependency statement.
3. The nmake program processes the pgmb.obj dependency line. It notes that pgmb.obj is older than pgmb.hla (since we just changed the pgmb.hla source file). Therefore, nmake executes the DOS command following on the next line. This generates a new pgmb.obj file that is now up to date.
4. Having processed the pgma.obj and pgmb.obj dependencies, nmake now returns its attention to the first dependency line. Since nmake just created a new pgmb.obj file, its date/time stamp will be newer than pgm.exe's. Therefore, nmake will execute the HLA command that links pgma.obj and pgmb.obj together to form the new pgm.exe file.

Note that a properly written make file will instruct the nmake program to assemble only those modules absolutely necessary to produce a consistent executable file. In the example above, nmake did not bother to assemble pgma.hla since its object file was already up to date.

There is one final thing to emphasize with respect to dependencies. Often, object files are dependent not only on the source file that produces the object file, but any files that the source file includes as well. In the previous example, there (apparently) were no such include files. Often, this is not the case. A more typical make file might look like the following:

```
pgm.exe: pgma.obj pgmb.obj
        hla -opgm.exe pgma.obj pgmb.obj

pgma.obj: pgma.hla pgm.hhf
        hla -c pgma.hla

pgmb.obj: pgmb.hla pgm.hhf
        hla -c pgmb.hla
```

Note that any changes to the pgm.hhf file will force nmake.exe to recompile *both* pgma.hla and pgmb.hla since the pgma.obj and pgmb.obj files both depend upon the pgm.hhf include file. Leaving include files out of a dependency list is a common mistake programmers make that can produce inconsistent .exe files.

Note that you would not normally need to specify the HLA Standard Library include files nor the Standard Library .lib files in the dependency list. True, your resulting .exe file does depend on this code, but the Standard Library rarely changes, so you can safely leave it out of your dependency list. Should you make a modification to the Standard Library, simply delete any old .exe and .obj files and force a reassembly of the entire system.

The nmake program, by default, assumes that it will be processing a make file named "makefile". When you run nmake.exe, it looks for "makefile" in the current directory. If it doesn't find this file, it complains and terminates⁹. Therefore, it is a good idea to collect the files for each project you work on into their own subdirectory and give each project its own makefile. Then to create an executable, you need only change into the appropriate subdirectory and run the nmake program.

9. There is a command line option that lets you specify the name of the makefile. See the nmake documentation in the MASM manuals for more details.

Although this section discusses the `nmake` program in sufficient detail to handle most projects you will be working on, keep in mind that the `nmake` program provides considerable functionality that this chapter does not discuss. To learn more about the `nmake.exe` program, consult the the appropriate documentation. Note that several versions of `MAKE` exist. Microsoft produces `nmake.exe`, Borland has their own `MAKE.EXE` program and various versions of `MAKE` have been ported to Windows from UNIX systems (e.g., `GMAKE`). While these systems are not equivalent, they all do a pretty good job of handling the simple make syntax that this chapter describes.

9.7 Code Reuse

One of the principle goals of Software Engineering is to reduce program development time. Although the techniques we've studied in this chapter will certainly reduce development effort, there are bigger prizes to be had here. Consider for a moment a simple program that reads an integer from the user and then displays the value of that integer on the standard output device. You can easily write a trivial version of this program with about eight lines of HLA code. That's not too difficult. However, suppose you did not have the HLA Standard Library at your disposal. Now, instead of an eight line program, you'd be faced with writing a program that hundreds if not thousands of lines long. Obviously, this program will take a lot longer to write than the original eight-line version. The difference between these two applications is the fact that in the first version of this program you got to reuse some code that was already written; in the second version of the program you had to write everything from scratch. This concept of code reuse is very important when writing large programs – you can get large programs working much more quickly if you reuse code from previous projects.

The idea behind code reuse is that many code sequences you write will be usable in future programs. As time passes and you write more code, progress on your projects will be faster since you can reuse code you've written (or others have written) on previous projects. The HLA Standard Library functions are the classic example, somebody had to write those functions so you could use them. And use them you do. As of this writing, the Standard Library represented about 50,000 lines of HLA source code. Imagine having to write a fair portion of that everytime you wanted to write an HLA program!

Although the HLA Standard Library contains lots of very useful routines and functions, this code base cannot possible predict the type of code you will need in every future project. The HLA Standard Library provides some of the more common routines you'll need when writing programs, but you're certainly going to have need for routines that the HLA Standard Library cannot satisfy. Unless you can find a source for the code you need from some third party, you're probably going to have to write the new routines yourself.

The trick when writing a program is to try and figure out which routines are general purpose and could be used in future programs; once you make this determination, you should write such routines separately from the rest of your application (i.e., put them in a separate source file for compilation). By keeping them separate, you can use them in future projects. If “try and figure out which routines are general purpose...” sounds a bit difficult, well, you're right it is. Even after 30 years of Software Engineering research, no one has really figured out how to effectively reuse code. There are some obvious routines we can reuse (that's why there are “standard libraries”) but it is quite difficult for the practicing engineer to successfully predict which routines s/he will need in the future and write these as separate modules.

Attempting to teach you how to decide which routines are worthy of saving for future programs and which are specific to your current application is well beyond the scope of this text. There are several Software Engineering texts out there that try to explain how to do this, but keep in mind that even after the publication of these texts, practicing engineers still have problems picking the right routines to save. Hopefully, as you gain experience, you will begin to recognize those routines that are worth keeping for future programs and those that aren't worth bothering with. This text will take the easy way out and assume that you know which routines you want to keep and which you don't.

9.8 Creating and Managing Libraries

Imagine that you've created a few hundred routines over the past couple of years and you would like to have the object code ready to link with any new projects you begin. You could move all this code into a single source file, stick in a bunch of EXTERNAL declarations, and then link the resulting object file with any new programs you write that can use the routines in your "library". Unfortunately, there are a couple of problems with this approach. Let's take a look at some of these problems.

Problem number one is that your library will grow to a fairly good size with time; if you put the source code to every routine in a single source file, small additions or changes to the file will require a complete recompilation of the whole library. That's clearly not what we want to do, based on what you've learned from this chapter.

Another problem with this "solution" is that whenever you link this object file to your new applications, you link in the entire library, not just the routines you want to use. This makes your applications unnecessarily large, especially if your library has grown. Were you to link your simple projects with the entire HLA Standard library, for example, the result would be positively huge.

A solution to both of the above problems is to compile each routine in a separate file and produce a unique OBJ file for it. Unfortunately, with hundreds of routines you're going to wind up with hundreds of OBJ files; any time you want to call a dozen or so library routines, you'd have to link your main application with a dozen or so OBJ modules from your library. Clearly, this isn't acceptable either.

You may have noticed by now that when you link your applications with the HLA Standard Library, you only link with a single file: *hlalib.lib*. LIB (library) files are a collection of OBJ files. When the linker processes a LIB file, it pulls out only the OBJ files it needs, it does not link the entire LIB file with your application. Hence you get to work with a single file and your applications don't grow unnecessarily large.

To collect your library OBJ files into a single LIB file, you need to use a library manager program. This is actually built into Microsoft's linker program, although Microsoft provides a LIB.EXE program that acts as a front end to LINK.EXE and processes command line parameter specifically for creating library files. In this section we'll discuss how to use LIB.EXE to construct library files.

Warning: section describes the use of Microsoft's LIB program version 6.00.8168. Microsoft has a history of changing the user (command line) interface to their tools between even minor revisions of their products. Please be aware that the specific examples in this section may need to be modified for the version of LIB.EXE that you are actually using. The basic principles, however, will be the same. See the Microsoft manuals if you have any questions about the use of the LIB.EXE program. You should also be able to type "LIB /?" from the command line prompt to get an idea of the LIB.EXE invocation syntax.

The LIB.EXE program uses the following general syntax (from a command window prompt):

```
lib {options} {files}
```

options:

```

/CONVERT
/DEBUGTYPE:CV
/DEF[:filename]
/EXPORT:symbol
/EXTRACT:membername
/INCLUDE:symbol
/LIBPATH:dir
/LINK50COMPAT
/LIST[:filename]
/MACHINE:{ALPHA|ARM|IX86|MIPS|MIPS16|MIPSR41XX|PPC|SH3|SH4}
/NAME:filename
/NODEFAULTLIB[:library]
/NOLOGO
/OUT:filename
```

```

/REMOVE:membername
/SUBSYSTEM: {NATIVE|WINDOWS|CONSOLE|WINDOWSCE|POSIX} [, # [.##] ]
/VERBOSE

```

Most of these options are not of interest to us, but there are a few important ones. First of all, you should always use the “/out:filename” to specify the name of your library file. For example, you would often begin a LIB.EXE command line with the following:

```
lib /out:mylib.lib ... (or whatever library name you want to use)
```

The second option you’re probably going to use all the time is the “/subsystem:xxxxx” option. For console mode (i.e., text-based command window) programs you would use “/subsystem:console”. For Windows programs you write that use the graphical user interface, you’d probably use the “/subsystem:windows” option. The HLA Standard Library, since it’s mostly intended for console applications, uses the “/subsystem:console” option. You probably won’t need to use most of the other options since LIB.EXE uses appropriate default values for them. If you’re doing some advanced stuff, or if you’re just curious, check out Microsoft’s documentation on the LIB.EXE program for more details.

Following any options on the command line come the OBJ filenames that you want to merge together when creating the library file. A typical LIB.EXE command line might look something like the following:

```
lib /out:mylib.lib /subsystem:console file1.obj file2.obj file3.obj
```

If you want to merge dozens or hundreds of files into a single library, you’re going to run into a problem. The command window command line doesn’t allow arbitrarily long lines. This will severely limit the number of files you can add to your library at one time. The easiest way to handle this problem is to create a text file containing the commands and filenames for LIB.EXE. Here’s the file from HLA’s “bits.lib” library module:

```

/out:..\bits.lib
/subsystem:console
cnt.obj
reverse.obj
merge.obj

```

(This file was chosen because it’s really short.)

The first line tells LIB.EXE to create a library module named “bits.lib” in the parent subdirectory. Like most HLA Standard Library modules, this module is intended for use in console applications (not that it makes any difference to this module), hence the “/subsystem:console” option. The next three lines of the file contain the files to merge together when creating the bits.lib file. A separate call to LIB.EXE elsewhere combines bits.lib, strings.lib, chars.lib, etc., into a single library module: hlalib.lib. To specify that LIB.EXE should read this file instead of extracting this information from the command line, you use “@responsefile” in place of the operands on the LIB.EXE command line. For example, if the file above is named “bits.txt” (which it is, by the way), then you could tell LIB.EXE to read its commands from this file using the following command line:

```
lib @bits.txt
```

Once you’ve created a library file, you can tell HLA to automatically extract any important files from the file by specifying its name on the HLA command line, e.g.,

```
hla mypgm.hla mylib.lib
```

Assuming all the necessary modules you need are present in mylib.lib, the command line above will compile mypgm and link in the appropriate OBJ modules found in the mylib.lib library file. Note that HLA automatically links in hlalib.lib, so you don’t have to specify this on the command line when compiling your programs.

For more examples of using the LIB.EXE program, take a look at the makefiles in the HLA library source file directories. These makefiles contain several calls to LIB.EXE that build the hlalib.lib file. Hopefully you can see how to use LIB.EXE by looking at these files.

9.9 Name Space Pollution

One problem with creating libraries with lots of different modules is name space pollution. A typical library module will have a `#INCLUDE` file associated with it that provides external definitions for all the routines, constants, variables, and other symbols provided in the library. Whenever you want to use some routines or other objects from the library, you would typically `#INCLUDE` the library's header file in your project. As your libraries get larger and you add more declarations in the header file, it becomes more and more likely that the names you've chosen for your library's identifiers will conflict with names you want to use in your current project. This conflict is what is meant by name space pollution: library header files pollute the name space with many names you typically don't need in order to gain easy access to the few routines in the library you actually use. Most of the time those names don't harm anything – unless you want to use those names yourself in your program.

HLA requires that you declare all external symbols at the global (PROGRAM/UNIT) level. You cannot, therefore, include a header file with external declarations within a procedure¹⁰. As such, there will be no naming conflicts between external library symbols and symbols you declare locally within a procedure; the conflicts will only occur between the external symbols and your global symbols. While this is a good argument for avoiding global symbols as much as possible in your program, the fact remains that most symbols in an assembly language program will have global scope. So another solution is necessary.

HLA's solution, which it certainly uses in the Standard Library, is to put most of the library names in a `NAMESPACE` declaration section. A `NAMESPACE` declaration encapsulates all declarations and exposes only a single name (the `NAMESPACE` identifier) at the global level. You access the names within the `NAMESPACE` by using the familiar dot-notation (see "Namespaces" on page 477). This reduces the effect of namespace pollution from many dozens or hundreds of names down to a single name.

Of course, one disadvantage of using a `NAMESPACE` declaration is that you have to type a longer name in order to reference a particular identifier in that name space (i.e., you have to type the `NAMESPACE` identifier, a period, and then the specific identifier you wish to use). For a few identifiers you use frequently, you might elect to leave those identifiers outside of any `NAMESPACE` declaration. For example, the HLA Standard Library does not define the symbols *malloc*, *free*, or *nl* (among others) within a `NAMESPACE`. However, you want to minimize such declarations in your libraries to avoid conflicts with names in your own programs. Often, you can choose a `NAMESPACE` identifier to complement your routine names. For example, the HLA Standard Libraries string copy routine was named after the equivalent C Standard Library function, *strcpy*. HLA's version is *str.cpy*. The actual function name is *cpy*; it happens to be a member of the *str* `NAMESPACE`, hence the full name *str.cpy* which is very similar to the comparable C function. The HLA Standard Library contains several examples of this convention. The *arg.c* and *arg.v* functions are another pair of such identifiers (corresponding to the C identifiers *argc* and *argv*).

Using a `NAMESPACE` in a header file is no different than using a `NAMESPACE` in a PROGRAM or UNIT. Here's an example of a typical header file containing a `NAMESPACE` declaration:

```
// myHeader.hhf -
//
// Routines supported in the myLibrary.lib file.

namespace myLib;

    procedure func1; external;
    procedure func2; external;
    procedure func3; external;

end myLib;
```

Typically, you would compile each of the functions (func1..func3) as separate units (so each has its own OBJ file and linking in one function doesn't link them all). Here's what a sample UNIT declaration for one of these functions:

10. Or within an Iterator or Method, as you will see in later chapters.

```

unit func1Unit;
#includeonce( "myHeader.hhf" )

procedure myLib.func1;
begin func1;

    << code for func1 >>

end func1;

end func1Unit;

```

You should notice two important things about this unit. First, you do not put the actual *func1* procedure code within a NAMESPACE declaration block. By using the identifier *myLib.func1* as the procedure's name, HLA automatically realizes that this procedure declaration belongs in a name space. The second thing to note is that you do not preface *func1* with the "myLib." prefix after the BEGIN and END clauses in the procedure. HLA automatically associates the BEGIN and END identifiers with the PROCEDURE declaration, so it knows that these identifiers are part of the *myLib* name space and it doesn't make you type the whole name again.

Important note: when you declare external names within a name space, as was done in *func1Unit* above, HLA uses only the function name (*func1* in this example) as the external name. This creates a name space pollution problem in the external name space. For example, if you have two different name spaces, *myLib* and *yourLib* and they both define a *func1* procedure, the linker will complain about a duplicate definition for *func1* if you attempt to use functions from both these library modules. There is an easy work-around to this problem: use the extended form of the EXTERNAL directive to explicitly supply an external name for all external identifiers appearing in a NAMESPACE declaration. For example, you could solve this problem with the following simple modification to the myHeader.hhf file above:

```

// myHeader.hhf -
//
// Routines supported in the myLibrary.lib file.

namespace myLib;

    procedure func1; external( "myLib_func1" );
    procedure func2; external( "myLib_func2" );
    procedure func3; external( "myLib_func3" );

end myLib;

```

This example demonstrates an excellent convention you should adopt: when exporting names from a name space, always supply an explicit external name and construct that name by concatenating the NAMESPACE identifier with an underscore and the object's internal name.

The use of NAMESPACE declarations does not completely eliminate the problems of name space pollution (after all, the name space identifier is still a global object, as anyone who has included *stdlib.hhf* and attempted to define a "cs" variable can attest), but NAMESPACE declarations come pretty close to eliminating this problem. Therefore, you should use NAMESPACE everywhere practical when creating your own libraries.

9.10 Putting It All Together

Managing large projects is considerably easier if you break your program up into separate modules and work on them independently. In this chapter you learned about HLA's UNITS, include files, and the EXTERNAL directive. These provide the tools you need to break a program up into smaller modules. In addition to HLA's facilities, you'll also use a separate tool, *nmake.exe*, to automatically compile and link only those files that are necessary in a large project.

This chapter provided a very basic introduction to the use of makefiles and the nmake utility. Note that the MAKE programs are quite sophisticated. The presentation of the nmake program in this chapter barely scratches the surface. If you're interested in more information about MAKE facilities you should consult one of the excellent texts available on this subject. Lots of good information is also available on the Internet (just use the usual search tools).

This chapter also presented a brief introduction to the Microsoft Library Manager program (LIB.EXE) that lets you combine several different OBJ files into a single LIB file. A single library file is much easier to work with than dozens or hundreds of OBJ files. If you write lots of little subroutines and compile them as separate modules for use with future projects, you will definitely want to create a library file from those OBJ files.

In addition to breaking up large HLA projects, UNITS are also the basis for letting you write assembly language functions that you can call from high level languages like C/C++ and Delphi. A later volume in this text will describe how you can use UNITS for this purpose.

Integer Arithmetic

Chapter Ten

10.1 Chapter Overview

This chapter discusses the implementation of arithmetic computation in assembly language. By the conclusion of this chapter you should be able to translate arithmetic expressions and assignment statements from high level languages like Pascal and C/C++ into 80x86 assembly language.

10.2 80x86 Integer Arithmetic Instructions

Before describing how to encode arithmetic expressions in assembly language, it would be a good idea to first discuss the remaining arithmetic instructions in the 80x86 instruction set. Previous chapters have covered most of the arithmetic and logical instructions, so this section will cover the few remaining instructions you'll need.

10.2.1 The MUL and IMUL Instructions

The multiplication instructions provide you with your first taste of irregularity in the 80x86's instruction set. Instructions like ADD, SUB, and many others in the 80x86 instruction set support two operands. Unfortunately, there weren't enough bits in the 80x86's opcode byte to support all instructions, so the 80x86 treats the MUL (unsigned multiply) and IMUL (signed integer multiply) instructions as single operand instructions, like the INC, DEC, and NEG instructions.

Of course, multiplication *is* a two operand function. To work around this fact, the 80x86 always assumes the accumulator (AL, AX, or EAX) is the destination operand. This irregularity makes using multiplication on the 80x86 a little more difficult than other instructions because one operand has to be in the accumulator. Intel adopted this unorthogonal approach because they felt that programmers would use multiplication far less often than instructions like ADD and SUB.

Another problem with the MUL and IMUL instructions is that you cannot multiply the accumulator by a constant using these instructions. Intel quickly discovered the need to support multiplication by a constant and added the INTMUL instruction to overcome this problem. Nevertheless, you must be aware that the basic MUL and IMUL instructions do not support the full range of operands that INTMUL does.

There are two forms of the multiply instruction: unsigned multiplication (MUL) and signed multiplication (IMUL). Unlike addition and subtraction, you need separate instructions for these two operations.

The multiply instructions take the following forms:

Unsigned Multiplication:

```
mul ( reg8 );           // returns "ax"
mul ( reg16 );          // returns "dx:ax"
mul ( reg32 );          // returns "edx:eax"

mul ( mem8 );           // returns "ax"
mul ( mem16 );          // returns "dx:ax"
mul ( mem32 );          // returns "edx:eax"
```

Signed (Integer) Multiplication:

```
imul ( reg8 );           // returns "ax"
imul ( reg16 );          // returns "dx:ax"
imul ( reg32 );          // returns "edx:eax"
```

```

imul( mem8 );      // returns "ax"
imul( mem16 );     // returns "dx:ax"
imul( mem32 );     // returns "edx:eax"

```

The “returns” values above are the strings these instructions return for use with instruction composition in HLA (see “Instruction Composition in HLA” on page 538).

(I)MUL, available on all 80x86 processors, multiplies eight, sixteen, or thirty-two bit operands. Note that when multiplying two n-bit values, the result may require as many as 2*n bits. Therefore, if the operand is an eight bit quantity, the result could require sixteen bits. Likewise, a 16 bit operand produces a 32 bit result and a 32 bit operand requires 64 bits for the result.

The (I)MUL instruction, with an eight bit operand, multiplies the AL register by the operand and leaves the 16 bit product in AX. So

```

mul( operand8 );
or  imul( operand8 );

```

computes:

```
AX := AL * operand8
```

“*” represents an unsigned multiplication for MUL and a signed multiplication for IMUL.

If you specify a 16 bit operand, then MUL and IMUL compute:

```
DX:AX := AX * operand16
```

“*” has the same meanings as above and DX:AX means that DX contains the H.O. word of the 32 bit result and AX contains the L.O. word of the 32 bit result. If you’re wondering why Intel didn’t put the 32-bit result in EAX, just note that Intel introduced the MUL and IMUL instructions in the earliest 80x86 processors, before the advent of 32-bit registers in the 80386 CPU.

If you specify a 32 bit operand, then MUL and IMUL compute the following:

```
EDX:EAX := EAX * operand32
```

“*” has the same meanings as above and EDX:EAX means that EDX contains the H.O. double word of the 64 bit result and EAX contains the L.O. double word of the 64 bit result.

If an 8x8, 16x16, or 32x32 bit product requires more than eight, sixteen, or thirty-two bits (respectively), the MUL and IMUL instructions set the carry and overflow flags. MUL and IMUL scramble the sign, and zero flags. Especially note that the sign and zero flags do not contain meaningful values after the execution of these two instructions.

To help reduce some of the problems with the use of the MUL and IMUL instructions, HLA provides an extended syntax that allows the following two-operand forms:

Unsigned Multiplication:

```

mul( reg8, al );
mul( reg16, ax );
mul( reg32, eax );

mul( mem8, al );
mul( mem16, ax );
mul( mem32, eax );

mul( constant8, al );
mul( constant16, ax );
mul( constant32, eax );

```

Signed (Integer) Multiplication:

```

imul( reg8, al );
imul( reg16, ax );

```

```

imul( reg32, eax );

imul( mem8, al );
imul( mem16, ax );
imul( mem32, eax );

imul( constant8, al );
imul( constant16, ax );
imul( constant32, eax );

```

The two operand forms let you specify the (L.O.) destination register. The instructions whose first operand is a register or memory location are completely identical to the instructions above. By specifying the destination register, however, you can make your programs easier to read; therefore, it's probably a good idea to go ahead and specify the destination register. Note that just because HLA allows two operands here, you can't specify an arbitrary register. The destination operand must always be AL, AX, or EAX, depending on the source operand.

Note that HLA allows a form that lets you specify a constant. The 80x86 doesn't actually support a MUL or IMUL instruction that has a constant operand. HLA will take the constant you specify and create a "variable" in the special "const" segment in memory and initialize that variable with this value. Then HLA converts the instruction to the "(IMUL(memory);)" instruction. Generally, you won't need to use this special form since the INTMUL instruction will multiply a register by a constant.

You'll use the MUL and IMUL instructions quite a bit when you learn about extended precision arithmetic in the chapter on Advanced Arithmetic. Until you get to that chapter, you'll probably just want to use the INTMUL instruction in place of the MUL or IMUL since it is more general. However, INTMUL is not a complete replacement for these two instructions. Besides the number of operands, there are several differences between the INTMUL instruction you've learned about earlier and the MUL and IMUL instructions. Specifically for the INTMUL instruction:

- There isn't an 8x8 bit INTMUL instruction available (the immediate₈ operands simply provide a shorter form of the instruction. Internally, the CPU sign extends the operand to 16 or 32 bits as necessary).
- The INTMUL instruction does not produce a 2*n bit result. That is, a 16x16 multiply produces a 16 bit result. Likewise, a 32x32 bit multiply produces a 32 bit result. These instructions set the carry and overflow flags if the result does not fit into the destination register.

10.2.2 The DIV and IDIV Instructions

The 80x86 divide instructions perform a 64/32 division, a 32/16 division or a 16/8 division. These instructions take the form:

```

div( reg8 );           // returns "al"
div( reg16 );         // returns "ax"
div( reg32 );         // returns "eax"

div( reg8, AX );      // returns "al"
div( reg16, DX:AX );
div( reg32, EDX:EAX );

div( mem8 );           // returns "al"
div( mem16 );         // returns "ax"
div( mem32 );         // returns "eax"

div( mem8, AX );      // returns "al"
div( mem16, DX:AX ); // returns "ax"
div( mem32, EDX:EAX ); // returns "eax"

```

```

div( constant8, AX );           // returns "al"
div( constant16, DX:AX );       // returns "ax"
div( constant32, EDX:EAX );     // returns "eax"

idiv( reg8 );                   // returns "al"
idiv( reg16 );                  // returns "ax"
idiv( reg32 );                  // returns "eax"

idiv( reg8, AX );               // returns "al"
idiv( reg16, DX:AX );          // returns "ax"
idiv( reg32, EDX:EAX );        // returns "eax"

idiv( mem8 );                   // returns "al"
idiv( mem16 );                  // returns "ax"
idiv( mem32 );                  // returns "eax"

idiv( mem8, AX );               // returns "al"
idiv( mem16, DX:AX );          // returns "ax"
idiv( mem32, EDX:EAX );        // returns "eax"

idiv( constant8, AX );         // returns "al"
idiv( constant16, DX:AX );     // returns "ax"
idiv( constant32, EDX:EAX );   // returns "eax"

```

The DIV instruction computes an unsigned division. If the operand is an eight bit operand, DIV divides the AX register by the operand leaving the quotient in AL and the remainder (modulo) in AH. If the operand is a 16 bit quantity, then the DIV instruction divides the 32 bit quantity in DX:AX by the operand leaving the quotient in AX and the remainder in DX. With 32 bit operands DIV divides the 64 bit value in EDX:EAX by the operand leaving the quotient in EAX and the remainder in EDX.

You cannot, on the 80x86, simply divide one eight bit value by another. If the denominator is an eight bit value, the numerator must be a sixteen bit value. If you need to divide one unsigned eight bit value by another, you must zero extend the numerator to sixteen bits. You can accomplish this by loading the numerator into the AL register and then moving zero into the AH register. Then you can divide AX by the denominator operand to produce the correct result. *Failing to zero extend AL before executing DIV may cause the 80x86 to produce incorrect results!*

When you need to divide two 16 bit unsigned values, you must zero extend the AX register (which contains the numerator) into the DX register. To do this, just load zero into the DX register. If you need to divide one 32-bit value by another, you must zero extend the EAX register into EDX (by loading a zero into EDX) before the division.

When dealing with signed integer values, you will need to sign extend AL into AX, AX into DX or EAX into EDX before executing IDIV. To do so, use the CBW, CWD, CDQ, or MOVSX instructions. If the H.O. byte or word does not already contain significant bits, then you must sign extend the value in the accumulator (AL/AX/EAX) before doing the IDIV operation. Failure to do so may produce incorrect results.

There is one other catch to the 80x86's divide instructions: you can get a fatal error when using this instruction. First, of course, you can attempt to divide a value by zero. Second, the quotient may be too large to fit into the EAX, AX, or AL register. For example, the 16/8 division "\$8000 / 2" produces the quotient \$4000 with a remainder of zero. \$4000 will not fit into eight bits. If this happens, or you attempt to divide by zero, the 80x86 will generate an *ex.DivisionError* exception or integer overflow error (*ex.IntoInstr*). This usually means your program will display the appropriate dialog box and abort your program. If this happens to you, chances are you didn't sign or zero extend your numerator before executing the division operation. Since this error will cause your program to crash, you should be very careful about the values you select when using division. Of course, you can use the TRY..ENDTRY block with the *ex.DivisionError* and *ex.IntoInstr* to trap this problem in your program.

The carry, overflow, sign, and zero flags are undefined after a division operation. Like MUL and IMUL, HLA provides special syntax to allow the use of constant operands even though these instructions don't really support them.

The 80x86 does not provide a separate instruction to compute the remainder of one number divided by another. The DIV and IDIV instructions automatically compute the remainder at the same time they compute the quotient. HLA, however, provide mnemonics (instructions) for the MOD and IMOD instructions. These special HLA instructions compile into the exact same code as their DIV and IDIV counterparts. The only difference is the "returns" value for the instruction (since these instructions return the remainder in a different location than the quotient). The MOD and IMOD instructions that HLA supports are

```

mod( reg8 );           // returns "ah"
mod( reg16 );          // returns "dx"
mod( reg32 );          // returns "edx"

mod( reg8, AX );       // returns "ah"
mod( reg16, DX:AX );   // returns "dx"
mod( reg32, EDX:EAX ); // returns "edx"

mod( mem8 );           // returns "ah"
mod( mem16 );          // returns "dx"
mod( mem32 );          // returns "edx"

mod( mem8, AX );       // returns "ah"
mod( mem16, DX:AX );   // returns "dx"
mod( mem32, EDX:EAX ); // returns "edx"

mod( constant8, AX ); // returns "ah"
mod( constant16, DX:AX ); // returns "dx"
mod( constant32, EDX:EAX ); // returns "edx"

imod( reg8 );           // returns "ah"
imod( reg16 );          // returns "dx"
imod( reg32 );          // returns "edx"

imod( reg8, AX );       // returns "ah"
imod( reg16, DX:AX );   // returns "dx"
imod( reg32, EDX:EAX ); // returns "edx"

imod( mem8 );           // returns "ah"
imod( mem16 );          // returns "dx"
imod( mem32 );          // returns "edx"

imod( mem8, AX );       // returns "ah"
imod( mem16, DX:AX );   // returns "dx"
imod( mem32, EDX:EAX ); // returns "edx"

imod( constant8, AX ); // returns "ah"
imod( constant16, DX:AX ); // returns "dx"
imod( constant32, EDX:EAX ); // returns "edx"

```

10.2.3 The CMP Instruction

The CMP (compare) instruction is identical to the SUB instruction with one crucial difference – it does not store the difference back into the destination operand. The syntax for the CMP instruction is very similar to SUB, the generic form is

```
cmp( LeftOperand, RightOperand );
```

The specific forms are

```
cmp( reg, reg );      // Registers must be the same size (8, 16, or 32 bits)
cmp( reg, mem );     // Sizes must match.
cmp( reg, constant );
cmp( mem, constant );
```

The CMP instruction updates the 80x86's flags according to the result of the subtraction operation (LeftOperand - RightOperand). The flags are generally set in an appropriate fashion so that we can read this instruction as “compare LeftOperand to RightOperand”. You can test the result of the comparison by checking the appropriate flags in the flags register using the conditional set instructions (see the next section) or the conditional jump instructions (see the next chapter).

Probably the first place to start when exploring the CMP instruction is to take a look at exactly how the CMP instruction affects the flags. Consider the following CMP instruction:

```
cmp( ax, bx );
```

This instruction performs the computation AX - BX and sets the flags depending upon the result of the computation. The flags are set as follows:

- Z: The zero flag is set if and only if AX = BX. This is the only time AX - BX produces a zero result. Hence, you can use the zero flag to test for equality or inequality.
- S: The sign flag is set to one if the result is negative. At first glance, you might think that this flag would be set if AX is less than BX but this isn't always the case. If AX=\$7FFF and BX= -1 (\$FFFF) subtracting AX from BX produces \$8000, which is negative (and so the sign flag will be set). So, for signed comparisons anyway, the sign flag doesn't contain the proper status. For unsigned operands, consider AX=\$FFFF and BX=1. AX is greater than BX but their difference is \$FFFE which is still negative. As it turns out, the sign flag and the overflow flag, taken together, can be used for comparing two signed values.
- O: The overflow flag is set after a CMP operation if the difference of AX and BX produced an overflow or underflow. As mentioned above, the sign flag and the overflow flag are both used when performing signed comparisons.
- C: The carry flag is set after a CMP operation if subtracting BX from AX requires a borrow. This occurs only when AX is less than BX where AX and BX are both unsigned values.

Given that the CMP instruction sets the flags in this fashion, you can test the comparison of the two operands with the following flags:

```
cmp( Left, Right );
```

Table 1: Condition Code Settings After CMP

| Unsigned operands: | Signed operands: |
|--|------------------------|
| Z: equality/inequality | Z: equality/inequality |
| C: Left < Right (C=1) Left >= Right (C=0) | C: no meaning |
| S: no meaning | S: see below |
| O: no meaning | O: see below |

For signed comparisons, the S (sign) and O (overflow) flags, taken together, have the following meaning:

If ((S=0) and (O=1)) or ((S=1) and (O=0)) then Left < Right when using a signed comparison.

If ((S=0) and (O=0)) or ((S=1) and (O=1)) then Left >= Right when using a signed comparison.

Note that (S xor O) is one if the left operand is less than the right operand. Conversely, (S xor O) is zero if the left operand is greater or equal to the right operand.

To understand why these flags are set in this manner, consider the following examples:

| Left | minus | Right | S | O |
|----------------|-------|-------------|---|---|
| ----- | | ----- | - | - |
| \$FFFF (-1) | - | \$FFFE (-2) | 0 | 0 |
| \$8000 | - | \$0001 | 0 | 1 |
| \$FFFE (-2) | - | \$FFFF (-1) | 1 | 0 |
| \$7FFF (32767) | - | \$FFFF (-1) | 1 | 1 |

Remember, the CMP operation is really a subtraction, therefore, the first example above computes (-1)-(-2) which is (+1). The result is positive and an overflow did not occur so both the S and O flags are zero. Since (S xor O) is zero, Left is greater than or equal to Right.

In the second example, the CMP instruction would compute (-32768)-(+1) which is (-32769). Since a 16-bit signed integer cannot represent this value, the value wraps around to \$7FFF (+32767) and sets the overflow flag. The result is positive (at least as a 16 bit value) so the CPU clears the sign flag. (S xor O) is one here, so *Left* is less than *Right*.

In the third example above, CMP computes (-2)-(-1) which produces (-1). No overflow occurred so the O flag is zero, the result is negative so the sign flag is one. Since (S xor O) is one, Left is less than Right.

In the fourth (and final) example, CMP computes (+32767)-(-1). This produces (+32768), setting the overflow flag. Furthermore, the value wraps around to \$8000 (-32768) so the sign flag is set as well. Since (S xor O) is zero, Left is greater than or equal to Right.

10.2.4 The SETcc Instructions

The *set on condition* (or SETcc) instructions set a single byte operand (register or memory location) to zero or one depending on the values in the flags register. The general formats for the SETcc instructions are

```
setcc( reg8 );
setcc( mem8 );
```

SETcc represents a mnemonic appearing in the following tables. These instructions store a zero into the corresponding operand if the condition is false, they store a one into the eight bit operand if the condition is true.

Table 2: SETcc Instructions That Test Flags

| Instruction | Description | Condition | Comments |
|-------------|--------------------|------------|----------------------|
| SETC | Set if carry | Carry = 1 | Same as SETB, SETNAE |
| SETNC | Set if no carry | Carry = 0 | Same as SETNB, SETAE |
| SETZ | Set if zero | Zero = 1 | Same as SETE |
| SETNZ | Set if not zero | Zero = 0 | Same as SETNE |
| SETS | Set if sign | Sign = 1 | |
| SETNS | Set if no sign | Sign = 0 | |
| SETO | Set if overflow | Ovrflw=1 | |
| SETNO | Set if no overflow | Ovrflw=0 | |
| SETP | Set if parity | Parity = 1 | Same as SETPE |
| SETPE | Set if parity even | Parity = 1 | Same as SETP |
| SETNP | Set if no parity | Parity = 0 | Same as SETPO |
| SETPO | Set if parity odd | Parity = 0 | Same as SETNP |

The SETcc instructions above simply test the flags without any other meaning attached to the operation. You could, for example, use SETC to check the carry flag after a shift, rotate, bit test, or arithmetic operation. You might notice the SETP, SETPE, and SETNP instructions above. They check the *parity* flag. These instructions appear here for completeness, but this text will not consider the uses of the parity flag.

The CMP instruction works synergistically with the SETcc instructions. Immediately after a CMP operation the processor flags provide information concerning the relative values of those operands. They allow you to see if one operand is less than, equal to, greater than, or any combination of these.

There are two additional groups of SETcc instructions that are very useful after a CMP operation. The first group deals with the result of an *unsigned* comparison, the second group deals with the result of a *signed* comparison.

Table 3: SETcc Instructions for Unsigned Comparisons

| Instruction | Description | Condition | Comments |
|-------------|------------------------------------|-----------------------|----------------------|
| SETA | Set if above (>) | Carry=0, Zero=0 | Same as SETNBE |
| SETNBE | Set if not below or equal (not <=) | Carry=0, Zero=0 | Same as SETA |
| SETAE | Set if above or equal (>=) | Carry = 0 | Same as SETNC, SETNB |
| SETNB | Set if not below (not <) | Carry = 0 | Same as SETNC, SETAE |
| SETB | Set if below (<) | Carry = 1 | Same as SETC, SETNAE |
| SETNAE | Set if not above or equal (not >=) | Carry = 1 | Same as SETC, SETB |
| SETBE | Set if below or equal (<=) | Carry = 1 or Zero = 1 | Same as SETNA |
| SETNA | Set if not above (not >) | Carry = 1 or Zero = 1 | Same as SETBE |
| SETE | Set if equal (=) | Zero = 1 | Same as SETZ |
| SETNE | Set if not equal (≠) | Zero = 0 | Same as SETNZ |

The corresponding table for signed comparisons is

Table 4: SETcc Instructions for Signed Comparisons

| Instruction | Description | Condition | Comments |
|-------------|--|---------------------------|----------------|
| SETG | Set if greater (>) | Sign = Ovrflw and Zero=0 | Same as SETNLE |
| SETNLE | Set if not less than or equal (not <=) | Sign = Ovrflw or Zero=0 | Same as SETG |
| SETGE | Set if greater than or equal (>=) | Sign = Ovrflw | Same as SETNL |
| SETNL | Set if not less than (not <) | Sign = Ovrflw | Same as SETGE |
| SETL | Set if less than (<) | Sign ≠ Ovrflw | Same as SETNGE |
| SETNGE | Set if not greater or equal (not >=) | Sign ≠ Ovrflw | Same as SETL |
| SETLE | Set if less than or equal (<=) | Sign ≠ Ovrflw or Zero = 1 | Same as SETNG |
| SETNG | Set if not greater than (not >) | Sign ≠ Ovrflw or Zero = 1 | Same as SETLE |

Table 4: SETcc Instructions for Signed Comparisons

| Instruction | Description | Condition | Comments |
|-------------|----------------------|-----------|---------------|
| SETE | Set if equal (=) | Zero = 1 | Same as SETZ |
| SETNE | Set if not equal (≠) | Zero = 0 | Same as SETNZ |

The SETcc instructions are particularly valuable because they can convert the result of a comparison to a boolean value (false/true or 0/1). This is especially important when translating statements from a high level language like Pascal or C/C++ into assembly language. The following example shows how to use these instructions in this manner:

```
// Bool := A <= B

mov( A, eax );
cmp( eax, B );
setle( bool ); // bool is a boolean or byte variable.
```

Since the SETcc instructions always produce zero or one, you can use the results with the AND and OR instructions to compute complex boolean values:

```
// Bool := ((A <= B) and (D = E))

mov( A, eax );
cmp( eax, B );
setle( bl );
mov( D, eax );
cmp( eax, E );
sete( bh );
and( bl, bh );
mov( bh, Bool );
```

For more examples, see “Logical (Boolean) Expressions” on page 584.

10.2.5 The TEST Instruction

The 80x86 TEST instruction is to the AND instruction what the CMP instruction is to SUB. That is, the TEST instruction computes the logical AND of its two operands and sets the condition code flags based on the result; it does not, however, store the result of the logical AND back into the destination operand. The syntax for the TEST instruction is similar to AND, it is

```
test( operand1, operand2 );
```

The TEST instruction sets the zero flag if the result of the logical AND operation is zero. It sets the sign flag if the H.O. bit of the result contains a one. TEST always clears the carry and overflow flags.

The primary use of the TEST instruction is to check to see if an individual bit contains a zero or a one. Consider the instruction “test(1, AL);” This instruction logically ANDs AL with the value one; if bit one of AL contains zero, the result will be zero (setting the zero flag) since all the other bits in the constant one are zero. Conversely, if bit one of AL contains one, then the result is not zero so TEST clears the zero flag. Therefore, you can test the zero flag after this TEST instruction to see if bit zero contains a zero or a one.

The TEST instruction is also useful to see if all the bits in a specified set of bits contain zero. The instruction “test(\$F, AL);” sets the zero flag if and only if the L.O. four bits of AL all contain zero.

One very important use of the TEST instruction is to check to see if a register contains zero. The instruction “TEST(reg, reg);” where both operands are the same register will logically AND that register with itself. If the register contains zero, then the result is zero and the CPU will set the zero flag. However, if the register contains a non-zero value, logically ANDing that value with itself produces that same non-zero value, so the CPU clears the zero flag. Therefore, you can test the zero flag immediately after the execution of this instruction (e.g., using the SETZ or SETNZ instructions) to see if the register contains zero. E.g.,

```
test( eax, eax );
setz( bl );           // BL is set to one if EAX contains zero.
```

10.3 Arithmetic Expressions

Probably the biggest shock to beginners facing assembly language for the very first time is the lack of familiar arithmetic expressions. Arithmetic expressions, in most high level languages, look similar to their algebraic equivalents, e.g.,

```
X:=Y*Z;
```

In assembly language, you'll need several statements to accomplish this same task, e.g.,

```
mov( y, eax );
intmul( z, eax );
mov( eax, x );
```

Obviously the HLL version is much easier to type, read, and understand. This point, more than any other, is responsible for scaring people away from assembly language.

Although there is a lot of typing involved, converting an arithmetic expression into assembly language isn't difficult at all. By attacking the problem in steps, the same way you would solve the problem by hand, you can easily break down any arithmetic expression into an equivalent sequence of assembly language statements. By learning how to convert such expressions to assembly language in three steps, you'll discover there is little difficulty to this task.

10.3.1 Simple Assignments

The easiest expressions to convert to assembly language are the simple assignments. Simple assignments copy a single value into a variable and take one of two forms:

```
variable := constant
```

or

```
variable := variable
```

Converting the first form to assembly language is easy, just use the assembly language statement:

```
mov( constant, variable );
```

This MOV instruction copies the constant into the variable.

The second assignment above is somewhat complicated since the 80x86 doesn't provide a memory-to-memory MOV instruction. Therefore, to copy one memory variable into another, you must move the data through a register. By convention (and for slight efficiency reasons), most programmers tend to use AL/AX/EAX for this purpose. If the AL, AX, or EAX register is available, you should use it for this operation. For example,

```
var1 := var2;
```

becomes

```
mov( var2, eax );
mov( eax, var1 );
```

This is assuming, of course, that *var1* and *var2* are 32-bit variables. Use AL if they are eight bit variables, use AX if they are 16-bit variables.

Of course, if you're already using AL, AX, or EAX for something else, one of the other registers will suffice. Regardless, you must use a register to transfer one memory location to another.

Although the 80x86 does not support a memory-to-memory move, HLA does provide an extended syntax for the MOV instruction that allows two memory operands. However, both operands have to be 16-bit or

32-bit values; eight-bit values won't work. Assuming you want to copy the value of a *word* or *dword* object to another variable, you can use the following syntax:

```
mov( var2, var1 );
```

HLA translates this "instruction" into the following two instruction sequence:

```
push( var2 );
pop( var1 );
```

Although this is slightly slower than the two MOV instructions, it is convenient.

10.3.2 Simple Expressions

The next level of complexity up from a simple assignment is a simple expression. A simple expression takes the form:

```
var1 := term1 op term2;
```

Var1 is a variable, *term1* and *term2* are variables or constants, and *op* is some arithmetic operator (addition, subtraction, multiplication, etc.).

As simple as this expression appears, most expressions take this form. It should come as no surprise then, that the 80x86 architecture was optimized for just this type of expression.

A typical conversion for this type of expression takes the following form:

```
mov( term1, eax );
op( term2, eax );
mov( eax, var1 )
```

Op is the mnemonic that corresponds to the specified operation (e.g., "+" = add, "-" = sub, etc.).

There are a few inconsistencies you need to be aware of. Of course, when dealing with the multiply and divide instructions on the 80x86, you must use the AL/AX/EAX and DX/EDX registers. You cannot use arbitrary registers as you can with other operations. Also, don't forget the sign extension instructions if you're performing a division operation and you're dividing one 16/32 bit number by another. Finally, don't forget that some instructions may cause overflow. You may want to check for an overflow (or underflow) condition after an arithmetic operation.

Examples of common simple expressions:

```
x := y + z;
```

```
mov( y, eax );
add( z, eax );
mov( eax, x );
```

```
x := y - z;
```

```
mov( y, eax );
sub( z, eax );
mov( eax, x );
```

```
x := y * z; {unsigned}
```

```
mov( y, eax );
mul( z, eax ); // Don't forget this wipes out EDX.
mov( eax, x );
```

```

x := y div z; {unsigned div}

    mov( y, eax );
    mov( 0, edx );      // Zero extend EAX into EDX.
    div( z, edx:eax );
    mov( eax, x );

x := y idiv z; {signed div}

    mov( y, eax );
    cdq();              // Sign extend EAX into EDX.
    idiv( z, edx:eax );
    mov( eax, x );

x := y mod z; {unsigned remainder}

    mov( y, eax );
    mov( 0, edx );      // Zero extend EAX into EDX.
    mod( z, edx:eax );
    mov( edx, x );      // Note that remainder is in EDX.

x := y imod z; {signed remainder}

    mov( y, eax );
    cdq();              // Sign extend EAX into EDX.
    imod( z, edx:eax );
    mov( edx, x );      // Remainder is in EDX.

```

Certain unary operations also qualify as simple expressions. A good example of a unary operation is negation. In a high level language negation takes one of two possible forms:

```
var := -var or var1 := -var2
```

Note that `var := -constant` is really a simple assignment, not a simple expression. You can specify a negative constant as an operand to the MOV instruction:

```
mov( -14, var );
```

To handle “`var = -var;`” use the single assembly language statement:

```
// var = -var;

neg( var );
```

If two different variables are involved, then use the following:

```
// var1 = -var2;

mov( var2, eax );
neg( eax );
mov( eax, var1 );
```

10.3.3 Complex Expressions

A complex expression is any arithmetic expression involving more than two terms and one operator. Such expressions are commonly found in programs written in a high level language. Complex expressions may include parentheses to override operator precedence, function calls, array accesses, etc. While the conversion of some complex expressions to assembly language is fairly straight-forward, others require some effort. This section outlines the rules you use to convert such expressions.

A complex expression that is easy to convert to assembly language is one that involves three terms and two operators, for example:

```
w := w - y - z;
```

Clearly the straight-forward assembly language conversion of this statement will require two SUB instructions. However, even with an expression as simple as this one, the conversion is not trivial. There are actually *two ways* to convert this from the statement above into assembly language:

```

    mov( w,  eax );
    sub( y,  eax );
    sub( z,  eax );
    mov( eax, w );
and
    mov( y,  eax );
    sub( z,  eax );
    sub( eax, w );

```

The second conversion, since it is shorter, looks better. However, it produces an incorrect result (assuming Pascal-like semantics for the original statement). Associativity is the problem. The second sequence above computes $W := W - (Y - Z)$ which is not the same as $W := (W - Y) - Z$. How we place the parentheses around the subexpressions can affect the result. Note that if you are interested in a shorter form, you can use the following sequence:

```

    mov( y,  eax );
    add( z,  eax );
    sub( eax, w );

```

This computes $W := W - (Y + Z)$. This is equivalent to $W := (W - Y) - Z$.

Precedence is another issue. Consider the Pascal expression:

```
X := W * Y + Z;
```

Once again there are two ways we can evaluate this expression:

```

X := (W * Y) + Z;
or
X := W * (Y + Z);

```

By now, you're probably thinking that this text is crazy. Everyone knows the correct way to evaluate these expressions is the second form provided in these two examples. However, you're wrong to think that way. The APL programming language, for example, evaluates expressions solely from right to left and does not give one operator precedence over another.

Most high level languages use a fixed set of precedence rules to describe the order of evaluation in an expression involving two or more different operators. Such programming languages usually compute multiplication and division before addition and subtraction. Those that support exponentiation (e.g., FORTRAN and BASIC) usually compute that before multiplication and division. These rules are intuitive since almost everyone learns them before high school. Consider the expression:

```
X op1 Y op2 Z
```

If op_1 takes precedence over op_2 then this evaluates to $(X op_1 Y) op_2 Z$ otherwise if op_2 takes precedence over op_1 then this evaluates to $X op_1 (Y op_2 Z)$. Depending upon the operators and operands involved, these two computations could produce different results.

When converting an expression of this form into assembly language, you must be sure to compute the subexpression with the highest precedence first. The following example demonstrates this technique:

```

// w := x + y * z;

    mov( x,  ebx );
    mov( y,  eax );           // Must compute y*z first since "*"
    intmul( z, eax );        // has higher precedence than "+".
    add( ebx, eax );
    mov( eax, w );

```

If two operators appearing within an expression have the same precedence, then you determine the order of evaluation using *associativity* rules. Most operators are *left associative* meaning that they evaluate from left to right. Addition, subtraction, multiplication, and division are all left associative. A *right associative*

operator evaluates from right to left. The exponentiation operator in FORTRAN and BASIC is a good example of a right associative operator:

2^{2^3} is equal to $2^{(2^3)}$ not $(2^2)^3$

The precedence and associativity rules determine the order of evaluation. Indirectly, these rules tell you where to place parentheses in an expression to determine the order of evaluation. Of course, you can always use parentheses to override the default precedence and associativity. However, the ultimate point is that your assembly code must complete certain operations before others to correctly compute the value of a given expression. The following examples demonstrate this principle:

```
// w := x - y - z

    mov( x, eax ); // All the same operator, so we need
    sub( y, eax ); // to evaluate from left to right
    sub( z, eax ); // because they all have the same
    mov( eax, w ); // precedence and are left associative.

// w := x + y * z

    mov( y, eax ); // Must compute Y * Z first since
    intmul( z, eax ); // multiplication has a higher
    add( x, eax ); // precedence than addition.
    mov( eax, w );

// w := x / y - z

    mov( x, eax ); // Here we need to compute division
    cdq(); // first since it has the highest
    idiv( y, edx:eax ); // precedence.
    sub( z, eax );
    mov( eax, w );

// w := x * y * z

    mov( y, eax ); // Addition and multiplication are
    intmul( z, eax ); // commutative, therefore the order
    intmul( x, eax ); // of evaluation does not matter
    mov( eax, w );
```

There is one exception to the associativity rule. If an expression involves multiplication and division it is generally better to perform the multiplication first. For example, given an expression of the form:

$W := X/Y * Z$ // Note: this is $\frac{x}{y} \times z$ not $\frac{x}{y \times z}$!

It is usually better to compute $X*Z$ and then divide the result by Y rather than divide X by Y and multiply the quotient by Z . There are two reasons this approach is better. First, remember that the `IMUL` instruction always produces a 64 bit result (assuming 32 bit operands). By doing the multiplication first, you automatically *sign extend* the product into the `EDX` register so you do not have to sign extend `EAX` prior to the division. This saves the execution of the `CDQ` instruction. A second reason for doing the multiplication first is to increase the accuracy of the computation. Remember, (integer) division often produces an inexact result. For example, if you compute $5/2$ you will get the value two, not 2.5. Computing $(5/2)*3$ produces six. However, if you compute $(5*3)/2$ you get the value seven which is a little closer to the real quotient (7.5). Therefore, if you encounter an expression of the form:

$w := x/y*z;$

You can usually convert this to assembly code:

```
    mov( x, eax );
    imul( z, eax ); // Note the use of IMUL, not INTMUL!
    idiv( y, edx:eax );
    mov( eax, w );
```

Of course, if the algorithm you're encoding depends on the truncation effect of the division operation, you cannot use this trick to improve the algorithm. Moral of the story: always make sure you fully understand any expression you are converting to assembly language. Obviously if the semantics dictate that you must perform the division first, do so.

Consider the following Pascal statement:

```
w := x - y * x;
```

This is similar to a previous example except it uses subtraction rather than addition. Since subtraction is not commutative, you cannot compute $y * z$ and then subtract x from this result. This tends to complicate the conversion a tiny amount. Rather than a straight forward multiply and addition sequence, you'll have to load x into a register, multiply y and z leaving their product in a different register, and then subtract this product from x , e.g.,

```
mov( x, ebx );
mov( y, eax );
intmul( x, eax );
sub( eax, ebx );
mov( ebx, w );
```

This is a trivial example that demonstrates the need for *temporary variables* in an expression. This code uses the EBX register to temporarily hold a copy of x until it computes the product of y and z . As your expressions increase in complexity, the need for temporaries grows. Consider the following Pascal statement:

```
w := (a + b) * (y + z);
```

Following the normal rules of algebraic evaluation, you compute the subexpressions inside the parentheses (i.e., the two subexpressions with the highest precedence) first and set their values aside. When you computed the values for both subexpressions you can compute their sum. One way to deal with complex expressions like this one is to reduce it to a sequence of simple expressions whose results wind up in temporary variables. For example, we can convert the single expression above into the following sequence:

```
Temp1 := a + b;
Temp2 := y + z;
w := Temp1 * Temp2;
```

Since converting simple expressions to assembly language is quite easy, it's now a snap to compute the former, complex, expression in assembly. The code is

```
mov( a, eax );
add( b, eax );
mov( eax, Temp1 );
mov( y, eax );
add( z, eax );
mov( eax, Temp2 );
mov( Temp1, eax );
intmul( Temp2, eax );
mov( eax, w );
```

Of course, this code is grossly inefficient and it requires that you declare a couple of temporary variables in your data segment. However, it is very easy to optimize this code by keeping temporary variables, as much as possible, in 80x86 registers. By using 80x86 registers to hold the temporary results this code becomes:

```
mov( a, eax );
add( b, eax );
mov( y, ebx );
add( z, ebx );
intmul( ebx, eax );
mov( eax, w );
```

Yet another example:

```
x := (y+z) * (a-b) / 10;
```

This can be converted to a set of four simple expressions:

```
Temp1 := (y+z)
Temp2 := (a-b)
Temp1 := Temp1 * Temp2
X := Temp1 / 10
```

You can convert these four simple expressions into the assembly language statements:

```
mov( y, eax );      // Compute eax = y+z
add( z, eax );
mov( a, ebx );      // Compute ebx = a-b
sub( b, ebx );
imul( ebx, eax );   // This also sign extends eax into edx.
idiv( 10, edx:eax );
mov( eax, x );
```

The most important thing to keep in mind is that temporary values, if possible, should be kept in registers. Remember, accessing an 80x86 register is much more efficient than accessing a memory location. Use memory locations to hold temporaries only if you've run out of registers to use.

Ultimately, converting a complex expression to assembly language is little different than solving the expression by hand. Instead of actually computing the result at each stage of the computation, you simply write the assembly code that computes the results. Since you were probably taught to compute only one operation at a time, this means that manual computation works on "simple expressions" that exist in a complex expression. Of course, converting those simple expressions to assembly is fairly trivial. Therefore, anyone who can solve a complex expression by hand can convert it to assembly language following the rules for simple expressions.

10.3.4 Commutative Operators

If "@" represents some operator, that operator is *commutative* if the following relationship is always true:

$$(A @ B) = (B @ A)$$

As you saw in the previous section, commutative operators are nice because the order of their operands is immaterial and this lets you rearrange a computation, often making that computation easier or more efficient. Often, rearranging a computation allows you to use fewer temporary variables. Whenever you encounter a commutative operator in an expression, you should always check to see if there is a better sequence you can use to improve the size or speed of your code. The following tables list the commutative and non-commutative operators you typically find in high level languages:

Table 5: Some Common Commutative Binary Operators

| Pascal | C/C++ | Description |
|--------|---------|-----------------------------------|
| + | + | Addition |
| * | * | Multiplication |
| AND | && or & | Logical or bitwise AND |
| OR | or | Logical or bitwise OR |
| XOR | ^ | (Logical or) Bitwise exclusive-OR |
| = | == | Equality |
| <> | != | Inequality |

Table 6: Some Common Noncommutative Binary Operators

| Pascal | C/C++ | Description |
|----------|-------|-----------------------|
| - | - | Subtraction |
| / or DIV | / | Division |
| MOD | % | Modulo or remainder |
| < | < | Less than |
| <= | <= | Less than or equal |
| > | > | Greater than |
| >= | >= | Greater than or equal |

10.4 Logical (Boolean) Expressions

Consider the following expression from a Pascal program:

```
B := ((X=Y) and (A <= C)) or ((Z-A) <> 5);
```

B is a boolean variable and the remaining variables are all integers.

How do we represent boolean variables in assembly language? Although it takes only a single bit to represent a boolean value, most assembly language programmers allocate a whole byte or word for this purpose (as such, HLA also allocates a whole byte for a BOOLEAN variable). With a byte, there are 256 possible values we can use to represent the two values *true* and *false*. So which two values (or which two sets of values) do we use to represent these boolean values? Because of the machine's architecture, it's much easier to test for conditions like zero or not zero and positive or negative rather than to test for one of two particular boolean values. Most programmers (and, indeed, some programming languages like "C") choose zero to represent false and anything else to represent true. Some people prefer to represent true and false with one and zero (respectively) and not allow any other values. Others select all one bits (\$FFFF_FFFF, \$FFFF, or \$FF) for true and 0 for false. You could also use a positive value for true and a negative value for false. All these mechanisms have their own advantages and drawbacks.

Using only zero and one to represent false and true offers two very big advantages: (1) The SETcc instructions produce these results so this scheme is compatible with those instructions; (2) the 80x86 logical instructions (AND, OR, XOR and, to a lesser extent, NOT) operate on these values exactly as you would expect. That is, if you have two boolean variables A and B, then the following instructions perform the basic logical operations on these two variables:

```
// c = a AND b;

    mov( a, al );
    and( b, al );
    mov( al, c );

// c = a OR b;

    mov( a, al );
    or( b, al );
    mov( al, c );

// c = a XOR b;
```

```

mov( a, al );
xor( b, al );
mov( al, c );

// b = not a;

mov( a, al );    // Note that the NOT instruction does not
not( al );       // properly compute al = not al by itself.
and( 1, al );    // I.e., (not 0) does not equal one. The AND
mov( al, b );    // instruction corrects this problem.

mov( a, al );    // Another way to do b = not a;
xor( 1, al );    // Inverts bit zero.
mov( al, b );

```

Note, as pointed out above, that the NOT instruction will not properly compute logical negation. The bitwise not of zero is \$FF and the bitwise not of one is \$FE. Neither result is zero or one. However, by ANDing the result with one you get the proper result. Note that you can implement the NOT operation more efficiently using the “xor(1, ax);” instruction since it only affects the L.O. bit.

As it turns out, using zero for false and anything else for true has a lot of subtle advantages. Specifically, the test for true or false is often implicit in the execution of any logical instruction. However, this mechanism suffers from a very big disadvantage: you cannot use the 80x86 AND, OR, XOR, and NOT instructions to implement the boolean operations of the same name. Consider the two values \$55 and \$AA. They’re both non-zero so they both represent the value true. However, if you logically and \$55 and \$AA together using the 80x86 AND instruction, the result is zero. True AND true should produce true, not false. Although you can account for situations like this, it usually requires a few extra instructions and is somewhat less efficient when computing boolean operations.

A system that uses non-zero values to represent true and zero to represent false is an *arithmetic logical system*. A system that uses the two distinct values like zero and one to represent false and true is called a *boolean logical system*, or simply a boolean system. You can use either system, as convenient. Consider again the boolean expression:

$$B := ((X=Y) \text{ and } (A \leq D)) \text{ or } ((Z-A) > 5);$$

The simple expressions resulting from this expression might be:

```

mov( x, eax );
cmp( y, eax );
sete( al );      // AL := x = y;

mov( a, ebx );
cmp( ebx, d );
setle( bl );    // BL := a <= d;
and( al, bl );  // BL := (x=y) and (a <= d);

mov( z, eax );
sub( a, eax );
cmp( eax, 5 );
setne( al );
or( bl, al );   // AL := ((X=Y) and (A <= D)) or ((Z-A) > 5);
mov( al, b );

```

When working with boolean expressions don’t forget the that you might be able to optimize your code by simplifying those boolean expressions. You can use algebraic transformations (especially DeMorgan’s theorems) to help reduce the complexity of an expression. In the next chapter you’ll also see how to use control flow to calculate a boolean result. This is generally quite a bit more efficient than using *complete boolean evaluation* as the examples in this section teach.

10.5 Machine and Arithmetic Idioms

An idiom is an idiosyncrasy. Several arithmetic operations and 80x86 instructions have idiosyncrasies that you can take advantage of when writing assembly language code. Some people refer to the use of machine and arithmetic idioms as “tricky programming” that you should always avoid in well written programs. While it is wise to avoid tricks just for the sake of tricks, many machine and arithmetic idioms are well-known and commonly found in assembly language programs. Some of them can be really tricky, but a good number of them are simply “tricks of the trade.” This text cannot even begin to present all of the idioms in common use today; they are too numerous and the list is constantly changing. Nevertheless, there are some very important idioms that you will see all the time, so it makes sense to discuss those.

10.5.1 Multiplying without MUL, IMUL, or INTMUL

If you take a quick look at the timing for the multiply instruction, you’ll notice that the execution time for this instruction is often long¹. When multiplying by a constant, you can sometimes avoid the performance penalty of the MUL, IMUL, and INTMUL instructions by using shifts, additions, and subtractions to perform the multiplication.

Remember, a SHL instruction computes the same result as multiplying the specified operand by two. Shifting to the left two bit positions multiplies the operand by four. Shifting to the left three bit positions multiplies the operand by eight. In general, shifting an operand to the left n bits multiplies it by 2^n . Any value can be multiplied by some constant using a series of shifts and adds or shifts and subtractions. For example, to multiply the AX register by ten, you need only multiply it by eight and then add in two times the original value. That is, $10*AX = 8*AX + 2*AX$. The code to accomplish this is

```
shl( 1, ax );    // Multiply AX by two.
mov( ax, bx );  // Save 2*AX for later.
shl( 2, ax );    // Multiply ax by eight (*4 really, but it contains *2).
add( bx, ax );  // Add in AX*2 to AX*8 to get AX*10.
```

The AX register (or just about any register, for that matter) can often be multiplied by many constant values much faster using SHL than by using the MUL instruction. This may seem hard to believe since it only takes one instruction to compute this product:

```
intmul( 10, ax );
```

However, if you look at the timings, the shift and add example above requires fewer clock cycles on many processors in the 80x86 family than the MUL instruction. Of course, the code is somewhat larger (by a few bytes), but the performance improvement is usually worth it. Of course, on the later 80x86 processors, the multiply instructions are quite a bit faster than the earlier processors, but the shift and add scheme is often faster on these processors as well.

You can also use subtraction with shifts to perform a multiplication operation. Consider the following multiplication by seven:

```
mov( eax, ebx );    // Save EAX * 1
shl( 3, eax );      // EAX = EAX * 8
sub( ebx, eax );    // EAX*8 - EAX*1 is EAX*7
```

This follows directly from the fact that $eax*7 = (eax*8)-eax$.

A common error made by beginning assembly language students is subtracting or adding one or two rather than $EAX*1$ or $EAX*2$. The following does *not* compute $eax*7$:

```
shl( 3, eax );
sub( 1, eax );
```

It computes $(8*EAX)-1$, something entirely different (unless, of course, $EAX = 1$). Beware of this pitfall when using shifts, additions, and subtractions to perform multiplication operations.

1. Actually, this is specific to a given processor. Some processors execute the INTMUL instruction fairly fast.

You can also use the LEA instruction to compute certain products. The trick is to use the scaled index addressing modes. The following examples demonstrate some simple cases:

```
lea ( eax, [ecx][ecx] );      // EAX := ECX * 2
lea ( eax, [eax]eax*2 );     // EAX := EAX * 3
lea ( eax, [eax*4] );        // EAX := EAX * 4
lea ( eax, [ebx][ebx*4] );   // EAX := EBX * 5
lea ( eax, [eax*8] );        // EAX := EAX * 8
lea ( eax, [edx][edx*8] );   // EAX := EDX * 9
```

10.5.2 Division Without DIV or IDIV

Much as the SHL instruction can be used for simulating a multiplication by some power of two, the SHR and SAR instructions can be used to simulate a division by a power of two. Unfortunately, you cannot use shifts, additions, and subtractions to perform a division by an arbitrary constant as easily as you can use these instructions to perform a multiplication operation.

Another way to perform division is to use the multiply instructions. You can divide by some value by multiplying by its reciprocal. Since the multiply instruction is faster than the divide instruction; multiplying by a reciprocal is usually faster than division.

Now you're probably wondering "how does one multiply by a reciprocal when the values we're dealing with are all integers?" The answer, of course, is that we must cheat to do this. If you want to multiply by one tenth, there is no way you can load the value $1/10^{\text{th}}$ into an 80x86 register prior to performing the multiplication. However, we could multiply $1/10^{\text{th}}$ by 10, perform the multiplication, and then divide the result by ten to get the final result. Of course, this wouldn't buy you anything at all, in fact it would make things worse since you're now doing a multiplication by ten as well as a division by ten. However, suppose you multiply $1/10^{\text{th}}$ by 65,536 (6553), perform the multiplication, and then divide by 65,536. This would still perform the correct operation and, as it turns out, if you set up the problem correctly, you can get the division operation for free. Consider the following code that divides AX by ten:

```
mov ( 6554, dx );           // 6554 = round( 65,536/10 ).
mul ( dx, ax );
```

This code leaves AX/10 in the DX register.

To understand how this works, consider what happens when you multiply AX by 65,536 (\$10000). This simply moves AX into DX and sets AX to zero (a multiply by \$10000 is equivalent to a shift left by sixteen bits). Multiplying by 6,554 (65,536 divided by ten) puts AX divided by ten into the DX register. Since MUL is faster than DIV, this technique runs a little faster than using a straight division.

Multiplying by the reciprocal works well when you need to divide by a constant. You could even use it to divide by a variable, but the overhead to compute the reciprocal only pays off if you perform the division many, many times (by the same value).

10.5.3 Implementing Modulo-N Counters with AND

If you want to implement a counter variable that counts up to 2^n-1 and then resets to zero, simply using the following code:

```
inc ( CounterVar );
and ( nBits, CounterVar );
```

where *nBits* is a binary value containing n one bits right justified in the number. For example, to create a counter that cycles between zero and fifteen, you could use the following:

```
inc ( CounterVar );
and ( %00001111, CounterVar );
```

10.5.4 Careless Use of Machine Idioms

One problem with using machine idioms is that the machines change over time. The DOS/16-bit version of this text recommends the use of several machine idioms in addition to those this chapter presents. Unfortunately, as time passed Intel improved the processor and tricks that used to provide a performance benefit are actually slower on the newer processors. Therefore, you should be careful about employing common “tricks” you pick up; they may not actually improve the code.

10.6 The HLA (Pseudo) Random Number Unit

The HLA `rand.hhf` module provides a set of pseudo-random generators that returns seemingly random values on each call. These pseudo-random number generator functions are great for writing games and other simulations that require a sequence of values that the user can not easily guess. These functions return a 32-bit value in the EAX register. You can treat the result as a signed or unsigned value as appropriate for your application.

The `rand.hhf` library module includes the following functions:

```
procedure rand.random; returns( "eax" );
procedure rand.range( startRange:dword; endRange:dword ); returns( "eax" );

procedure rand.uniform; returns( "eax" );
procedure rand.urange( startRange:dword; endRange:dword ); returns( "eax" );

procedure rand.randomize;
```

The `rand.random` and `rand.uniform` procedures are both functions that return a 32-bit pseudo-random number in the EAX register. They differ only in the algorithm they use to compute the random number sequence (`rand.random` uses a standard linear congruential generator, `rand.uniform` uses an additive generator. See Knuth’s “The Art of Computer Programming” Volume Two for details on these two algorithms).

The `rand.range` and `rand.urange` functions return a pseudo-random number that falls between two values passed as parameters (inclusive). These routines use better algorithms than the typical “mod the result by the range of values and add the starting value” algorithm that naive users often employ to limit random numbers to a specific range (that naive algorithm generally produces a stream of numbers that is somewhat less than random).

By default, the random number generators in the HLA Standard Library generate the same sequence of numbers every time you run a program. While this may not seem random at all (and statistically, it certainly is not random), this is generally what you want in a random number generator. The numbers should appear to be random but you usually need to be able to generate the same sequence over and over again when testing your program. After all, a defect you encounter with one random sequence may not be apparent when using a different random number sequence. By emitting the same sequence over and over again, your programs become deterministic so you can properly test them across several runs of the program.

Once your program is tested and operational, you might want your random number generator to generate a different sequence every time you run the program. For example, if you write a game and that game uses a pseudo-random sequence to control the action, the end user may detect a pattern and play the game accordingly if the random number generator always returns the same sequence of numbers.

To alleviate this problem, the HLA Standard Library `rand` module provides the `rand.randomize` procedure. This procedure reads the current date and time (in milliseconds) and, on processors that support it, reads the CPU’s timestamp counter to generate an almost random set of bits as the starting random number generator value. Calling the `rand.randomize` procedure at the beginning of your program essentially guarantees that different executions of the program will produce a different sequence of random numbers.

Note that you cannot make the sequence “more random” by calling `rand.randomize` multiple times. In fact, since `rand.randomize` generates a new seed based on the date and time, calling `rand.randomize` multiple times in your program will actually generate a less random sequence (since time is an ever increasing value,

not a random value). So make at most one call to *rand.randomize* and leave it up to the random number generators to take it from there.

Note that *rand.randomize* will randomize both the *rand.random* and *rand.uniform* random number generators. You do not need separate calls for the two different generators nor can you randomize one without randomizing the other.

One attribute of a random number generator is “how uniform are the results the generator returns.” A uniform random number generator² that produces a 32-bit result returns a sequence of values that are evenly distributed throughout the 32-bit range of values. That is, any return result is as equally likely as any other return result. Good random number generators don’t tend to bunch numbers up in groups.

The following program code provides a simple test of the random number generators by plotting asterisks at random positions on the screen. This program works by choosing two random numbers, one between zero and 79, the other between zero and 23. Then the program uses the *console.puts* function to print a single asterisk at the (X,Y) coordinate on the screen specified by these two random numbers. After 10,000 iterations of this process the program stops and lets you observe the result. **Note:** since random number generators generate random numbers, you should not expect this program to fill the entire screen with asterisks in only 10,000 iterations.

```

program testRandom;
#include( "stdlib.hhf" );

begin testRandom;

    console.cls();
    mov( 10_000, ecx );
    repeat

        // Generate a random X-coordinate
        // using rand.range.

        rand.range( 0, 79 );
        mov( eax, ebx );           // Save the X-coordinate for now.

        // Generate a random Y-coordinate
        // using rand.urange.

        rand.urange( 0, 23 );

        // Print an asterisk at
        // the specified coordinate on the screen.

        console.puts( ax, bx, "*" );

        // Repeat this 10,000 times to get
        // a good distribution of values.

        dec( ecx );

    until( @z );

    // Position the cursor at the bottom of the
    // screen so we can observe the results.

    console.gotoxy( 24, 0 );

```

2. Despite their names, both *rand.uniform* and *rand.random* generate a uniformly distributed set of pseudo-random numbers.

```
end testRandom;
```

Program 10.1 Screen Plot Test of the HLA Random Number Generators

The `rand.hhf` module also provides an *iterator* that generates a random sequence of value in the range 0..n-1. However, a discussion of this function must wait until we cover iterators in a later chapter.

10.7 Putting It All Together

This chapter finished the presentation of the integer arithmetic instructions on the 80x86. Then it demonstrated how to convert expressions from a high level language syntax into assembly language. This chapter concluded by teaching you a few assembly language tricks you will commonly find in programs. By the conclusion of this chapter you are (hopefully) in a position where you can easily evaluate arithmetic expressions in your assembly language programs.

11.1 Chapter Overview

This chapter discusses the implementation of floating point arithmetic computation in assembly language. By the conclusion of this chapter you should be able to translate arithmetic expressions and assignment statements involving floating point operands from high level languages like Pascal and C/C++ into 80x86 assembly language.

11.2 Floating Point Arithmetic

When the 8086 CPU first appeared in the late 1970's, semiconductor technology was not to the point where Intel could put floating point instructions directly on the 8086 CPU. Therefore, they devised a scheme whereby they could use a second chip to perform the floating point calculations – the floating point unit (or FPU)¹. They released their original floating point chip, the 8087, in 1980. This particular FPU worked with the 8086, 8088, 80186, and 80188 CPUs. When Intel introduced the 80286 CPU, they released a redesigned 80287 FPU chip to accompany it. Although the 80287 was compatible with the 80386 CPU, Intel designed a better FPU, the 80387, for use in 80386 systems. The 80486 CPU was the first Intel CPU to include an on-chip floating point unit. Shortly after the release of the 80486, Intel introduced the 80486sx CPU that was an 80486 without the built-in FPU. To get floating point capabilities on this chip, you had to add an 80487 chip, although the 80487 was really nothing more than a full-blown 80486 which took over for the “sx” chip in the system. Intel's Pentium chips provide a high-performance floating point unit directly on the CPU. There is no floating point coprocessor available for the Pentium chip.

Collectively, we will refer to all these chips as the 80x87 FPU. Given the obsolescence of the 8086, 80286, 8087, 80287, 80387, and 80487 chips, this text will concentrate on the Pentium and later chips. There are some differences between the Pentium floating point units and the earlier FPUs. If you need to write code that will execute on those earlier machines, you should consult the appropriate Intel documentation for those devices.

11.2.1 FPU Registers

The 80x86 FPUs add 13 registers to the 80x86 and later processors: eight floating point data registers, a control register, a status register, a tag register, an instruction pointer, and a data pointer. The data registers are similar to the 80x86's general purpose register set insofar as all floating point calculations take place in these registers. The control register contains bits that let you decide how the FPU handles certain degenerate cases like rounding of inaccurate computations, it contains bits that control precision, and so on. The status register is similar to the 80x86's flags register; it contains the condition code bits and several other floating point flags that describe the state of the FPU. The tag register contains several groups of bits that determine the state of the value in each of the eight general purpose registers. The instruction and data pointer registers contain certain state information about the last floating point instruction executed. We will not consider the last three registers in this text, see the Intel documentation for more details.

1. Intel has also referred to this device as the Numeric Data Processor (NDP), Numeric Processor Extension (NPX), and math coprocessor.

11.2.1.1 FPU Data Registers

The FPUs provide eight 80 bit data registers organized as a stack. This is a significant departure from the organization of the general purpose registers on the 80x86 CPU that comprise a standard general-purpose register set. HLA refers to these registers as ST0, ST1, ..., ST7.

The biggest difference between the FPU register set and the 80x86 register set is the stack organization. On the 80x86 CPU, the AX register is always the AX register, no matter what happens. On the FPU, however, the register set is an eight element stack of 80 bit floating point values (see Figure 11.1).

Figure 11.1 FPU Floating Point Register Stack

ST0 refers to the item on the top of the stack, ST1 refers to the next item on the stack, and so on. Many floating point instructions push and pop items on the stack; therefore, ST1 will refer to the previous contents of ST0 after you push something onto the stack. It will take some thought and practice to get used to the fact that the registers are changing under you, but this is an easy problem to overcome.

11.2.1.2 The FPU Control Register

When Intel designed the 80x87 (and, essentially, the IEEE floating point standard), there were no standards in floating point hardware. Different (mainframe and mini) computer manufacturers all had different and incompatible floating point formats. Unfortunately, much application software had been written taking into account the idiosyncrasies of these different floating point formats. Intel wanted to design an FPU that could work with the majority of the software out there (keep in mind, the IBM PC was three to four years away when Intel began designing the 8087, they couldn't rely on that "mountain" of software available for the PC to make their chip popular). Unfortunately, many of the features found in these older floating point formats were mutually incompatible. For example, in some floating point systems rounding would occur when there was insufficient precision; in others, truncation would occur. Some applications would work with one floating point system but not with the other. Intel wanted as many applications as possible to work with as few changes as possible on their 80x87 FPUs, so they added a special register, the FPU *control register*, that lets the user choose one of several possible operating modes for their FPU.

The 80x87 control register contains 16 bits organized as shown in Figure 11.2.

Figure 11.2 FPU Control Register

Bit 12 of the control register is only present on the 8087 and 80287 chips. It controls how the 80x87 responds to infinity. The 80387 and later chips always use a form of infinity known and *affine closure* because this is the only form supported by the IEEE 754/854 standards. As such, we will ignore any further use of this bit and assume that it is always programmed with a one.

Bits 10 and 11 provide rounding control according to the following values:

Table 1: Rounding Control

| Bits 10 & 11 | Function |
|--------------|--------------------|
| 00 | To nearest or even |
| 01 | Round down |
| 10 | Round up |
| 11 | Truncate |

The “00” setting is the default. The FPU rounds values above one-half of the least significant bit up. It rounds values below one-half of the least significant bit down. If the value below the least significant bit is exactly one-half of the least significant bit, the FPU rounds the value towards the value whose least significant bit is zero. For long strings of computations, this provides a reasonable, automatic, way to maintain maximum precision.

The round up and round down options are present for those computations where it is important to keep track of the accuracy during a computation. By setting the rounding control to round down and performing the operation, then repeating the operation with the rounding control set to round up, you can determine the minimum and maximum ranges between which the true result will fall.

The truncate option forces all computations to truncate any excess bits during the computation. You will rarely use this option if accuracy is important to you. However, if you are porting older software to the FPU,

you might use this option to help when porting the software. One place where this option is extremely useful is when converting a floating point value to an integer. Since most software expects floating point to integer conversions to truncate the result, you will need to use the truncation rounding mode to achieve this.

Bits eight and nine of the control register specify the precision during computation. This capability is provided to allow compatibility with older software as required by the IEEE 754 standard. The precision control bits use the following values:

Table 2: Mantissa Precision Control Bits

| Bits 8 & 9 | Precision Control |
|------------|-------------------|
| 00 | 24 bits |
| 01 | Reserved |
| 10 | 53 bits |
| 11 | 64 bits |

Some CPUs may operate faster with floating point values whose precision is 53 bits (i.e., 64-bit floating point format) rather than 64 bits (i.e., 80-bit floating point format). Please see the documentation for your specific processor for details. Generally, the CPU defaults these bits to %11 to select the 64-bit mantissa precision.

Bits zero through five are the *exception masks*. These are similar to the interrupt enable bit in the 80x86's flags register. If these bits contain a one, the corresponding condition is ignored by the FPU. However, if any bit contains zero, and the corresponding condition occurs, then the FPU immediately generates an interrupt so the program can handle the degenerate condition.

Bit zero corresponds to an invalid operation error. This generally occurs as the result of a programming error. Problems which raise the invalid operation exception include pushing more than eight items onto the stack or attempting to pop an item off an empty stack, taking the square root of a negative number, or loading a non-empty register.

Bit one masks the *denormalized* interrupt that occurs whenever you try to manipulate denormalized values. Denormalized exceptions occur when you load arbitrary extended precision values into the FPU or work with very small numbers just beyond the range of the FPU's capabilities. Normally, you would probably *not* enable this exception. If you enable this exception and the FPU generates this interrupt, the HLA run-time system raises the *ex.fDenormal* exception.

Bit two masks the *zero divide* exception. If this bit contains zero, the FPU will generate an interrupt if you attempt to divide a nonzero value by zero. If you do not enable the zero division exception, the FPU will produce NaN (not a number) whenever you perform a zero division. It's probably a good idea to enable this exception by programming a zero into this bit. Note that if your program generates this interrupt, the HLA run-time system will raise the *ex.fDivByZero* exception.

Bit three masks the *overflow* exception. The FPU will raise the overflow exception if a calculation overflows or if you attempt to store a value which is too large to fit into a destination operand (e.g., storing a large extended precision value into a single precision variable). If you enable this exception and the FPU generates this interrupt, the HLA run-time system raises the *ex.fOverflow* exception.

Bit four, if set, masks the *underflow* exception. Underflow occurs when the result is too *small* to fit in the destination operand. Like overflow, this exception can occur whenever you store a small extended precision value into a smaller variable (single or double precision) or when the result of a computation is too small for extended precision. If you enable this exception and the FPU generates this interrupt, the HLA run-time system raises the *ex.fUnderflow* exception.

Bit five controls whether the *precision* exception can occur. A precision exception occurs whenever the FPU produces an imprecise result, generally the result of an internal rounding operation. Although many operations will produce an exact result, many more will not. For example, dividing one by ten will produce an inexact result. Therefore, this bit is usually one since inexact results are very common. If you enable this

exception and the FPU generates this interrupt, the HLA run-time system raises the *ex.InexactResult* exception.

Bits six and thirteen through fifteen in the control register are currently undefined and reserved for future use. Bit seven is the interrupt enable mask, but it is only active on the 8087 FPU; a zero in this bit enables 8087 interrupts and a one disables FPU interrupts.

The FPU provides two instructions, FLDCW (load control word) and FSTCW (store control word), that let you load and store the contents of the control register. The single operand to these instructions must be a 16 bit memory location. The FLDCW instruction loads the control register from the specified memory location, FSTCW stores the control register into the specified memory location. The syntax for these instructions is

```
fldcw( mem16 );
fstcw( mem16 );
```

Here's some example code that sets the rounding control to "truncate result" and sets the rounding precision to 24 bits:

```
static
fcw16: word;
.
.
.
fstcw( fcw16 );
mov( fcw16, ax );
and( $f0ff, ax ); // Clears bits 8-11.
or( $0c00, ax ); // Rounding control=%11, Precision = %00.
mov( ax, fcw16 );
fldcw( fcw16 );
```

11.2.1.3 The FPU Status Register

The FPU status register provides the status of the coprocessor at the instant you read it. The FSTSW instruction stores the 16 bit floating point status register into a word variable. The status register is a 16 bit register, its layout appears in Figure 11.3.

Figure 11.3 The FPU Status Register

Bits zero through five are the exception flags. These bits appear in the same order as the exception masks in the control register. If the corresponding condition exists, then the bit is set. These bits are independent of the exception masks in the control register. The FPU sets and clears these bits regardless of the corresponding mask setting.

Bit six indicates a *stack fault*. A stack fault occurs whenever there is a stack overflow or underflow. When this bit is set, the C₁ condition code bit determines whether there was a stack overflow (C₁=1) or stack underflow (C₁=0) condition.

Bit seven of the status register is set if *any* error condition bit is set. It is the logical OR of bits zero through five. A program can test this bit to quickly determine if an error condition exists.

Bits eight, nine, ten, and fourteen are the coprocessor condition code bits. Various instructions set the condition code bits as shown in the following table:

Table 3: FPU Condition Code Bits

| Instruction | Condition Code Bits | | | | Condition |

Bits 11-13 of the FPU status register provide the register number of the top of stack. During computations, the FPU adds (modulo eight) the *logical* register numbers supplied by the programmer to these three bits to determine the *physical* register number at run time.

Bit 15 of the status register is the *busy* bit. It is set whenever the FPU is busy. Most programs will have little reason to access this bit.

11.2.2 FPU Data Types

The FPU supports seven different data types: three integer types, a packed decimal type, and three floating point types. The integer type provides for 64-bit integers, although it is often faster to do the 64-bit arithmetic using the integer unit of the CPU (see the chapter on Advanced Arithmetic). Certainly it is often faster to do 16-bit and 32-bit integer arithmetic using the standard integer registers. The packed decimal type provides a 17 digit signed decimal (BCD) integer. The primary purpose of the BCD format is to convert between strings and floating point values. The remaining three data types are the 32 bit, 64 bit, and 80 bit floating point data types we've looked at so far. The 80x87 data types appear in Figure 11.4, Figure 11.5, and Figure 11.6.

Figure 11.4 FPU Floating Point Formats

Figure 11.5 FPU Integer Formats

80 Bit Packed Decimal Integer (BCD)

Figure 11.6 FPU Packed Decimal Format

The FPU generally stores values in a *normalized* format. When a floating point number is normalized, the H.O. bit of the mantissa is always one. In the 32 and 64 bit floating point formats, the FPU does not actually store this bit, the FPU always assumes that it is one. Therefore, 32 and 64 bit floating point numbers are always normalized. In the extended precision 80 bit floating point format, the FPU does *not* assume that the H.O. bit of the mantissa is one, the H.O. bit of the mantissa appears as part of the string of bits.

Normalized values provide the greatest precision for a given number of bits. However, there are a large number of non-normalized values which we *cannot* represent with the 80-bit format. These values are very close to zero and represent the set of values whose mantissa H.O. bit is not zero. The FPUs support a special 80-bit form known as *denormalized* values. Denormalized values allow the FPU to encode very small values it cannot encode using normalized values, but at a price. Denormalized values offer fewer bits of precision than normalized values. Therefore, using denormalized values in a computation may introduce some slight inaccuracy into a computation. Of course, this is always better than underflowing the denormalized value to zero (which could make the computation even less accurate), but you must keep in mind that if you work with very small values you may lose some accuracy in your computations. Note that the FPU status register contains a bit you can use to detect when the FPU uses a denormalized value in a computation.

11.2.3 The FPU Instruction Set

The FPU adds over 80 new instructions to the 80x86 instruction set. We can classify these instructions as *data movement instructions*, *conversions*, *arithmetic instructions*, *comparisons*, *constant instructions*, *transcendental instructions*, and *miscellaneous instructions*. The following sections describe each of the instructions in these categories.

11.2.4 FPU Data Movement Instructions

The data movement instructions transfer data between the internal FPU registers and memory. The instructions in this category are FLD, FST, FSTP, and FXCH. The FLD instruction always pushes its operand onto the floating point stack. The FSTP instruction always pops the top of stack after storing the top of stack (tos). The remaining instructions do not affect the number of items on the stack.

11.2.4.1 The FLD Instruction

The FLD instruction loads a 32 bit, 64 bit, or 80 bit floating point value onto the stack. This instruction converts 32 and 64 bit operands to an 80 bit extended precision value before pushing the value onto the floating point stack.

The FLD instruction first decrements the top of stack (TOS) pointer (bits 11-13 of the status register) and then stores the 80 bit value in the physical register specified by the new TOS pointer. If the source operand of the FLD instruction is a floating point data register, ST_i, then the actual register the FPU uses for the

load operation is the register number *before* decrementing the tos pointer. Therefore, “fld(st0);” duplicates the value on the top of the stack.

The FLD instruction sets the stack fault bit if stack overflow occurs. It sets the denormalized exception bit if you load an 80-bit denormalized value. It sets the invalid operation bit if you attempt to load an empty floating point register onto the stop of stack (or perform some other invalid operation).

Examples:

```
fld( st1 );
fld( real32_variable );
fld( real64_variable );
fld( real80_variable );
fld( real_constant );
```

Note that there is no way to directly load a 32-bit integer register onto the floating point stack, even if that register contains a REAL32 value. To accomplish this, you must first store the integer register into a memory location then you can push that memory location onto the FPU stack using the FLD instruction. E.g.,

```
mov( eax, tempReal32 ); // Save REAL32 value in EAX to memory.
fld( tempReal32 ); // Push that real value onto the FPU stack.
```

Note: loading a constant via FLD is actually an HLA extension. The FPU doesn’t support this instruction type. HLA creates a REAL80 object in the “constants” segment and uses the address of this memory object as the true operand for FLD.

11.2.4.2 The FST and FSTP Instructions

The FST and FSTP instructions copy the value on the top of the floating point register stack to another floating point register or to a 32, 64, or 80 bit memory variable. When copying data to a 32 or 64 bit memory variable, the 80 bit extended precision value on the top of stack is rounded to the smaller format as specified by the rounding control bits in the FPU control register.

The FSTP instruction pops the value off the top of stack when moving it to the destination location. It does this by incrementing the top of stack pointer in the status register after accessing the data in ST0. If the destination operand is a floating point register, the FPU stores the value at the specified register number *before* popping the data off the top of the stack.

Executing an “fstp(st0);” instruction effectively pops the data off the top of stack with no data transfer.

Examples:

```
fst( real32_variable );
fst( real64_variable );
fst( realArray[ ebx*8 ] );
fst( real80_variable );
fst( st2 );
fstp( st1 );
```

The last example above effectively pops ST1 while leaving ST0 on the top of the stack.

The FST and FSTP instructions will set the stack exception bit if a stack underflow occurs (attempting to store a value from an empty register stack). They will set the precision bit if there is a loss of precision during the store operation (this will occur, for example, when storing an 80 bit extended precision value into a 32 or 64 bit memory variable and there are some bits lost during conversion). They will set the underflow exception bit when storing an 80 bit value into a 32 or 64 bit memory variable, but the value is too small to fit into the destination operand. Likewise, these instructions will set the overflow exception bit if the value on the top of stack is too big to fit into a 32 or 64 bit memory variable. The FST and FSTP instructions set the denormalized flag when you try to store a denormalized value into an 80 bit register or variable². They set the invalid operation flag if an invalid operation (such as storing into an empty register) occurs. Finally, these

2. Storing a denormalized value into a 32 or 64 bit memory variable will always set the underflow exception bit.

instructions set the C_1 condition bit if rounding occurs during the store operation (this only occurs when storing into a 32 or 64 bit memory variable and you have to round the mantissa to fit into the destination).

Note: Because of an idiosyncrasy in the FPU instruction set related to the encoding of the instructions, you cannot use the FST instruction to store data into a real80 memory variable. You may, however, store 80-bit data using the FSTP instruction.

11.2.4.3 The FXCH Instruction

The FXCH instruction exchanges the value on the top of stack with one of the other FPU registers. This instruction takes two forms: one with a single FPU register as an operand, the second without any operands. The first form exchanges the top of stack (tos) with the specified register. The second form of FXCH swaps the top of stack with ST1.

Many FPU instructions, e.g., FSQRT, operate only on the top of the register stack. If you want to perform such an operation on a value that is not on the top of stack, you can use the FXCH instruction to swap that register with tos, perform the desired operation, and then use the FXCH to swap the tos with the original register. The following example takes the square root of ST2:

```
fxch( st2 );
fsqrt();
fxch( st2 );
```

The FXCH instruction sets the stack exception bit if the stack is empty. It sets the invalid operation bit if you specify an empty register as the operand. This instruction always clears the C_1 condition code bit.

11.2.5 Conversions

The FPU performs all arithmetic operations on 80 bit real quantities. In a sense, the FLD and FST/FSTP instructions are conversion instructions as well as data movement instructions because they automatically convert between the internal 80 bit real format and the 32 and 64 bit memory formats. Nonetheless, we'll simply classify them as data movement operations, rather than conversions, because they are moving real values to and from memory. The FPU provides five other instructions that convert to or from integer or binary coded decimal (BCD) format when moving data. These instructions are FILD, FIST, FISTP, FBLD, and FBSTP.

11.2.5.1 The FILD Instruction

The FILD (integer load) instruction converts a 16, 32, or 64 bit two's complement integer to the 80 bit extended precision format and pushes the result onto the stack. This instruction always expects a single operand. This operand must be the address of a word, double word, or quad word integer variable. You cannot specify one of the 80x86's 16 or 32 bit general purpose registers. If you want to push an 80x86 general purpose register onto the FPU stack, you must first store it into a memory variable and then use FILD to push that value of that memory variable.

The FILD instruction sets the stack exception bit and C_1 (accordingly) if stack overflow occurs while pushing the converted value. Examples:

```
fild( word_variable );
fild( dword_val[ ecx*4 ] );
fild( qword_variable );
```

11.2.5.2 The FIST and FISTP Instructions

The FIST and FISTP instructions convert the 80 bit extended precision variable on the top of stack to a 16, 32, or 64 bit integer and store the result away into the memory variable specified by the single operand. These instructions convert the value on tos to an integer according to the rounding setting in the FPU control register (bits 10 and 11). As for the FILD instruction, the FIST and FISTP instructions will not let you specify one of the 80x86's general purpose 16 or 32 bit registers as the destination operand.

The FIST instruction converts the value on the top of stack to an integer and then stores the result; it does not otherwise affect the floating point register stack. The FISTP instruction pops the value off the floating point register stack after storing the converted value.

These instructions set the stack exception bit if the floating point register stack is empty (this will also clear C_1). They set the precision (imprecise operation) and C_1 bits if rounding occurs (that is, if there is any fractional component to the value in ST0). These instructions set the underflow exception bit if the result is too small (i.e., less than one but greater than zero or less than zero but greater than -1). Examples:

```
fist( word_var[ ebx*2 ] );
fist( qword_var );
fistp( dword_var );
```

Don't forget that these instructions use the rounding control settings to determine how they will convert the floating point data to an integer during the store operation. Be default, the rounding control is usually set to "round" mode; yet most programmers expect FIST/FISTP to truncate the decimal portion during conversion. If you want FIST/FISTP to truncate floating point values when converting them to an integer, you will need to set the rounding control bits appropriately in the floating point control register, e.g.,

```
static
fcw16:      word;
fcw16_2:   word;
IntResult: int32;
.
.
.
fstcw( fcw16 );
mov( fcw16, ax );
or( $0c00, ax );      // Rounding control=%11 (truncate).
mov( ax, fcw16_2 );  // Store into memory and reload the ctrl word.
fldcw( fcw16_2 );

fistp( IntResult );  // Truncate ST0 and store as int32 object.

fldcw( fcw16 );     // Restore original rounding control
```

11.2.5.3 The FBLD and FBSTP Instructions

The FBLD and FBSTP instructions load and store 80 bit BCD values. The FBLD instruction converts a BCD value to its 80 bit extended precision equivalent and pushes the result onto the stack. The FBSTP instruction pops the extended precision real value on TOS, converts it to an 80 bit BCD value (rounding according to the bits in the floating point control register), and stores the converted result at the address specified by the destination memory operand. Note that there is no FBST instruction which stores the value on tos without popping it.

The FBLD instruction sets the stack exception bit and C_1 if stack overflow occurs. It sets the invalid operation bit if you attempt to load an invalid BCD value. The FBSTP instruction sets the stack exception bit and clears C_1 if stack underflow occurs (the stack is empty). It sets the underflow flag under the same conditions as FIST and FISTP. Examples:

```
// Assuming fewer than eight items on the stack, the following
```

```
// code sequence is equivalent to an fbst instruction:

    fld( st0 );
    fbstp( tbyte_var );

// The following example easily converts an 80 bit BCD value to
// a 64 bit integer:

    fbld( tbyte_var );
    fist( qword_var );
```

11.2.6 Arithmetic Instructions

The arithmetic instructions make up a small, but important, subset of the FPU's instruction set. These instructions fall into two general categories – those which operate on real values and those which operate on a real and an integer value.

11.2.6.1 The FADD and FADDP Instructions

These two instructions take the following forms:

```
fadd()
faddp()
fadd( st0, sti );
fadd( sti, st0 );
faddp( st0, sti );
fadd( mem_32_64 );
fadd( real_constant );
```

The first two forms are equivalent. They pop the two values on the top of stack, add them, and push their sum back onto the stack.

The next two forms of the FADD instruction, those with two FPU register operands, behave like the 80x86's ADD instruction. They add the value in the source register operand to the value in the destination register operand. Note that one of the register operands must be ST0.

The FADDP instruction with two operands adds ST0 (which must always be the source operand) to the destination operand and then pops ST0. The destination operand must be one of the other FPU registers.

The last form above, FADD with a memory operand, adds a 32 or 64 bit floating point variable to the value in ST0. This instruction will convert the 32 or 64 bit operands to an 80 bit extended precision value before performing the addition. Note that this instruction does *not* allow an 80 bit memory operand.

These instructions can raise the stack, precision, underflow, overflow, denormalized, and illegal operation exceptions, as appropriate. If a stack fault exception occurs, C₁ denotes stack overflow or underflow.

Like FLD(real_constant), the FADD(real_constant) instruction is an HLA extension. Note that it creates a 64-bit variable holding the constant value and emits the FADD(mem64) instruction, specifying the read-only object it creates in the constants segment.

11.2.6.2 The FSUB, FSUBP, FSUBR, and FSUBRP Instructions

These four instructions take the following forms:

```
fsub()
fsubp()
fsubr()
fsubrp()

fsub( st0, sti )
```

```

fsub( sti, st0 );
fsubp( st0, sti );
fsub( mem_32_64 );
fsub( real_constant );

fsubr( st0, sti )
fsubr( sti, st0 );
fsubrp( st0, sti );
fsubr( mem_32_64 );
fsubr( real_constant );

```

With no operands, the FSUB and FSUBP instructions operate identically. They pop ST0 and ST1 from the register stack, compute ST0-ST1, and then push the difference back onto the stack. The FSUBR and FSUBRP instructions (reverse subtraction) operate in an almost identical fashion except they compute ST1-ST0 and push that difference.

With two register operands (*source*, *destination*) the FSUB instruction computes $destination := destination - source$. One of the two registers must be ST0. With two registers as operands, the FSUBP also computes $destination := destination - source$ and then it pops ST0 off the stack after computing the difference. For the FSUBP instruction, the source operand must be ST0.

With two register operands, the FSUBR and FSUBRP instruction work in a similar fashion to FSUB and FSUBP, except they compute $destination := source - destination$.

The FSUB(mem) and FSUBR(mem) instructions accept a 32 or 64 bit memory operand. They convert the memory operand to an 80 bit extended precision value and subtract this from ST0 (FSUB) or subtract ST0 from this value (FSUBR) and store the result back into ST0.

These instructions can raise the stack, precision, underflow, overflow, denormalized, and illegal operation exceptions, as appropriate. If a stack fault exception occurs, C₁ denotes stack overflow or underflow.

Note: the instructions that have real constants as operands aren't true FPU instructions. These are extensions provided by HLA. HLA generates a constant segment memory object initialized with the constant's value.

11.2.6.3 The FMUL and FMULP Instructions

The FMUL and FMULP instructions multiply two floating point values. These instructions allow the following forms:

```

fmul()
fmulp()

fmul( sti, st0 );
fmul( st0, sti );
fmul( mem_32_64 );
fmul( real_constant );

fmulp( st0, sti );

```

With no operands, FMUL and FMULP both do the same thing – they pop ST0 and ST1, multiply these values, and push their product back onto the stack. The FMUL instructions with two register operands compute $destination := destination * source$. One of the registers (source or destination) must be ST0.

The FMULP(ST0, ST_{*i*}) instruction computes $ST_i := ST_i * ST0$ and then pops ST0. This instruction uses the value for *i* before popping ST0. The FMUL(mem) instruction requires a 32 or 64 bit memory operand. It converts the specified memory variable to an 80 bit extended precision value and then multiplies ST0 by this value.

These instructions can raise the stack, precision, underflow, overflow, denormalized, and illegal operation exceptions, as appropriate. If rounding occurs during the computation, these instructions set the C₁ condition code bit. If a stack fault exception occurs, C₁ denotes stack overflow or underflow.

Note: the instruction that has a real constant as its operand isn't a true FPU instruction. It is an extension provided by HLA (see the note at the end of the previous section for details).

11.2.6.4 The FDIV, FDIVP, FDIVR, and FDIVRP Instructions

These four instructions allow the following forms:

```

fdiv()
fdivp()
fdivr()
fdivrp()

fdiv( sti, st0 );
fdiv( st0, sti );
fdivp( st0, sti );

fdivr( sti, st0 );
fdivr( st0, sti );
fdivrp( st0, sti );

fdiv( mem_32_64 );
fdivr( mem_32_64 );
fdiv( real_constant );
fdivr( real_constant );

```

With no operands, the FDIV and FDIVP instructions pop ST0 and ST1, compute ST0/ST1, and push the result back onto the stack. The FDIVR and FDIVRP instructions also pop ST0 and ST1 but compute ST1/ST0 before pushing the quotient onto the stack.

With two register operands, these instructions compute the following quotients:

```

fdiv( sti, st0 );    // ST0 := ST0/STi
fdiv( st0, sti );   // STi := STi/ST0
fdivp( st0, sti );  // STi := STi/ST0 then pop ST0
fdivr( st0, sti );  // ST0 := ST0/STi
fdivrp( st0, sti ); // STi := ST0/STi then pop ST0

```

The FDIVP and FDIVRP instructions also pop ST0 after performing the division operation. The value for *i* in these two instructions is computed before popping ST0.

These instructions can raise the stack, precision, underflow, overflow, denormalized, zero divide, and illegal operation exceptions, as appropriate. If rounding occurs during the computation, these instructions set the C₁ condition code bit. If a stack fault exception occurs, C₁ denotes stack overflow or underflow.

Note: the instructions that have real constants as operands aren't true FPU instructions. These are extensions provided by HLA.

11.2.6.5 The FSQRT Instruction

The FSQRT routine does not allow any operands. It computes the square root of the value on top of stack (TOS) and replaces ST0 with this result. The value on TOS must be zero or positive, otherwise FSQRT will generate an invalid operation exception.

This instruction can raise the stack, precision, denormalized, and invalid operation exceptions, as appropriate. If rounding occurs during the computation, FSQRT sets the C₁ condition code bit. If a stack fault exception occurs, C₁ denotes stack overflow or underflow.

Example:

```
// Compute Z := sqrt(x**2 + y**2);
```

```

fld( x );      // Load X.
fld( st0 );   // Duplicate X on TOS.
fmul();       // Compute X**2.

fld( y );     // Load Y
fld( st0 );   // Duplicate Y.
fmul();       // Compute Y**2.

fadd();       // Compute X**2 + Y**2.
fsqrt();     // Compute sqrt( X**2 + Y**2 ).
fstp( z );    // Store result away into Z.

```

11.2.6.6 The FPREM and FPREM1 Instructions

The FPREM and FPREM1 instructions compute a *partial remainder*. Intel designed the FPREM instruction before the IEEE finalized their floating point standard. In the final draft of the IEEE floating point standard, the definition of FPREM was a little different than Intel's original design. Unfortunately, Intel needed to maintain compatibility with the existing software that used the FPREM instruction, so they designed a new version to handle the IEEE partial remainder operation, FPREM1. You should always use FPREM1 in new software you write, therefore we will only discuss FPREM1 here, although you use FPREM in an identical fashion.

FPREM1 computes the *partial* remainder of ST0/ST1. If the difference between the exponents of ST0 and ST1 is less than 64, FPREM1 can compute the exact remainder in one operation. Otherwise you will have to execute the FPREM1 two or more times to get the correct remainder value. The C₂ condition code bit determines when the computation is complete. Note that FPREM1 does *not* pop the two operands off the stack; it leaves the partial remainder in ST0 and the original divisor in ST1 in case you need to compute another partial product to complete the result.

The FPREM1 instruction sets the stack exception flag if there aren't two values on the top of stack. It sets the underflow and denormal exception bits if the result is too small. It sets the invalid operation bit if the values on tos are inappropriate for this operation. It sets the C₂ condition code bit if the partial remainder operation is not complete. Finally, it loads C₃, C₁, and C₀ with bits zero, one, and two of the quotient, respectively.

Example:

```

// Compute Z := X mod Y

fld( y );
fld( x );
repeat

    fprem1();
    fstsw( ax );    // Get condition code bits into AX.
    and( 1, ah );  // See if C2 is set.

until( @z );      // Repeat until C2 is clear.
fstp( z );        // Store away the remainder.
fstp( st0 );      // Pop old Y value.

```

11.2.6.7 The FRNDINT Instruction

The FRNDINT instruction rounds the value on the top of stack (TOS) to the nearest integer using the rounding algorithm specified in the control register.

This instruction sets the stack exception flag if there is no value on the TOS (it will also clear C₁ in this case). It sets the precision and denormal exception bits if there was a loss of precision. It sets the invalid

operation flag if the value on the tos is not a valid number. Note that the result on tos is still a floating point value, it simply does not have a fractional component.

11.2.6.8 The FABS Instruction

FABS computes the absolute value of ST0 by clearing the mantissa sign bit of ST0. It sets the stack exception bit and invalid operation bits if the stack is empty.

Example:

```
// Compute X := sqrt(abs(x));

    fld( x );
    fabs();
    fsqrt();
    fstp( x );
```

11.2.6.9 The FCHS Instruction

FCHS changes the sign of ST0's value by inverting the mantissa sign bit (that is, this is the floating point negation instruction). It sets the stack exception bit and invalid operation bits if the stack is empty. Example:

```
// Compute X := -X if X is positive, X := X if X is negative.

    fld( x );
    fabs();
    fchs();
    fstp( x );
```

11.2.7 Comparison Instructions

The FPU provides several instructions for comparing real values. The FCOM, FCOMP, and FCOMPP instructions compare the two values on the top of stack and set the condition codes appropriately. The FTST instruction compares the value on the top of stack with zero.

Generally, most programs test the condition code bits immediately after a comparison. Unfortunately, there are no conditional jump instructions that branch based on the FPU condition codes. Instead, you can use the FSTSW instruction to copy the floating point status register (see “The FPU Status Register” on page 595) into the AX register; then you can use the SAHF instruction to copy the AH register into the 80x86's condition code bits. After doing this, you can use the conditional jump instructions to test some condition. This technique copies C_0 into the carry flag, C_2 into the parity flag, and C_3 into the zero flag. The SAHF instruction does not copy C_1 into any of the 80x86's flag bits.

Since the SAHF instruction does not copy any FPU status bits into the sign or overflow flags, you cannot use signed comparison instructions. Instead, use unsigned operations (e.g., SETA, SETB) when testing the results of a floating point comparison. *Yes, these instructions normally test unsigned values and floating point numbers are signed values.* However, use the unsigned operations anyway; the FSTSW and SAHF instructions set the 80x86 flags register as though you had compared unsigned values with the CMP instruction.

The Pentium II and (upwards) compatible processors provide an extra set of floating point comparison instructions that directly affect the 80x86 condition code flags. These instructions circumvent having to use FSTSW and SAHF to copy the FPU status into the 80x86 condition codes. These instructions include FCOMI and FCOMIP. You use them just like the FCOM and FCOMP instructions except, of course, you do not have to manually copy the status bits to the FLAGS register. Do be aware that these instructions are not available on many processors in common use today (as of 1/1/2000). However, as time passes it may be safe

to begin assuming that everyone's CPU supports these instructions. Since this text assumes a minimum Pentium CPU, it will not discuss these two instructions any further.

11.2.7.1 The FCOM, FCOMP, and FCOMPP Instructions

The FCOM, FCOMP, and FCOMPP instructions compare ST0 to the specified operand and set the corresponding FPU condition code bits based on the result of the comparison. The legal forms for these instructions are

```
fcom()
fcomp()
fcompp()

fcom( sti )
fcomp( sti )

fcom( mem_32_64 )
fcomp( mem_32_64 )
fcom( real_constant )
fcomp( real_constant )
```

With no operands, FCOM, FCOMP, and FCOMPP compare ST0 against ST1 and set the processor flags accordingly. In addition, FCOMP pops ST0 off the stack and FCOMPP pops both ST0 and ST1 off the stack.

With a single register operand, FCOM and FCOMP compare ST0 against the specified register. FCOMP also pops ST0 after the comparison.

With a 32 or 64 bit memory operand, the FCOM and FCOMP instructions convert the memory variable to an 80 bit extended precision value and then compare ST0 against this value, setting the condition code bits accordingly. FCOMP also pops ST0 after the comparison.

These instructions set C₂ (which winds up in the parity flag) if the two operands are not comparable (e.g., NaN). If it is possible for an illegal floating point value to wind up in a comparison, you should check the parity flag for an error before checking the desired condition.

These instructions set the stack fault bit if there aren't two items on the top of the register stack. They set the denormalized exception bit if either or both operands are denormalized. They set the invalid operation flag if either or both operands are quite NaNs. These instructions always clear the C₁ condition code.

Note: the instructions that have real constants as operands aren't true FPU instructions. These are extensions provided by HLA. When HLA encounters such an instruction, it creates a real64 read-only variable in the constants segment and initializes this variable with the specified constant. Then HLA translates the instruction to one that specifies a real64 memory operand. *Note that because of the precision differences (64 bits vs. 80 bits), if you use a constant operand in a floating point instruction you may not get results that are as precise as you would expect.*

Example of a floating point comparison:

```
fcompp();
fstsw( ax );
sahf();
setb( al ); // AL = true if ST1 < ST0.
.
.
.
```

Note that you cannot compare floating point values in an HLA run-time boolean expression (e.g., within an IF statement).

11.2.7.2 The FTST Instruction

The FTST instruction compares the value in ST0 against 0.0. It behaves just like the FCOM instruction would if ST1 contained 0.0. Note that this instruction does not differentiate -0.0 from +0.0. If the value in ST0 is either of these values, fstst will set C₃ to denote equality. Note that this instruction does *not* pop st(0) off the stack. Example:

```

fstst();
fstsw( ax );
sahf();
sete( al );           // Set AL to 1 if TOS = 0.0

```

11.2.8 Constant Instructions

The FPU provides several instructions that let you load commonly used constants onto the FPU's register stack. These instructions set the stack fault, invalid operation, and C₁ flags if a stack overflow occurs; they do not otherwise affect the FPU flags. The specific instructions in this category include:

```

fldz()      ;Pushes +0.0.
fld1()      ;Pushes +1.0.
fldpi()     ;Pushes π.
fldl2t()    ;Pushes log2(10).
fldl2e()    ;Pushes log2(e).
fldlg2()    ;Pushes log10(2).
fldln2()    ;Pushes ln(2).

```

11.2.9 Transcendental Instructions

The FPU provides eight transcendental (log and trigonometric) instructions to compute sin, cos, partial tangent, partial arctangent, 2^x-1 , $y * \log_2(x)$, and $y * \log_2(x+1)$. Using various algebraic identities, it is easy to compute most of the other common transcendental functions using these instructions.

11.2.9.1 The F2XM1 Instruction

F2XM1 computes $2^{st0}-1$. The value in ST0 must be in the range $-1.0 \leq ST0 \leq +1.0$. If ST0 is out of range F2XM1 generates an undefined result but raises no exceptions. The computed value replaces the value in ST0. Example:

; Compute 10^x using the identity: $10^x = 2^{x \cdot \lg(10)}$ ($\lg = \log_2$).

```

fld( x );
fldl2t();
fmul();
f2xm1();
fld1();
fadd();

```

Note that F2XM1 computes 2^x-1 , which is why the code above adds 1.0 to the result at the end of the computation.

11.2.9.2 The FSIN, FCOS, and FSINCOS Instructions

These instructions pop the value off the top of the register stack and compute the sine, cosine, or both, and push the result(s) back onto the stack. The FSINCOS pushes the sine followed by the cosine of the original operand, hence it leaves $\cos(ST0)$ in $ST0$ and $\sin(ST0)$ in $ST1$.

These instructions assume $ST0$ specifies an angle in radians and this angle must be in the range $-2^{63} < ST0 < +2^{63}$. If the original operand is out of range, these instructions set the C_2 flag and leave $ST0$ unchanged. You can use the FPREM1 instruction, with a divisor of 2π , to reduce the operand to a reasonable range.

These instructions set the stack fault/ C_1 , precision, underflow, denormalized, and invalid operation flags according to the result of the computation.

11.2.9.3 The FPTAN Instruction

FPTAN computes the tangent of $ST0$ and pushes this value and then it pushes 1.0 onto the stack. Like the FSIN and FCOS instructions, the value of $ST0$ is assumed to be in radians and must be in the range $-2^{63} < ST0 < +2^{63}$. If the value is outside this range, FPTAN sets C_2 to indicate that the conversion did not take place. As with the FSIN, FCOS, and FSINCOS instructions, you can use the FPREM1 instruction to reduce this operand to a reasonable range using a divisor of 2π .

If the argument is invalid (i.e., zero or π radians, which causes a division by zero) the result is undefined and this instruction raises no exceptions. FPTAN will set the stack fault, precision, underflow, denormal, invalid operation, C_2 , and C_1 bits as required by the operation.

11.2.9.4 The FPATAN Instruction

This instruction expects two values on the top of stack. It pops them and computes the following:

$$ST0 = \tan^{-1}(ST1 / ST0)$$

The resulting value is the arctangent of the ratio on the stack expressed in radians. If you have a value you wish to compute the tangent of, use FLD1 to create the appropriate ratio and then execute the FPATAN instruction.

This instruction affects the stack fault/ C_1 , precision, underflow, denormal, and invalid operation bits if a problem occurs during the computation. It sets the C_1 condition code bit if it has to round the result.

11.2.9.5 The FYL2X Instruction

This instruction expects two operands on the FPU stack: y is found in $ST1$ and x is found in $ST0$. This function computes:

$$ST0 = ST1 * \log_2(ST0)$$

This instruction has no operands (to the instruction itself). The instruction uses the following syntax:

```
fy12x( );
```

Note that this instruction computes the base two logarithm. Of course, it is a trivial matter to compute the log of any other base by multiplying by the appropriate constant.

11.2.9.6 The FYL2XP1 Instruction

This instruction expects two operands on the FPU stack: y is found in $ST1$ and x is found in $ST0$. This function computes:

$$ST0 = ST1 * \log_2(ST0 + 1.0)$$

The syntax for this instruction is

```
fy12xp1();
```

Otherwise, the instruction is identical to FYL2X.

11.2.10 Miscellaneous instructions

The FPU includes several additional instructions which control the FPU, synchronize operations, and let you test or set various status bits. These instructions include FINIT/FNINIT, FLDCW, FSTCW, FCLEX/FNCLEX, and FSTSW.

11.2.10.1 The FINIT and FNINIT Instructions

The FINIT instruction initializes the FPU for proper operation. Your applications should execute this instruction before executing any other FPU instructions. This instruction initializes the control register to 37Fh (see “The FPU Control Register” on page 592), the status register to zero (see “The FPU Status Register” on page 595) and the tag word to 0FFFFh. The other registers are unaffected. Examples:

```
FINIT();
FNINIT();
```

The difference between FINIT and FNINIT is that FINIT first checks for any pending floating point exceptions before initializing the FPU; FNINIT does not.

11.2.10.2 The FLDCW and FSTCW Instructions

The FLDCW and FSTCW instructions require a single 16 bit memory operand:

```
fldcw( mem_16 );
fstcw( mem_16 );
```

These two instructions load the control register (see “The FPU Control Register” on page 592) from a memory location (FLDCW) or store the control word to a 16 bit memory location (FSTCW).

When using the FLDCW instruction to turn on one of the exceptions, if the corresponding exception flag is set when you enable that exception, the FPU will generate an immediate interrupt before the CPU executes the next instruction. Therefore, you should use the FCLEX instruction to clear any pending interrupts before changing the FPU exception enable bits.

11.2.10.3 The FCLEX and FNCLEX Instructions

The FCLEX and FNCLEX instructions clear all exception bits the stack fault bit, and the busy flag in the FPU status register (see “The FPU Status Register” on page 595). Examples:

```
fclex();
fnclex();
```

The difference between these instructions is the same as FINIT and FNINIT.

11.2.10.4 The FSTSW and FNSTSW Instructions

```
fstsw( ax )
fnstsw( ax )
fstsw( mem_16 )
fnstsw( mem_16 )
```

These instructions store the FPU status register (see “The FPU Status Register” on page 595) into a 16 bit memory location or the AX register. These instructions are unusual in the sense that they can copy an FPU value into one of the 80x86 general purpose registers (specifically, AX). Of course, the whole purpose behind allowing the transfer of the status register into AX is to allow the CPU to easily test the condition code register with the SAHF instruction. The difference between FSTSW and FNSTSW is the same as for FCLEX and FNCLEX.

11.2.11 Integer Operations

The 80x87 FPUs provide special instructions that combine integer to extended precision conversion along with various arithmetic and comparison operations. These instructions are the following:

```
fiadd( int_16_32 )
fisub( int_16_32 )
fisubr( int_16_32 )
fimul( int_16_32 )
fidiv( int_16_32 )
fidivr( int_16_32 )

ficom( int_16_32 )
ficomp( int_16_32 )
```

These instructions convert their 16 or 32 bit integer operands to an 80 bit extended precision floating point value and then use this value as the source operand for the specified operation. These instructions use ST0 as the destination operand.

11.3 Converting Floating Point Expressions to Assembly Language

Because the FPU register organization is different than the 80x86 integer register set, translating arithmetic expressions involving floating point operands is a little different than the techniques for translating integer expressions. Therefore, it makes sense to spend some time discussing how to manually translate floating point expressions into assembly language.

In one respect, it's actually easier to translate floating point expressions into assembly language. The stack architecture of the Intel FPU eases the translation of arithmetic expressions into assembly language. If you've ever used a Hewlett-Packard calculator, you'll be right at home on the FPU because, like the HP calculator, the FPU uses *reverse polish notation*, or *RPN*, for arithmetic calculations. Once you get used to using RPN, it's actually a bit more convenient for translating expressions because you don't have to worry about allocating temporary variables - they always wind up on the FPU stack.

RPN, as opposed to standard *infix notation*, places the operands before the operator. The following examples give some simple examples of infix notation and the corresponding RPN notation:

| infix notation | RPN notation |
|----------------|--------------|
| 5 + 6 | 5 6 + |
| 7 - 2 | 7 2 - |
| x * y | x y * |
| a / b | a b / |

An RPN expression like “5 6 +” says “push five onto the stack, push six onto the stack, then pop the value off the top of stack (six) and add it to the new top of stack.” Sound familiar? This is exactly what the FLD and FADD instructions do. In fact, you can calculate this using the following code:

```
fld( 5.0 );
fld( 6.0 );
fadd();      // 11.0 is now on the top of the FPU stack.
```

As you can see, RPN is a convenient notation because it’s very easy to translate this code into FPU instructions.

One advantage to RPN (or *postfix notation*) is that it doesn’t require any parentheses. The following examples demonstrate some slightly more complex infix to postfix conversions:

| infix notation | postfix notation |
|---------------------|------------------|
| $(x + y) * 2$ | $x y + 2 *$ |
| $x * 2 - (a + b)$ | $x 2 * a b + -$ |
| $(a + b) * (c + d)$ | $a b + c d + *$ |

The postfix expression “ $x y + 2 *$ ” says “push x , then push y ; next, add those values on the stack (producing $X+Y$ on the stack). Next, push 2 and then multiply the two values (two and $X+Y$) on the stack to produce two times the quantity $X+Y$.” Once again, we can translate these postfix expressions directly into assembly language. The following code demonstrates the conversion for each of the above expressions:

```
//      x y + 2 *

      fld( x );
      fld( y );
      fadd();
      fld( 2.0 );
      fmul();

//      x 2 * a b + -

      fld( x );
      fld( 2.0 );
      fmul();
      fld( a );
      fld( b );
      fadd();
      fsub();

//      a b + c d + *

      fld( a );
      fld( b );
      fadd();
      fld( c );
      fld( d );
      fadd();
      fmul();
```

11.3.1 Converting Arithmetic Expressions to Postfix Notation

Since the process of translating arithmetic expressions into assembly language involves postfix (RPN) notation, converting arithmetic expressions into postfix notation seems like the right place to start. This section will concentrate on that conversion.

For simple expressions, those involving two operands and a single expression, the translation is trivial. Simply move the operator from the infix position to the postfix position (that is, move the operator from

inbetween the operands to after the second operand). For example, “5 + 6” becomes “5 6 +”. Other than separating your operands so you don’t confuse them (i.e., is it “5” and “6” or “56”?) there isn’t much to converting simple infix expressions into postfix notation.

For complex expressions, the idea is to convert the simple sub-expressions into postfix notation and then treat each converted subexpression as a single operand in the remaining expression. The following discussion will surround completed conversions in square brackets so it is easy to see which text needs to be treated as a single operand in the conversion.

As for integer expression conversion, the best place to start is in the inner-most parenthetical sub-expression and then work your way outward considering precedence, associativity, and other parenthetical sub-expressions. As a concrete working example, consider the following expression:

$$x = ((y-z)*a) - (a + b * c) / 3.14159$$

A possible first translation is to convert the subexpression “(y-z)” into postfix notation. This is accomplished as follows:

$$x = ([y z -] * a) - (a + b * c) / 3.14159$$

Square brackets surround the converted postfix code just to separate it from the infix code. These exist only to make the partial translations more readable. Remember, for the purposes of conversion we will treat the text inside the square brackets as a single operand. Therefore, you would treat “[y z -]” as though it were a single variable name or constant.

The next step is to translate the subexpression “([y z -] * a)” into postfix form. This yields the following:

$$x = [y z - a *] - (a + b * c) / 3.14159$$

Next, we work on the parenthetical expression “(a + b * c).” Since multiplication has higher precedence than addition, we convert “b*c” first:

$$x = [y z - a *] - (a + [b c *]) / 3.14159$$

After converting “b*c” we finish the parenthetical expression:

$$x = [y z - a *] - [a b c * +] / 3.14159$$

This leaves only two infix operators: subtraction and division. Since division has the higher precedence, we’ll convert that first:

$$x = [y z - a *] - [a b c * + 3.14159 /]$$

Finally, we convert the entire expression into postfix notation by dealing with the last infix operation, subtraction:

$$x = [y z - a *] [a b c * + 3.14159 /] -$$

Removing the square brackets to give us true postfix notation yields the following RPN expression:

$$x = y z - a * a b c * + 3.14159 / -$$

Here is another example of an infix to postfix conversion:

$$a = (x * y - z + t) / 2.0$$

Step 1: Work inside the parentheses. Since multiplication has the highest precedence, convert that first:

$$a = ([x y *] - z + t) / 2.0$$

Step 2: Still working inside the parentheses, we note that addition and subtraction have the same precedence, so we rely upon associativity to determine what to do next. These operators are left associative, so we must translate the expressions in a left to right order. This means translate the subtraction operator first:

$$a = ([x y * z -] + t) / 2.0$$

Step 3: Now translate the addition operator inside the parentheses. Since this finishes the parenthetical operators, we can drop the parentheses:

$$a = [x y * z - t +] / 2.0$$

Step 4: Translate the final infix operator (division). This yields the following:

$$a = [x y * z - t + 2.0 /]$$

Step 5: Drop the square brackets and we're done:

$$a = x y * z - t + 2.0 /$$

11.3.2 Converting Postfix Notation to Assembly Language

Once you've translated an arithmetic expression into postfix notation, finishing the conversion to assembly language is especially easy. All you have to do is issue an FLD instruction whenever you encounter an operand and issue an appropriate arithmetic instruction when you encounter an operator. This section will use the completed examples from the previous section to demonstrate how little there is to this process.

$$x = y z - a * a b c * + 3.14159 / -$$

- Step 1: Convert y to FLD(y);
- Step 2: Convert z to FLD(z);
- Step 3: Convert “-” to FSUB();
- Step 4: Convert a to FLD(a);
- Step 5: Convert “*” to FMUL();
- Steps 6-n: Continuing in a left-to-right fashion, generate the following code for the expression:

```
fld( y );
fld( z );
fsub();
fld( a );
fmul();
fld( a );
fld( b );
fld( c );
fmul();
fadd();
fldpi();      // Loads pi (3.14159)
fdiv();
fsub();

fstp( x );    // Store result away into x.
```

Here's the translation for the second example in the previous section:

$$a = x y * z - t + 2.0 /$$

```
fld( x );
```

```

fld( y );
fmul();
fld( z );
fsub();
fld( t );
fadd();
fld( 2.0 );
fdiv();

fstp( a );    // Store result away into a.

```

As you can see, the translation is fairly trivial once you've converted the infix notation to postfix notation. Also note that, unlike integer expression conversion, you don't need any explicit temporaries. It turns out that the FPU stack provides the temporaries for you³. For these reasons, conversion of floating point expressions into assembly language is actually easier than converting integer expressions.

11.3.3 Mixed Integer and Floating Point Arithmetic

Throughout the previous sections on floating point arithmetic an unstated assumption was made: all operands in the expressions were floating point variables or constants. In the real world, you'll often need to mix integer and floating point operands in the same expression. Thanks to the FILD instruction, this is a trivial exercise.

Of course, the FPU cannot operate on integer operands. That is, you cannot push an integer operand (in integer format) onto the FPU stack and add this integer to a floating point value that is also on the stack. Instead, you use the FILD instruction to load and translate the integer value; this winds up pushing the floating point equivalent of the integer onto the FPU stack. Once the value is converted to a floating point number, you continue the calculation using the standard real arithmetic operations.

Embedding a floating point value in an integer expression is a little more problematic. In this case you must convert the floating point value to an integer value for use in the integer expression. To do this, you must use the FIST instruction. FIST converts the floating point value on the top of stack into an integer value according to the setting of the rounding bits in the floating point control register (See "The FPU Control Register" on page 592). By default, FIST will round the floating point value to the nearest integer before storing the value into memory; if you want to use the more common fraction truncation mode, you will need to change the value in the FPU control register. You compute the integer expression using the techniques from the previous chapter (see "Complex Expressions" on page 579). The FPU participates only to the point of converting the floating point value to an integer.

```

static
intVal1 : uns32 := 1;
intVal2 : uns32 := 2;
realVal : real64;
.
.
.
fld( intVal1 );
fld( intVal2 );
fadd();
fstp( realVal );
stdout.put( "realVal = ", realVal, nl );

```

3. Assuming, of course, that your calculations aren't so complex that you exceed the eight-element limitation of the FPU stack.

11.4 HLA Standard Library Support for Floating Point Arithmetic

The HLA Standard Library provides several routines that support the use of real number on the FPU. In Volume One you saw, with one exception, how the standard input and output routines operate. This section will not repeat that discussion, see “HLA Support for Floating Point Values” on page 83 for more details. One input function that Volume One only mentioned briefly was the *stdin.getf* function. This section will elaborate on that function. The HLA Standard Library also includes the “math.hhf” module that provides several mathematical functions that the FPU doesn’t directly support. This section will discuss those functions, as well.

11.4.1 The *stdin.getf* and *fileio.getf* Functions

The *stdin.getf* function reads a floating point value from the standard input device. It leaves the converted value in ST0 (i.e., on the top of the floating point stack). The only reason Chapter Two did not discuss this function thoroughly was because you hadn’t seen the FPU and FPU registers at that point.

The *stdin.getf* function accepts the same inputs that “*stdin.get*(fp_variable);” would except. The only difference between the two is where these functions store the floating point value.

As you’d probably surmise, there is a corresponding *fileio.getf* function as well. This function reads the floating point value from the file whose file handle is the single parameter in this function call. It, too, leaves the converted result on the top of the FPU stack.

11.4.2 Trigonometric Functions in the HLA Math Library

The FPU provides a small handful of trigonometric functions. It does not, however, support the full range of trig functions. The HLA MATH.HHF module fills in most of the missing functions. The trigonometric functions that HLA provides include

- ACOS(arc cosine)
- ACOT(arc cotangent)
- ACSC(arc cosecant)
- ASEC(arc secant)
- ASIN(arc sin)
- COT(cotangent)
- CSC(cosecant)
- SEC(secant)

The HLA Standard Library actually provides five different routines you can call for each of these functions. For example, the prototypes for the first four COT (cotangent) routines are:

```
procedure cot32( r32: real32 );
procedure cot64( r64: real64 );
procedure cot80( r80: real80 );
procedure _cot();
```

The first three routines push their parameter onto the FPU stack and compute the cotangent of the result. The fourth routine above (*_cot*) computes the cotangent of the value in ST0.

The fifth routine is actually an overloaded procedure that calls one of the four routines above depending on the parameter. This call uses the following syntax:

```
cot();           // Calls _cot() to compute cot(ST0).
cot( r32 );     // Calls cot32 to compute the cotangent of r32.
cot( r64 );     // Calls cot64 to compute the cotangent of r64.
cot( r80 );     // Calls cot80 to compute the cotangent of r80.
```

Using this fifth form is probably preferable since it is much more convenient. Note that there is no efficiency loss when you used *cot* rather than one of the other cotangent routines. HLA actually translates this statement directly into one of the other calls.

The HLA trigonometric functions that require an angle as a parameter expect that angle to be expressed in radians, not degrees. Keep in mind that some of these functions produce undefined results for certain input values. If you've enabled exceptions on the FPU, these functions will raise the appropriate FPU exception if an error occurs.

11.4.3 Exponential and Logarithmic Functions in the HLA Math Library

The HLA MATH.HHF module provides several exponential and logarithmic functions in addition to the trigonometric functions. Like the trig functions, the exponential and logarithmic functions provide five different interfaces to each function depending on the size and location of the parameter. The functions that MATH.HHF supports are

- TwoToX (raise 2.0 to the specified power).
- TenToX (raise 10.0 to the specified power).
- exp (raises e [2.718281828...] to the specified power).
- YtoX (raises first parameter to the power specified by the second parameter).
- log (computes base 10 logarithm).
- ln (computes base e logarithm).

Except for the *YtoX* function, all these functions provide the same sort of interface as the *cot* function mentioned in the previous section. For example, the *exp* function provides the following prototypes:

```
procedure exp32( r32: real32 );
procedure exp64( r64: real64 );
procedure exp80( r80: real80 );
procedure _exp();
```

The *exp* function, by itself, automatically calls one of the above functions depending on the parameter type (and presence of a parameter):

```
exp(); // Calls _exp() to compute exp(ST0).
exp( r32 ); // Calls exp32 to compute the e**r32.
exp( r64 ); // Calls exp64 to compute the e**r64.
exp( r80 ); // Calls exp80 to compute the e**r80.
```

The lone exception to the above is the *YtoX* function. *YtoX* has its own rules because it has two parameters rather than one (Y and X). *YtoX* provides the following function prototypes:

```
procedure YtoX32( y: real32; x: real32 );
procedure YtoX64( y: real64; x: real64 );
procedure YtoX80( y: real80; x: real80 );
procedure _YtoX();
```

The *_YtoX* function computes $ST1^{**}ST0$ (i.e., $ST1$ raised to the $ST0$ power).

The *YtoX* function provides the following interface:

```
YtoX(); // Calls _YtoX() to compute exp(ST0).
YtoX( y32, x32 ); // Calls YtoX32 to compute y32**x32.
YtoX( y64, x64 ); // Calls YtoX64 to compute y64**x64.
YtoX( y80, x80 ); // Calls YtoX80 to compute y80**x80.
```

11.5 Sample Program

This chapter presents a simple “Reverse Polish Notation” calculator that demonstrates the use of the 80x86 FPU. In addition to demonstrating the use of the FPU, this sample program also introduces a few new routines from the HLA Standard Library, specifically the *arg.c*, *arg.v*, and *conv.strToFlt* routines.

The HLA Standard Library conversions module (“conv.hhf”) contains dozens of procedures that translate data between various formats. A large percentage of these routines convert data between some internal numeric form and a corresponding string format. The *conv.strToFlt* routine, as its name suggests, converts string data to a floating point value. The prototype for this function is the following:

```
procedure conv.strToFlt( s:string; index:dword );
```

The first parameter is the string containing the textual representation of the floating point value. The second parameter contains an index into the string where the floating point text actually begins (usually the *index* parameter is zero if the string contains nothing but the floating point text). The *conv.strToFlt* procedure will attempt to convert the specified string to a floating point number. If there is a problem, this function will raise an appropriate exception (e.g., *ex.ConversionError*). In fact, the HLA *stdin* routines that read floating point values from the user actually read string data and call this same procedure to convert that data to a floating point value; hence, you should protect this procedure call with a TRY..ENDTRY statement exactly the same way you protect a call to *stdin.get* or *stdin.getf*. If this routine is successful, it leaves the converted floating point value on the top of the FPU stack.

The HLA Standard Library contains numerous other procedures that convert textual data to the corresponding internal format. Examples include *conv.strToi8*, *conv.strToi16*, *conv.strToi32*, *conv.strToi64*, and more. See the HLA Standard Library documentation for more details.

This sample program also uses the *arg.c* and *arg.v* routines from the HLA Standard Library’s command line arguments module (“args.hhf”). These functions provide access to the text following the program name when you run a program from the Windows command line prompt. This calculator program, for example, expects the user to supply the desired calculation on the command line immediately after the program name. For example to add the two values 18 and 22 together, you’d specify the following Windows command line:

```
rpncalc 18 22 +
```

The text “18 22 +” is an example of three *command line parameters*. Programs often use command line parameters to communicate filenames and other data to the application. For example, the HLA compiler uses command line parameters to pass the names of the source files to the compiler. The *rpncalc* program uses the command line to pass the RPN expression to the calculator.

The *arg.c* function (“argument count”) returns the number of parameters on the command line. This function returns the count in the EAX register. It does not have any parameters. In general, you can probably assume that the maximum possible number of command line arguments is between 64 and 128. Note that Windows counts the program’s name on the command line in this argument count. Therefore, this value will always be one or greater. If *arg.c* returns one, then there are no extra command line parameters; the single item is the program’s name.

A program that expects at least one command line parameter should always call *arg.c* and verify that it returns the value two or greater. Programs that process command line parameters typically execute a loop of some sort that executes the number of times specified by *arg.c*’s return value. Of course, when you use *arg.c*’s return value for this purpose, don’t forget to subtract one from the return result to account for the program’s name (unless you are treating the program name as one more parameter).

The *arg.v* function returns a string containing one of the program’s command line arguments. This function has the following prototype:

```
procedure arg.v( index:uns32 );
```

The *index* parameter specifies which command line parameter you wish to retrieve. The value zero returns a string containing the program’s name. The value one returns the first command line parameter following the program’s name. The value two returns a string containing the second command line parameter

following the program's name. Etc. The value you provide as a parameter to this function must fall in the range $0..arg.c()-1$ or *arg.v* will raise an exception.

The *arg.v* procedure allocates storage for the string it returns on the heap by calling *stralloc*. It returns a pointer to the allocated string in the EAX register. Don't forget to call *strfree* to return the storage to the system after you are done processing the command line parameter.

Well, without further ado, here is the RPN calculator program that uses the aforementioned functions.

```
// This sample program demonstrates how to use
// the FPU to create a simple RPN calculator.
// This program reads a string from the user
// and "parses" that string to figure out the
// calculation the user is requesting. This
// program assumes that any item beginning
// with a numeric digit is a numeric operand
// to push onto the FPU stack and all other
// items are operators.
//
// Example of typical user input:
//
//   calc 123.45 67.89 +
//
// The program responds by printing
//
//   Result = 1.9134000000000000e+2
//

Program 11.1 A Floating Point Calculator Program

11.6 Putting It All Together

Between the FPU and the HLA Standard Library, floating point arithmetic is actually quite simple. In this chapter you learned about the floating point instruction set and you learned how to convert arithmetic expressions involving real arithmetic into a sequence of floating point instructions. This chapter also presented several transcendental functions that the HLA Standard Library provides. Armed with the information from this chapter, you should be able to deal with floating point expressions just as easily as integer expressions.

Calculation Via Table Lookups

Chapter Twelve

12.1 Chapter Overview

This chapter discusses arithmetic computation via table lookup. By the conclusion of this chapter you should be able to use table lookups to quickly compute complex functions. You will also learn how to construct these table programmatically.

12.2 Tables

The term “table” has different meanings to different programmers. To most assembly language programmers, a table is nothing more than an array that is initialized with some data. The assembly language programmer often uses tables to compute complex or otherwise slow functions. Many very high level languages (e.g., SNOBOL4 and Icon) directly support a table data type. Tables in these languages are essentially arrays whose elements you can access with a non-integer index (e.g., floating point, string, or any other data type). HLA provides a table module that lets you index an array using a string. However, in this chapter we will adopt the assembly language programmer’s view of tables.

A table is an array containing preinitialized values that do not change during the execution of the program. A table can be compared to an array in the same way an integer constant can be compared to an integer variable. In assembly language, you can use tables for a variety of purposes: computing functions, controlling program flow, or simply “looking things up”. In general, tables provide a fast mechanism for performing some operation at the expense of some space in your program (the extra space holds the tabular data). In the following sections we’ll explore some of the many possible uses of tables in an assembly language program.

Note: since tables typically contain preinitialized data that does not change during program execution, the READONLY section is a good place to declare your table objects.

12.2.1 Function Computation via Table Look-up

Tables can do all kinds of things in assembly language. In HLLs, like Pascal, it’s real easy to create a formula which computes some value. A simple looking arithmetic expression is equivalent to a considerable amount of 80x86 assembly language code. Assembly language programmers tend to compute many values via table look up rather than through the execution of some function. This has the advantage of being easier, and often more efficient as well. Consider the following Pascal statement:

```
if (character >= 'a') and (character <= 'z') then character := chr(ord(character) - 32);
```

This Pascal if statement converts the character variable character from lower case to upper case if character is in the range ‘a’..‘z’. The HLA code that does the same thing is

```
mov( character, al );
if( al in 'a'..'z' ) then

    and( $5f, al );        // Same as SUB( 32, al ) in this code.

endif;
mov( al, character );
```

Note that HLA’s high level IF statement translates into four machine instructions in this particular example. Hence, this code requires a total of seven machine instructions.

Had you buried this code in a nested loop, you’d be hard pressed to improve the speed of this code without using a table look up. Using a table look up, however, allows you to reduce this sequence of instructions to just four instructions:

```

mov( character, al );
lea( ebx, CnvrtLower );
xlat
mov( al, character );

```

You're probably wondering how this code works and what is this new instruction, XLAT? The XLAT, or *translate*, instruction does the following:

```

mov( [ebx+al*1], al );

```

That is, it uses the current value of the AL register as an index into the array whose base address is contained in EBX. It fetches the byte at that index in the array and copies that byte into the AL register. Intel calls this the translate instruction because programmers typically use it to translate characters from one form to another using a lookup table. That's exactly how we are using it here.

In the previous example, *CnvrtLower* is a 256-byte table which contains the values 0..\$60 at indices 0..\$60, \$41..\$5A at indices \$61..\$7A, and \$7B..\$FF at indices \$7Bh..0FF. Therefore, if AL contains a value in the range 0..\$60, the XLAT instruction returns the value 0..\$60, effectively leaving AL unchanged. However, if AL contains a value in the range \$61..\$7A (the ASCII codes for 'a'..'z') then the XLAT instruction replaces the value in AL with a value in the range \$41..\$5A. \$41..\$5A just happen to be the ASCII codes for 'A'..'Z'. Therefore, if AL originally contains an lower case character (\$61..\$7A), the XLAT instruction replaces the value in AL with a corresponding value in the range \$61..\$7A, effectively converting the original lower case character (\$61..\$7A) to an upper case character (\$41..\$5A). The remaining entries in the table, like entries 0..\$60, simply contain the index into the table of their particular element. Therefore, if AL originally contains a value in the range \$7A..\$FF, the XLAT instruction will return the corresponding table entry that also contains \$7A..\$FF.

As the complexity of the function increases, the performance benefits of the table look up method increase dramatically. While you would almost never use a look up table to convert lower case to upper case, consider what happens if you want to swap cases:

Via computation:

```

mov( character, al );
if( al in 'a'..'z' ) then

    and( $5f, al );

elseif( al in 'A'..'Z' ) then

    or( $20, al );

endif;
mov( al, character );

```

The IF and ELSEIF statements generate four and five actual machine instructions, respectively, so this code is equivalent to 13 actual machine instructions.

The table look up code to compute this same function is:

```

mov( character, al );
lea( ebx, SwapUL );
xlat();
mov( al, character );

```

As you can see, when using a table look up to compute a function only the table changes, the code remains the same.

Table look ups suffer from one major problem – functions computed via table look up have a limited domain. The domain of a function is the set of possible input values (parameters) it will accept. For example, the upper/lower case conversion functions above have the 256-character ASCII character set as their domain.

A function such as SIN or COS accepts the set of real numbers as possible input values. Clearly the domain for SIN and COS is much larger than for the upper/lower case conversion function. If you are going

to do computations via table look up, you must limit the domain of a function to a small set. This is because each element in the domain of a function requires an entry in the look up table. You won't find it very practical to implement a function via table look up whose domain the set of real numbers.

Most look up tables are quite small, usually 10 to 128 entries. Rarely do look up tables grow beyond 1,000 entries. Most programmers don't have the patience to create (and verify the correctness) of a 1,000 entry table.

Another limitation of functions based on look up tables is that the elements in the domain of the function must be fairly contiguous. Table look ups take the input value for a function, use this input value as an index into the table, and return the value at that entry in the table. If you do not pass a function any values other than 0, 100, 1,000, and 10,000 it would seem an ideal candidate for implementation via table look up, its domain consists of only four items. However, the table would actually require 10,001 different elements due to the range of the input values. Therefore, you cannot efficiently create such a function via a table look up. Throughout this section on tables, we'll assume that the domain of the function is a fairly contiguous set of values.

The best functions you can implement via table look ups are those whose domain and range is always 0..255 (or some subset of this range). You can efficiently implement such functions on the 80x86 via the XLAT instruction. The upper/lower case conversion routines presented earlier are good examples of such a function. Any function in this class (those whose domain and range take on the values 0..255) can be computed using the same two instructions: "lea(table, ebx);" and "xlat();" The only thing that ever changes is the look up table.

The XLAT instruction cannot be (conveniently) used to compute a function value once the range or domain of the function takes on values outside 0..255. There are three situations to consider:

- The domain is outside 0..255 but the range is within 0..255,
- The domain is inside 0..255 but the range is outside 0..255, and
- Both the domain and range of the function take on values outside 0..255.

We will consider each of these cases separately.

If the domain of a function is outside 0..255 but the range of the function falls within this set of values, our look up table will require more than 256 entries but we can represent each entry with a single byte. Therefore, the look up table can be an array of bytes. Next to look ups involving the XLAT instruction, functions falling into this class are the most efficient. The following Pascal function invocation,

```
B := Func(X);
```

where *Func* is

```
function Func(X:dword):byte;
```

consists of the following HLA code:

```
mov( X, ebx );
mov( FuncTable[ ebx ], al );
mov( al, B );
```

This code loads the function parameter into EBX, uses this value (in the range 0..??) as an index into the *FuncTable* table, fetches the byte at that location, and stores the result into *B*. Obviously, the table must contain a valid entry for each possible value of *X*. For example, suppose you wanted to map a cursor position on the video screen in the range 0..1999 (there are 2,000 character positions on an 80x25 video display) to its *X* or *Y* coordinate on the screen. You could easily compute the *X* coordinate via the function:

$$X := \text{Posn} \bmod 80$$

and the *Y* coordinate with the formula

$$Y := \text{Posn} \text{ div } 80$$

(where *Posn* is the cursor position on the screen). This can be easily computed using the 80x86 code:

```

mov( Posn, ax );
div( 80, ax );

// X is now in AH, Y is now in AL

```

However, the DIV instruction on the 80x86 is very slow. If you need to do this computation for every character you write to the screen, you will seriously degrade the speed of your video display code. The following code, which realizes these two functions via table look up, would improve the performance of your code considerably:

```

movzx( Posn, ebx );           // Use a plain MOV instr if Posn is uns32
mov( YCoord[ebx], al );      // rather than an uns16 value.
mov( XCoord[ebx], ah );

```

If the domain of a function is within 0..255 but the range is outside this set, the look up table will contain 256 or fewer entries but each entry will require two or more bytes. If both the range and domains of the function are outside 0..255, each entry will require two or more bytes and the table will contain more than 256 entries.

Recall from the chapter on arrays that the formula for indexing into a single dimensional array (of which a table is a special case) is

$$\text{Address} := \text{Base} + \text{index} * \text{size}$$

If elements in the range of the function require two bytes, then the index must be multiplied by two before indexing into the table. Likewise, if each entry requires three, four, or more bytes, the index must be multiplied by the size of each table entry before being used as an index into the table. For example, suppose you have a function, $F(x)$, defined by the following (pseudo) Pascal declaration:

```
function F(x:dword):word;
```

You can easily create this function using the following 80x86 code (and, of course, the appropriate table named F):

```

mov( X, ebx );
mov( F[ebx*2], ax );

```

Any function whose domain is small and mostly contiguous is a good candidate for computation via table look up. In some cases, non-contiguous domains are acceptable as well, as long as the domain can be coerced into an appropriate set of values. Such operations are called conditioning and are the subject of the next section.

12.2.2 Domain Conditioning

Domain conditioning is taking a set of values in the domain of a function and massaging them so that they are more acceptable as inputs to that function. Consider the following function:

$$\sin x = \langle \sin x | x \in [-2\pi, 2\pi] \rangle$$

This says that the (computer) function $\text{SIN}(x)$ is equivalent to the (mathematical) function $\sin x$ where $-2\pi \leq x \leq 2\pi$

As we all know, sine is a circular function which will accept any real valued input. The formula used to compute sine, however, only accept a small set of these values.

This range limitation doesn't present any real problems, by simply computing $\text{SIN}(X \bmod (2*\pi))$ we can compute the sine of any input value. Modifying an input value so that we can easily compute a function is called conditioning the input. In the example above we computed " $X \bmod 2*\pi$ " and used the result as the input to the \sin function. This truncates X to the domain \sin needs without affecting the result. We can apply input conditioning to table look ups as well. In fact, scaling the index to handle word entries is a form of input conditioning. Consider the following Pascal function:

```

function val(x:word):word; begin
  case x of
    0: val := 1;
    1: val := 1;
    2: val := 4;
    3: val := 27;
    4: val := 256;
    otherwise val := 0;
  end;
end;

```

This function computes some value for x in the range 0..4 and it returns zero if x is outside this range. Since x can take on 65,536 different values (being a 16 bit word), creating a table containing 65,536 words where only the first five entries are non-zero seems to be quite wasteful. However, we can still compute this function using a table look up if we use input conditioning. The following assembly language code presents this principle:

```

mov( 0, ax );           // AX = 0, assume X > 4.
movzx( x, ebx );       // Note that H.O. bits of EBX must be zero!
if( bx <= 4 ) then

  mov( val[ ebx*2 ], ax );

endif;

```

This code checks to see if x is outside the range 0..4. If so, it manually sets AX to zero, otherwise it looks up the function value through the *val* table. With input conditioning, you can implement several functions that would otherwise be impractical to do via table look up.

12.2.3 Generating Tables

One big problem with using table look ups is creating the table in the first place. This is particularly true if there are a large number of entries in the table. Figuring out the data to place in the table, then laboriously entering the data, and, finally, checking that data to make sure it is valid, is a very time-staking and boring process. For many tables, there is no way around this process. For other tables there is a better way – use the computer to generate the table for you. An example is probably the best way to describe this. Consider the following modification to the sine function:

$$(\sin x) \times r = \left\langle \frac{(r \times (1000 \times \sin x))}{1000} \right\rangle_{x \in [0, 359]}$$

This states that x is an integer in the range 0..359 and r must be an integer. The computer can easily compute this with the following code:

```

movzx( x, ebx );
mov( Sines[ ebx*2 ], eax ); // Get SIN(X) * 1000
imul( r, eax );           // Note that this extends EAX into EDX.
idiv( 1000, edx:eax );    // Compute (R*(SIN(X)*1000)) / 1000

```

Note that integer multiplication and division are not associative. You cannot remove the multiplication by 1000 and the division by 1000 because they seem to cancel one another out. Furthermore, this code must compute this function in exactly this order. All that we need to complete this function is a table containing 360 different values corresponding to the sine of the angle (in degrees) times 1,000. Entering such a table into an assembly language program containing such values is extremely boring and you'd probably make several mistakes entering and verifying this data. However, you can have the program generate this table for you. Consider the following HLA program:

```
program GenerateSines;
#include( "stdlib.hhf" );

var
  outFile: dword;
  angle:   int32;
  r:      int32;

readonly
  RoundMode: uns16 := $23f;

begin GenerateSines;

  // Open the file:
  mov( fileio.openNew( "sines.hla" ), outFile );

  // Emit the initial part of the declaration to the output file:
  fileio.put
  (
    outFile,
    stdio.tab,
    "sines: int32[360] := " nl,
    stdio.tab, stdio.tab, stdio.tab, "[" nl );

  // Enable rounding control (round to the nearest integer).
  fldcw( RoundMode );

  // Emit the sines table:
  for( mov( 0, angle); angle < 359; inc( angle ) ) do

    // Convert angle in degrees to an angle in radians
    // using "radians := angle * 2.0 * pi / 360.0;"

    fild( angle );
    fld( 2.0 );
    fmul();
    fldpi();
    fmul();
    fld( 360.0 );
    fdiv();

    // Okay, compute the sine of ST0

    fsin();

    // Multiply by 1000 and store the rounded result into
    // the integer variable r.

    fld( 1000.0 );
    fmul();
    fistp( r );

    // Write out the integers eight per line to the source file:
```

```

// Note: if (angle AND %111) is zero, then angle is evenly
// divisible by eight and we should output a newline first.

test( %111, angle );
if( @z ) then

    fileio.put
    (
        outFile,
        nl,
        stdio.tab,
        stdio.tab,
        stdio.tab,
        stdio.tab,
        r:5,
        '\,'
    );

else

    fileio.put( outFile, r:5, '\,' );

endif;

endfor;

// Output sine(359) as a special case (no comma following it).
// Note: this value was computed manually with a calculator.

fileio.put
(
    outFile,
    " -17",
    nl,
    stdio.tab,
    stdio.tab,
    stdio.tab,
    "];",
    nl
);
fileio.close( outFile );

end GenerateSines;

```

Obviously it's much easier to write the HLA program that generated this data than to enter (and verify) this data by hand. Of course, you don't even have to write the table generation program in HLA. If you prefer, you might find it easier to write the program in Pascal/Delphi, C/C++, or some other high level language. Obviously, the program will only execute once, so the performance of the table generation program is not an issue. If it's easier to write the table generation program in a high level language, by all means do so. Note, also, that HLA has a built-in interpreter that allows you to easily create tables without having to use an external program. For more details, see the chapter on macros and the HLA compile-time language.

Once you run your table generation program, all that remains to be done is to cut and paste the table from the file (`sines.hla` in this example) into the program that will actually use the table.

12.3 High Performance Implementation of `cs.rangeChar`

Way back in Chapter Three this volume made the comment that the implementation of the `cs.rangeChar` was not very efficient when generating large character sets (see "Character Set Functions That Build Sets" on page 431). That chapter also mentioned that a table lookup would be a better solution for this function if you generate large character sets. That chapter also promised an table lookup implementation of `cs.rangeChar`. This section fulfills that promise.

Program 12.2 provides a table lookup implementation of this function. To understand how this function works, consider the two tables (*StartRange* and *EndRange*) appearing in this program.

Each element in the *StartRange* table is a character set whose binary representation contains all one bits from bit position zero through the index into the table. That is, element zero contains a single '1' bit in bit position zero; element one contains one bits in bit positions zero and one; element two contains one bits in bit positions zero, one, and two; etc.

Each element of the *EndRange* table contains one bits from the bit position specified by the index into the table through to bit position 127. Therefore, element zero of this array contains all one bits from positions zero through 127; element one of this array contains a zero in bit position zero and ones in bit positions one through 127; element two of this array contains zeros in bit positions zero and one and it contains ones in bit positions two through 127; etc.

The *fastRangeChar* function builds a character set containing all the characters between two characters specified as parameters. The calling sequence for this function is

```
fastRangeChar( LowBoundChar, HighBoundChar, CsetVariable );
```

This function constructs the character set "{ LowBoundChar..HighBoundChar }" and stores this character set into *CsetVariable*.

As you may recall from the discussion of *cs.rangeChar*'s low-level implementation, it constructed the character set by running a FOR loop from the *LowBoundChar* through to the *HighBoundChar* and set the corresponding bit in the character set on each iteration of the loop. So to build the character set {'a'..'z'} the loop would have to execute 26 times. The *fastRangeChar* function avoids this iteration by construction a set containing all elements from #0 to *HighBoundChar* and intersecting this set with a second character set containing all the characters from *LowBoundChar* to #127. The *fastRangeChar* function doesn't actually build these two sets, of course, it uses *HighBoundChar* and *LowBoundChar* as indices into the *StartRange* and *EndRange* tables, respectively. The intersection of these two table elements computes the desired result set. As you'll see by looking at *fastRangeChar*, this function computes the intersection of these two sets on the fly by using the AND instruction. Without further ado, here's the program:

```
program csRangeChar;
#include( "stdlib.hhf" )

static

Program 12.2 Table Lookup Implementation of cs.rangeChar

Naturally, the *StartRange* and *EndRange* tables were not hand-generated. An HLA program generated these two tables (with a combined 512 elements). Program 12.3 is the program that generated these tables.

```

program GenerateRangeChar;
#include( "stdlib.hhf" );

var
    outFile: dword;

begin GenerateRangeChar;

    // Open the file:
    mov( fileio.openNew( "rangeCharCset.hla" ), outFile );

    // Emit the initial part of the declaration to the output file:

    fileio.put
    (
        outFile,
        stdio.tab,
        "StartRange: cset[128] := " nl,
        stdio.tab, stdio.tab, stdio.tab, "[" nl,
        stdio.tab, stdio.tab, stdio.tab, stdio.tab, "{#0}," nl // element zero
    );
    for( mov( 1, ecx ); ecx < 127; inc( ecx ) ) do

        fileio.put
        (
            outFile,
            stdio.tab, stdio.tab, stdio.tab, stdio.tab,
            "{#0..#",
            (type uns32 ecx),
            "}," nl
        );
    endfor;
    fileio.put
    (
        outFile,
        stdio.tab, stdio.tab, stdio.tab, stdio.tab,
        "{#0..#127}" nl,
        stdio.tab, stdio.tab, stdio.tab, "]" nl
    );

```

```

);

// Now emit the second table to the file:

fileio.put
(
    outFile,
    nl,
    stdio.tab,
    "EndRange: cset[128] := " nl,
    stdio.tab, stdio.tab, stdio.tab, "[" nl
);
for( mov( 0, ecx ); ecx < 127; inc( ecx ) ) do

    fileio.put
    (
        outFile,
        stdio.tab, stdio.tab, stdio.tab, stdio.tab,
        "{#",
        (type uns32 ecx),
        "..#127}," nl
    );

endfor;
fileio.put
(

    stdio.tab, stdio.tab, stdio.tab, stdio.tab, "{#127}" nl,
    stdio.tab, stdio.tab, stdio.tab, "]" nl nl
);
fileio.close( outFile );

end GenerateRangeChar;

Program 12.3 Table Generation Program for the csRangeChar Program

Questions, Projects, and Labs

Chapter Thirteen

13.1 Questions

- 1) What is the purpose of the INTO instruction?
- 2) What was the main purpose for the INTMUL instruction in this volume? What was it introduced before the chapter on integer arithmetic?
- 3) Describe how to declare byte variables. Give several examples. What would you normally use byte variables for in a program?
- 4) Describe how to declare word variables. Give several examples. Describe what you would use them for in a program.
- 5) Repeat question 4 for double word variables.
- 6) What are qword and tbyte objects?
- 7) How does HLA differentiate string and character constants?
- 8) Explain the purpose of the TYPE section. Give several examples of its use.
- 9) What is a pointer variable?
- 10) How do you declare pointer variables in a program?
- 11) How do you access the object pointed at by a pointer. Give an example using 80x86 instructions.
- 12) What is the difference between a CONST object and a VAL object?
- 13) What is the “?” statement used for?
- 14) What is an enumerated data type?
- 15) Given the two literal string constants “Hello “ and “World”, provide two fundamentally different ways to concatenate these string literal constants into a single string within an HLA source file.
- 16) What is the difference between a STRING constant and a TEXT constant?
- 17) What is a pointer constant? What is the limitation on a pointer constant?
- 18) What is a pointer expression? What are the limitations on pointer expressions?
- 19) What is a dangling pointer? How do you avoid the problem of dangling pointers in your programs?
- 20) What is a memory leak? What causes it? How can you avoid memory leaks in your programs?
- 21) What is likely to happen if you use an uninitialized pointer?
- 22) What is a composite data type?
- 23) If you have a variable of type STRING, how many bytes in memory does this variable consume? What value(s) appear in this variable?
- 24) What is the data format for HLA string data?
- 25) What is the difference between a length-prefixed and a zero terminated string? What are the advantages and disadvantages of each?
- 26) Are HLA string zero terminated or length prefixed?
- 27) How do you directly obtain the length of an HLA string (i.e., w/o using the str.length function)?
- 28) What are the two pieces of length data maintained for each HLA string? What is the difference between them?
- 29) Why would you want to use the *str.cpy* routine (which is slow) rather than simply copying the pointer data from one string to another (which is fast)?

- 30) Many string functions contain the prefix “a_” in their name (e.g., str.cpy vs. str.a_cpy). What is the difference between the functions containing the “a_” prefix and those that do not contain this prefix?
- 31) Explain how to access the individual characters in an HLA string variable.
- 32) What is the purpose of string concatenation?
- 33) What is the difference between the str.cat and str.insert? Which is the more general of the two routines? How could you use the more general routine to simulate the other?
- 34) How can you perform a case-insensitive string comparison using the HLA Standard Library Strings module?
- 35) Explain how to convert an integer to its string representation using functions from the HLA Standard Library’s String module.
- 36) How does HLA implement character sets? How many bytes does a character set variable consume?
- 37) If *CST* is a character set constant, what does “-CST” produce?
- 38) Explain the purpose of the character classification routines in the HLA Standard Library chars.hhf module.
- 39) How do you compute the intersection, union, and difference of two character set constants in an HLA constant expression?
- 40) How do you compute the intersection, union, and difference of two character set variables in an HLA program at run-time?
- 41) What is the difference between a subset and a proper subset?
- 42) Explain how you can use a character set to validate user input to a program.
- 43) How do you declare arrays in assembly language? Give the code for the following arrays:
 - a) A two dimensional 4x4 array of bytes
 - b) An array containing 128 double words
 - c) An array containing 16 words
 - d) A 4x5x6 three dimensional array of words
- 44) Describe how you would access a single element of each of the above arrays. Provide the necessary formulae and 80x86 code to access said element (assume variable *I* is the index into single dimension arrays, *I* & *J* provide the index into two dimension arrays, and *I*, *J*, & *K* provide the index into the three dimensional array). Assume row major ordering, where appropriate.
- 45) Repeat question (44) using column major ordering.
- 46) Explain the difference between row major and column major array ordering.
- 47) Suppose you have a two-dimensional array of bytes whose values you want to initialize as follows:

$$\begin{bmatrix} 0 & 1 & 2 \\ 3 & 4 & 5 \\ 6 & 7 & 8 \end{bmatrix}$$

Provide the variable declaration to accomplish this. Note: Do not use 80x86 machine instructions to initialize the array. Initialize the array in your *STATIC* section.

Questions (48)-(52) use these HLA declarations:

type

```
Date: Record
      Month:int8;
      Day:int8;
      Year:int8;
endrecord;
```

```

Time= record
    Hours:int8;
    Minutes:int8;
    Seconds:int8;
endrecord;

VideoTape: record
    Title:string;
    ReleaseDate:Date;
    Price:Real32;
    Length: Time;
    Rating:char;
endrecord;

var
    TapeLibrary : VideoTape[128];

```

- 48) Suppose EBX points at an object of type VideoTape. What is the instruction that properly loads the *Rating* field into AL?
- 49) Provide an example of a STATIC *VideoTape* variable initialized with an appropriate constant (should be legal in the HLA STATIC section).
- 50) This data structure (Date) suffers from the good old “Y2K” bug. Provide a correction for this problem (See Chapter Six in this volume if you have any questions about “Y2K” or the solution to this problem).
- 51) A one-character rating is probably not sufficient since there are ratings like “PG” and “PG-13” on movies. On the other hand, the longest rating string is five characters, so a string variable (minimum of 16 characters between the pointer and the resident string data) is probably overkill. Describe a better way to handle this using a one-byte variable/data type.
- 52) Provide a variable declaration for a pointer to a *VideoTape* object.
- 53) Provide an example of an HLA array constant containing eight *uns8* values.
- 54) How many bytes of memory does a 4x5 array of *dwords* require?
- 55) What is the difference between an array of characters and a string?
- 56) What is the difference between the indexes you would use to access an HLA array constant and the indexes you would use to access an array element in memory at run-time?
- 57) Why is the bubble sort generally a poor choice of algorithm when sorting data? Under what circumstances is the bubble sort a good choice?
- 58) What is a dynamically allocated array? How do you create one?
- 59) Explain the use of the @size compile-time function when indexing into an array at run-time.
- 60)
- 61) How does HLA store the fields of a record in memory?
- 62) Provide an example of a *student* record constant (see “Records” on page 465 for a description of the *student* record).
- 63) If you have an array of records and you want to compute an index into the array, describe how HLA can compute the size of each element of the array (i.e., the record size) for you.
- 64) Given the following declaration, provide the code to access element a[i].b[j] of this array:

```

type
    bType: uns32[16];
    rType:
        record
            i:int32;

```

```

    u:uns32;
    b:bType;
endrecord;

```

```

pType:pointer to rType

```

```

static
  a:rType[32];

```

- 65) Given the definitions in question (64), explain how you would access the object the j^{th} element of the b field of the record where p points in assembly language (“ $p \rightarrow b[j]$ ” using C syntax, “ $p^{\wedge}.b[j]$ ” for Pascal programmers).
- 66) Explain how to set the offset of the first field in a record. Give an example of why you would want to do this.
- 67) Explain how to align a particular field in a record to a given boundary.
- 68) Describe how to pad a record so that its size is an even multiple of some number of bytes.
- 69) What is the difference between a record and a union?
- 70) What is an anonymous union? What would you use it for?
- 71) What is a variant type? What data structure(s) would you use to create a variant object?
- 72) What is a namespace? What is its purpose?
- 73) What is the difference between a namespace and a record?
- 74) What type of declaration may not appear in a namespace?
- 75) What is namespace pollution? How do namespaces solve this problem?
- 76) What is the data structure for an HLA Standard Library DATE data type?
- 77) What is the data structure for an HLA Standard Library TIME data type?
- 78) What is the rule for computing whether a given year is a leap year?
- 79) What Standard Library routines would you call to get the current date and current time?
- 80) What is a Julian Day Number? Why are such dates interesting to us?
- 81) What routines does the HLA Standard Library provide to perform date arithmetic?
- 82) What is the difference between a random access file and a sequential file?
- 83) What is the difference between a binary and a text file?
- 84) What is the difference between a variable-length record and a fixed length record? Which would you use in a random access file? Why?
- 85) What is an ISAM file? What is the purpose of an ISAM list?
- 86) Explain how to copy one file to another using the HLA *fileio* routines.
- 87) How does computing the file size help you determine the number of records in a random access file?
- 88) What is the syntax for an HLA procedure declaration?
- 89) What is the syntax for an HLA procedure invocation (call)?
- 90) Why is it important to save the machine state in a procedure?
- 91) What is lexical scope?
- 92) What is the lifetime of a variable?
- 93) What types of variables use automatic storage allocation?
- 94) What types of variables maintain their values across a procedure call (i.e., still have the value from the last call during the current call)?

- 95) What is the lifetime of a global variable?
- 96) What is the lifetime of a local variable?
- 97) What are the six different ways HLA lets you pass parameters?
- 98) What are two different ways to declare pass by value parameters in an HLA procedure?
- 99) How do you declare pass by reference parameters in an HLA procedure?
- 100) What are the advantages and disadvantages of callee-preservation and caller-preservation when saving registers inside a procedure?
- 101) How do pass by value parameters work?
- 102) How do pass by reference parameters work?
- 103) How would you load the value associated with a pass by value parameter, V, into the EAX register?
- 104) How would you load the value associated with a pass by reference parameter, R, into the EAX register?
- 105) What is the difference between a function and a procedure?
- 106) What is the syntactical difference between a function and a procedure in HLA?
- 107) Where do you typically return function results?
- 108) What is instruction composition?
- 109) What is the purpose of the RETURNS option in a procedure declaration?
- 110) What is a side effect?
- 111) What is wrong with side effects in your programs?
- 112) What is recursion?
- 113) What is the FORWARD procedure option used for?
- 114) What is the one time that a forward procedure declaration is absolutely necessary?
- 115) Give an example of when it would be convenient to use a forward declaration even if it was specifically required.
- 116) Explain how to return from a procedure in the middle of that procedure (i.e., without “running off the end” of the procedure).
- 117) What does the #INCLUDE directive do?
- 118) What do you normally use the #INCLUDE directive for?
- 119) What is the difference between the #INCLUDE and the #INCLUDEONCE directives?
- 120) What is the syntax for an HLA unit?
- 121) What is the purpose of an HLA unit?
- 122) What is the purpose of separate compilation?
- 123) How do you declare EXTERNAL procedures? Variables?
- 124) What variable types cannot be EXTERNAL?
- 125) How do you declare a public symbol in HLA?
- 126) What is a header file?
- 127) What is a file dependency?
- 128) What is the basic syntax for a makefile?
- 129) What is a recursive file inclusion? How can you prevent this?
- 130) What are the benefits of code reuse?
- 131) What is a library?
- 132) Why would you not want to compile all your library routines into a single OBJ file?

- 133) What types of files are merged together to form a .LIB file?
- 134) What program would you use to create a library file?
- 135) How does a library contribute to name space pollution? How can you solve this problem?
- 136) What are the differences between the INTMUL and the IMUL instruction?
- 137) What must you do before executing the DIV and IDIV instructions?
- 138) How do you compute the remainder after the division of two operands?
- 139) Assume that VAR1 and VAR2 are 32 bit variables declared with the DWORD type. Write code sequences that will compute the boolean result (true/false) of each of these, leaving the result in BL:
- VAR1 = VAR2
 - VAR1 <> VAR2
 - VAR1 < VAR2 (Unsigned and signed versions
 - VAR1 <= VAR2 for each of these)
 - VAR1 > VAR2
 - VAR1 >= VAR2
- 140) Provide the code sequence that will compute the result of the following expressions. Assume all variables are UNS32 values and you are computing unsigned results:
- A = (X-2) * (Y + 3);
 - B = (A+2)/(A - B);
 - C = A/X * B - C - D;
 - D = (A + B)/12 * D;
 - E = (X * Y) / (X-Y) / C+D;
 - F = (A <= B) && (C != D) || (E > F);
(note to Pascal users, the above is "F := (A <= B) and (C <> D) or (E > F);")
- 141) Repeat question (140) assuming all variables are INT32 objects and you are using signed integer arithmetic.
- 142) Repeat question (140) assuming all variables are REAL64 objects and you are using floating point arithmetic. Also assume that an acceptable error value for floating point comparisons is 1.0e-100.
- 143) Convert the following expressions into assembly language code employing shifts, additions, and subtractions in place of the multiplication:
- EAX*15
 - EAX*129
 - EAX*1024
 - EAX*20000
- 144) How could you use the TEST instruction (or a sequence of TEST instructions) to see if bits zero and four in the AL register are both set to one? How would the TEST instruction be used to see if either bit is set? How could the TEST instruction be used to see if neither bit is set?
- 145) Why are commutative operators easier to work with when converting expressions to assembly language (as opposed to non-commutative operators)?
- 146) Provide a single LEA instruction that will multiply the value in EAX by five.
- 147) What happens if INTMUL produces a result that is too large for the destination register?
- 148) What happens if IMUL or MUL produces a result that is too large for EAX?
- 149) Besides divide by zero, what is the other division error that can occur when executing IDIV or DIV?

- 150) What is the difference between the MOD instruction and the DIV instruction?
- 151) After a CMP instruction, how do the condition code bits indicate that one signed operand is less than another signed operand?
- 152) What instruction is CMP most similar to?
- 153) What instruction is TEST most similar to?
- 154) How can you compute a pseudo-random number between 1 and 10 using the HLA Standard Library rand.hhf module?
- 155) Explain how to copy the floating point status register bits into the 80x86 FLAGS register so you can use the SETcc instructions after a floating point comparison.
- 156) Why is it not a good idea to compare two floating point values for equality?
- 157) Explain how to activate floating point exceptions on the FPU.
- 158) What are the purpose of the rounding control bits in the FPU control register?
- 159) Besides where they leave their results, what is the difference between the FIST instruction and the FRND-INT instruction?
- 160) Where does *stdin.getf()* leave the input value?
- 161) What is a mantissa?
- 162) Why does the IEEE floating point format mantissa represent values between 1.0 and 2.0?
- 163) How can you control the precision of floating point calculations on the FPU? Provide an example that shows how to set the precision to real32.
- 164) When performing floating point comparisons, you use unsigned comparisons rather than signed comparisons, even though floating point values are signed. Explain.
- 165) What is postfix notation?
- 166) Convert the expression in question (140) to postfix notation.
- 167) Why is postfix notation convenient when working with the FPU?
- 168) Explain how the XLAT instruction operates.
- 169) Suppose you had a *cipher* (code) that swaps various characters in the alphabet. Explain how you could use the XLAT instruction to decode a message encoded with this cipher. Explain how you could encode the message.
- 170) What is the purpose of *domain conditioning*?
- 171) What is the maximum set of values for the domain and range when using the XLAT instruction?
- 172) Explain the benefits of using one program to generate the lookup tables for another program.

13.2 Programming Projects

- 1) Write a procedure, `PrintArray(var ary:int32; NumRows:uns32; NumCols:uns32)`, that will print a two-dimensional array in matrix form. Note that calls to the `PrintArray` function will need to coerce the actual array to an `int32`. Assume that the array is always an array of `int32` values. Write the procedure as part of a UNIT with an appropriate header file. Also write a sample main program to test the `PrintArray` function. Include a makefile that will compile and run the program. Here is an example of a typical call to `PrintArray`:

```
static
  MyArray: int32[4, 5];
  .
  .
  .
  PrintArray( (type int32 MyArray), 4, 5 );
```

- 2) Write a procedure that reads an unsigned integer value from the user and reprompts for the input if there is any type of error. The procedure should return the result in the EAX register. It shouldn't require any parameters. Compile this procedure in a UNIT. Provide an appropriate header file and a main program that will test the function. Include a makefile that will compile and run the program.
- 3) Extend the previous project (2) by writing a second routine for the UNIT that has two parameters: a minimum value and a maximum value. Not only should this routine handle all input problems, but it should also require that the input value fall between the two values passed as parameters.
- 4) Extend the unit in (3) by writing two addition procedures that provide the same facilities for signed integer values.
- 5) Write a program that reads a filename from the user and then counts the number of lines in the text file specified by the filename.
- 6) Write a program that reads a filename from the user and then counts the number of words in the specified text file. The program should display an accurate count of words. For our purposes, a "word" is defined as any sequence of non-whitespace characters. A whitespace character is the space (`#$20`), tab (`#$9`), carriage return (`#$d`), and the line feed (`#$a`). Read the text file a line at a time using `fileio.gets` or `fileio.a_gets`. Also remember that a zero byte (`#0`) marks the end of a string, so this clearly terminates a word as well.
- 7) Modify the CD database program in Laboratory Exercise 13.3.10 so that it reads the CD database from a text file. Your program should make two passes through the text file. On the first pass it should count the number of lines in the text file and divide this value by four (four lines per record) to determine how many records are in the database. Then it should dynamically allocate an array of CDs of the specified size. On the second pass, it should read the data from the text file into dynamically allocated array. Obviously, you must also modify the program so that it works with a variable number of CDs in the list rather than the fixed number currently specified by the `NumCDs` constant.
- 8) Modify program (7) to give the user the option of displaying all the records in the database sorted by title, artist, publisher, or date. Use the QuickSort algorithm appearing in this volume to do the sorting (note: the solution requiring the least amount of thought will require four different sort routines; a more intelligent version can get by with two versions of quicksort).
- 9) Write a "CD Database Input" program that reads the textfile database for program (7) into a fixed array in memory. Allow enough space for up to 500 records in the database (display an error and stop if the input exceeds this amount). Of course, the value 500 should be a symbolic constant that can easily be changed if you need a larger or smaller database. After reading the records into memory, the program should prompt the user to enter additional CDs for the database. When the user is through entering data, the program should write all the records back to the database file (including the new records).
- 10) Modify program (9) so that the user is given the option of deleting existing records (perhaps by specifying the index into the array) in addition to entering new entries into the database.

- 11) Write a `MsgBoxInput` procedure that has the following parameters:

```
procedure MsgBoxInput ( prompt:string; row:word; col:word; result:string );
```

The procedure should do the following:

- 1) Save the rectangular region of the screen specified by (row, col) as the upper left hand corner and (row+4, col+length(prompt) +2) as the lower right hand corner. Stop the program with an error if this rectangle is outside the bounds (0,0) <-> (24,79). Use the `console.a_getRect` function to save this portion of the screen.
- 2) Fill the rectangular region saved above with spaces and a dark blue background. Set the foreground attribute to yellow. (`console.fillRect`).
- 3) Print the prompt message starting at position (row+1, col+1).
- 4) Position the cursor at (row+2, col+1).
- 5) Read a string from the user with no more than length(prompt) characters (see below).
- 7) Restore the attributes in the rectangular region to black and white. (`console.fillRectAttr`)
- 8) Redraw the text saved in step one above.

Note that you cannot use `stdin.gets` or `stdin.a_gets` to read the string from the user since these functions won't limit the number of input characters. Instead, you will have to write your own input routine using `stdin.getc` to read the data a character at a time. Don't forget to properly handle the backspace character. Also, `stdin.getc` does not echo the character, so you will have to handle this yourself.

Put these procedures in a unit and write a companion main program that you can use to test your dialog box input routine.

- 12) The Windows console device is a *memory mapped I/O device*. That is, the display adapter maps each character on the text display to a character in memory. The display is an 80x25 array of characters declared as follows:

```
display:char [25, 80];
```

`Display[0,0]` corresponds to the upper left hand corner of the screen, `display[0,79]` is the upper right hand corner, `display[24,0]` is the lower left hand corner, and `display[24,79]` is the lower right hand corner of the display. Each array element contains the ASCII code of the character to appear on the screen.

The `lab4_10_7.hla` program demonstrates how to copy a matrix to a portion of the screen (or to the entire console, if you so desire). Currently, this program draws and erases a single asterisk over and over again on the screen to give the illusion of animation. Modify this program so that it draws a rectangular or triangular shape, based at the row/column address specified by the for-loops. Be sure you don't "draw" outside the bounds of the character array (*playingField*).

- 13) Create a program with a single dimension array of records. Place at least four fields (your choice) in the record. Write a code segment to access element *i* (*i* being a `DWORD` variable) in the array.
- 14) Modify the program above so that it contains two identical arrays of records. Have the program copy the data from the first array to the second array and then print the values in the second array to verify the copy operation.
- 15) Modify the program in (14) above to use a dynamically allocated array, rather than a statically allocated array, as the destination array.
- 16) Write a program which copies the data from a 4x4 array and stores the data into a second 4x4 array. For the first 4x4 array, store the data in row major order. For the second 4x4 array, store the data in column major order. Write the for loops to do this "transposition" yourself. Do not use the `array.transpose` routine in the HLA Standard library.

- 17) Modify program (16) so that a single constant controls the size of the matrices (they will always be square, having the same number of rows as columns, so a single constant will suffice).
- 18) Write a program that reads two lines of text from the user and displays all characters that appear on both lines, but does not display any characters that appear on only one of the two lines of text. (hint: use the character set functions.)
- 19) Modify program (18) so that it prints the characters common to both lines, the characters appearing only in the first string, and the characters appearing only in the second string. Print these three sets of characters on different lines with an appropriate message explaining their content.
- 20) Write a program that reads a line of text from the user and counts the number of occurrences of each character on the line. The program should display the character and count for each unique character found in the input line whose count is not zero (hint: create an array of 256 integers and use the ASCII code as an index into this array).
- 21) Modify program (20) so that it also displays the number of numeric characters, the number of alphabetic characters (upper and lower case), the number of uppercase alphabetic characters, the number of lower case alphabetic characters, the number of control characters (ASCII code \leq \$1f and \$7f), and the number of punctuation characters (this is all characters other than the previously mentioned sets). Display these counts one per line before the output of the count for each character from problem (20).
- 22) Write a program that reads a line of text from the user and counts the number of words on that line. For our purposes, a “word” is defined as any sequence of non-whitespace characters. A whitespace character is the space (#\$20), tab (#\$9), carriage return (#\$d), and the line feed (#\$a). Do not use the *str.tokenize* or *str.tokenize2* routines to implement this program.
- 23) Look up the *str.tokenize2* routine in the HLA Standard Library strings module. Implement problem (22) using this procedure.
- 24) Write a program that reads a string from the user and checks the string to see if it takes the form “mm/dd/yy”, or “mm-dd-yy” where *mm*, *dd*, and *yy* are all exactly two decimal digits. If the input string matches either of these patterns, extract these substrings into separate string variables and print them on separate lines with an appropriate description (i.e., month, day, and year).
- 25) Modify program (24) to verify that *mm* is in the range 01-12, *dd* is in the range 01-31, and *yy* is in the range 00-99. Report match/no match on the input depending upon whether the input string matches this format. Note: you will probably find this problem to be a whole lot less work if you look up the *conv.strTou8* procedure in the conversions module of the HLA Standard Library and do numeric comparisons rather than string comparisons).
- 26) Modify program (25) to allow single digit values for the month and day components when they fall in the range 1-10 (the year component, *yy*, still requires exactly two digits). Also allow leading or trailing whitespace in the string (hint: use the *char.ispace* function or the *str.trim* function). Display match/no match as before depending upon the validity of the string.
- 27) Modify program (26) so that it checks the validity of the date subject to the Gregorian Calendar. That is, the day value should not exceed the maximum number of days for each month. Note: you may use the *date.IsLeapYear* function but you may not use *date.IsValid* or *date.validate* for this project. Assume that the centuries portion of the date is in the range 2000..2099 (that is, add 2000 to the year value to obtain the correct year).
- 28) The Y2K problem): Modify program (27) as follows: (1) it reads a string from the user. (2) it searches for the pattern “mm/dd/yy” or “mm-dd-yy” anywhere in the string (there may be other text in the string in this program). If the program finds a string of the form “mm/dd/yy” or “mm-dd-yy” then it will replace that string with a string of the form “mm/dd/19yy” or “mm-dd-19yy” to make the string Y2K compatible (of course, a good programmer would use a string constant for “19” so it could be easily changed to “20” or any other two digits). If there is more than one date in the string that matches a valid Y2K date, you will need to find and convert that date as well (i.e., convert all possible dates found in the string). After the conversion process is complete, display the string which should be the original text typed by the user with these Y2K modifications. Do not translate any dates that don’t exactly match one of these two patterns:

Examples of strings containing good dates (ones you should translate):

```

01-01-01
02-29-96
End of the 1900s: 12/31/99
Today is '3/17/90'
Start of the 20th century: 1/1/01, end of the 20th century: 12/31/2000
(note: program must not convert 12/31/2000 above to 12/31/192000)
Yesterday was 7/4/76, tomorrow is 7/6/96.
(must convert both dates above.)

```

Examples of bad dates that your program must ignore:

```

01-01/01
02/29-96
End of the 1900s: 12/31/1999
Today is '123/17/90'
01/32/00
02/29/99

```

- 29) Write a program that reads a string of characters from the user and verifies that these characters are all decimal digits in the range '0'..'7'. Treat this string as an octal (base eight) number. Convert the string to an integer value. Note: values in the range 0..7 consume exactly three bits. You can easily construct the octal number using the SHL instruction; you will not need to use the INTMUL instruction for this assignment. Write a loop that reads the octal string from the user and, if the string is valid, converts the number to an integer and displays that integer value in decimal.
- 30) Modify the student database program in the laboratory exercises (see "Records, Arrays, and Pointers Laboratory Exercise" on page 676) to sort the students by their name prior to printing the result. Since the name field is a string, you will want to use the string comparison routines to compare them. You should also use the case insensitive string comparisons (e.g., *str.ile*) since upper and lower case are irrelevant to most people when viewing sorted lists of names.
- 31) Modify program (30) so that it uses two fields for the name (last name and first name). The user should still enter the full name. Under program control, extract the first and last names from the single input string and store these two name components into their respective fields in the record.
- 32) Write a program that computes the two solutions to the quadratic equation.

$$x_1 = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

$$x_2 = \frac{-b + \sqrt{b^2 - 4ac}}{2a}$$

The program should verify that a is non-zero and that the value $b^2 - 4ac$ is positive or zero before attempting to compute these roots.

- 33) Suppose you are given a line and two points on that line. Compute the point that is midway between the two points via the equations $X_{\text{mid}} = (x_1 + x_2)/2$ and $Y_{\text{mid}} = (y_1 + y_2)/2$. Read the X and Y coordinates for the two points from the user. Use a RECORD containing two fields, X and Y, to denote a single point in your program. Note: X and Y are real64 variables.
- 34) Write a program that computes the amount of interest earned on a savings account. The formula for computing interest is

$$\text{DollarsEarned} = \text{InitialDeposit} \times \left(1.0 + \frac{\text{InterestRate}}{100.0}\right)^{\text{Years}}$$

Hint: you will need to use routines from the “math.hhf” library module for this assignment.

- 35) Write a program that inputs a temperature in Celsius and converts it to degrees Fahrenheit. The translation is given by the following formula:

$$f = (9/5) \times c + 32$$

- 36) Solve the equation above (35) for c and write a program that also solves for Celsius given a temperature in Fahrenheit.
- 37) Write a program that inputs a set of grades for courses a student takes in a given quarter. The program should then compute the GPA for that student for the quarter. Assume the following grade points for each of the following possible letter grades:
- A+ 4.0
 - A 4.0
 - A- 3.7
 - B+ 3.3
 - B 3.0
 - B- 2.7
 - C+ 2.3
 - C 2.0
 - C- 1.7
 - D+ 1.3
 - D 1.0
 - D- 0.7
 - F 0

Display the GPA using the format X.XX.

- 38) Modify program (37) to handle courses where each course may have a different (integral) number of units. Multiply the grade points by the number of units for a given grade and then divide by the total number of units.
- 39) Write a program that accepts a dollars and cents amount as a floating point value and converts this to an integer representing the number of pennies in the entered amount (round the input to the nearest penny if

it is off a little bit). Translate this value into the minimum number of pennies, nickels, dimes, quarters, one dollar bills, five dollar bills, ten dollar bills, twenty dollar bills, and one hundred dollar bills that would be necessary to represent this result. Display your answer as follows:

```
The amount $xxx.xx requires no more than
    p pennies,
    n nickels,
    d dimes,
    q quarters,
    d $1 bills,
    f $5 bills,
    t $10 bills,
and   h $100 bills.
```

The italicized letters represent small integer constants (except *h* which can be a large integer constant). Do not display an entry if the count is zero (e.g., if there are zero \$100 bills required, do not display the line “0 \$100 bills.”)

- 40) Modify program (39) so that it displays a singular noun if there is only one of a given item (e.g., display “1 nickel,” rather than “1 nickels.”)
- 41) Write a program that plots a sine curve on the console (see “Bonus Section: The HLA Standard Library CONSOLE Module” on page 184 for a discussion of the console support routines). Begin by clearing the screen with `console.cls()`. Then draw a row of dashes along line 12 on the screen to form the X-axis. Draw a column of vertical bars in column 0 to denote the Y-axis. Finally, plot the sine curve by using `console.gotoxy` to position the cursor prior to printing an asterisk (“*”) to represent one point on the screen. Plot the curve between 0 and 4π radians. Each column on the screen should correspond to $4\pi/80$ radians. Since the FSIN instruction only returns values between -1 and +1, you will need to scale the result by adding one to the value and multiplying it by 12. This will give the Y-coordinate of the point to plot. Increment through each of the X-coordinate positions on the screen when plotting the points (remember, each X-coordinate is $4\pi/80$ radians greater than the previous X-coordinate).
- 42) Modify program (41) to simultaneously plot the COS curve at the same time you plot the SIN curve. Use at signs (“@”) to plot the cosine points.
- 43) Write a program that accepts an integer value as a decimal (base 10) number and outputs the value in a user specified base between two and ten.
- 44) Modify program (43) so that it accepts an integer in one user-specified base and outputs the number in a second user-specified base (bases 2-10).
- 45) The factorial of a non-negative integer, $n!$, is the product of all integers between one and n . For example, $3!$ is $3*2*1 = 6$. Write a function that computes $n!$ using integer arithmetic. What is the largest value of n for which you can compute $n!$ without overflow using 32-bit integers?
- 46) Since $n!$ overflows so rapidly when using 32-bit integers, use the 64-bit integer capabilities of the FPU to compute $n!$ (see problem 45). What is the maximum value of n for which you can compute $n!$ when using 64-bit numbers?
- 47) You can estimate the value of the constant e using the following equation:

$$e = \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots$$

Obviously, you cannot carry this out to an infinite number of terms, but the more terms you use the better the approximation. Write a program that will calculate e using this approximation that is accurate to at least 12 decimal places ($e=2.71828182846$).

- 48) You can compute the value of e^x using the following mathematical series:

$$e^x = \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots$$

Using the same number of terms required by problem (47), compute e^x with 12 digits of accuracy.

- 49) Write a program that reads the data from a text file and swaps the case of the alphabetic letters and writes the result to the console. Use a lookup table to perform the case swap (hint: it's probably easiest to have the program fill in the table using the first few instructions of the program rather than by typing the table by hand or write a separate program to generate the table). The program should prompt the user for the file name to translate.
- 50) Genokey Technologies manufactures portable keypads for laptop computers. They have boxes that will hold one, five, ten, twenty-five, and one hundred keypads. Write a program for the Genokey shipping clerk that will automatically choose the minimum number of boxes (and tell how many of each is required) that are necessary to ship n keypads to a distributor whenever that distributor orders n keypads.
- 51) Write a program that reads two eight-bit unsigned integer values from the user, zero-extends these integers to 16-bits, and then computes and prints their product as follows:
- ```

 123
x 241

 123
 492
 246

 29643

```
- 52) Extend the RPNcalculator program (found in the sample program section of the chapter on Real Arithmetic, see "Sample Program" on page 619) to add all the function which there are FPU instructions (e.g., COS, CHS, ABS, FPREM1, etc.).
- 53) Extend the calculator program above (52) to support the functions provided in the HLA "math.hhf" module.
- 54) Modify the RPN calculator program above (53) to support infix notation rather than postfix notation. For this assignment, remove the unary functions and operators.

## 13.3 Laboratory Exercises

*Note: since this volume is rather long you should allow about twice as much time as normal to complete the following laboratory exercises.*

Accompanying this text is a significant amount of software. The software can be found in the AoA\_Software directory. Inside this directory is a set of directories with names like *Volume2* and *Volume3*, with the names obviously corresponding to the volumes in this textbook. All the source code to the example programs in this volume can be found in the subdirectories found in the Volume3 subdirectory. The Volume3\Ch13 subdirectory also contains the programs for this chapter's laboratory exercises. Please see this directory for more details.

### 13.3.1 Using the BOUND Instruction to Check Array Indices

The following program (Program 13.1) demonstrates how to use the BOUND instruction to check array indices at run time. This simple program reads an unsigned integer from the user and uses that value as an index into an array containing 10 characters then displays the character at the specified index. However, if the array index is out of bounds, this triggers an *ex.BoundsInstr* exception and prints an error message (this program also handles a couple of other exceptions that *stdin.get* can raise).

---

```
// Program to demonstrate BOUND instruction.

program BoundLab;
#include("stdlib.hhf");

static

 index: uns32;
 arrayBounds: dword[2] := [0, 9];
 arrayOfChars: char[10] :=
 ['a', 'b', 'c', 'd', 'e', 'f', 'g', 'h', 'i', 'j'];

 answer: char;

begin BoundLab;

 repeat

 try

 // Read an integer index into "arrayOfChars" from the user:

 stdout.put("Enter an integer index between 0 and 9: ");
 stdin.flushInput();
 stdin.get(index);

 // Verify that the input is in the range 0..9:

 mov(index, eax);
 bound(eax, arrayBounds);

 // If it was a good index, display the character at that
 // index:

 mov(arrayOfChars[eax], al);
 stdout.put
```

```

 (
 "The character at that index is '",
 (type char al),
 "'"
 nl
);

// Handle the exceptions possible in the stdin.get call as well
// as the BOUND instruction exception.

exception(ex.BoundInstr)

 stdout.put("The index you entered is not in the range 0..9" nl);

exception(ex.ConversionError)

 stdout.put("You did not enter a valid unsigned integer" nl);

exception(ex.ValueOutOfRange)

 stdout.put("That integer value is way out of range!" nl);

endtry;

// Ask the user if they want to try again. Force the user to
// enter only a "Y" or an "N":
repeat

 stdout.put("Do you wish to try another index (Y/N)? ");
 stdin.flushInput();
 stdin.getc();

 // If the user enters a lower case character, convert it
 // to upper case.

 if(al in 'a'..'z') then

 and($5f, al);

 endif;
 mov(al, bl); // Because cs.member wipes out AL.

until(cs.member(al, {'Y', 'N'}));

until(bl = 'N');

end BoundLab;

```

---

---

### Program 13.1 Using the BOUND Instruction to Check Array Indices

---

---

Exercise A: Run this program and verify that it works in an acceptable fashion when the input is a legal integer in the range 0..9. Next, try entering a value greater than 10. Report the results of these experiments in your lab report.

Exercise B: At the end of the program, it asks you whether you want to rerun the program. The program uses the `cs.member` function to allow only a yes or no (“Y” or “N”) response. Verify that this program will not accept any data other than “Y” or “N” when asking the user if they want to retry the operation.

Exercise C: As you can see, there is code that converts the character in the AL register to an upper case character if it is a lower case character. After the conversion, the character set membership test only checks for upper case characters. Verify that you can enter upper or lower case “Y” or “N” characters and the program still works.

Exercise D: The HLA Standard Library includes the CHARS module that supplies various character classification routines including functions like `chars.isLower` and `chars.isUpper`. These functions take a single character parameter and return true or false in the EAX register if the parameter is a lower case alphabetic or upper case alphabetic character (respectively). Modify the code in this sample program to test for lower case by making a call to the `chars.isLower` routine rather than using the boolean expression “(al in ‘a’..‘z’)”. Rerun the program and verify that it is still working correctly.<sup>1</sup> Include a copy of this converted program with your lab report.

Exercise E: In addition to character classification routines, the CHARS module also includes a couple of character conversion routines. The `chars.toUpper` routine will convert its single character parameter to upper case if it is lower case (it returns all other characters unchanged). Likewise, the `chars.toLower` routine converts the input parameter to a lower case character (if it was upper case to begin with). Both routines return the character in the AL register. They both return the original character if it was not alphabetic. Modify this program to use the `chars.toUpper` routine to do the upper case conversion rather than the IF statement it currently uses. Test the resulting program. Include a copy of this converted program with your lab report.

Exercise F: HLA supports a special, extended, syntax for the BOUND instruction that has three parameters. The second and third parameters of BOUND are integer constants specifying the lower and upper bounds to check. This form is often more convenient than the BOUND instruction appearing in Program 13.1 because you don’t have to declare a two-element initialized array for use as the BOUND parameter. Modify your current program by eliminating the `arrayBounds` variable and using this form of the BOUND instruction. Verify that your program still allows indices in the range 0..9. Include the program listing of your modified program in your lab report.

Exercise G: Program 13.1 uses the literal constants nine and ten to denote the upper bounds on the array as well as the number of elements in the array. Using literal constants like this makes programs much more difficult to read and maintain. A better solution is to use a symbolic constant that you define once at the top of the program and reference throughout the code. By doing so, you can change the size of the array by changing only one or two statements in your program<sup>2</sup>. Modify this program so that it contains a single constant specifying the number of array elements. Use this constant wherever the number of array elements or the array’s upper bound appears in the program (hint: use constant expressions to compute the value nine from this constant). Verify that the program still works correctly and include the source code with your lab report.

Exercise H: HLA predefines a special boolean VAL constant, `@bound`, that controls the compilation of the BOUND instruction. If `@bound` is true (the default) then HLA will compile BOUND instructions found in your program. If `@bound` is false, then HLA ignores all BOUND instructions it encounters. You can change the value of the `@bound` constant by using a statement of the form:

```
?@bound := false;
```

Modify Program 13.1 (the original version) and set the `arrayBounds` value so that it only allows array indices in the range 0..5. Run the program and verify this new operation. Next, insert “`?@bound:=false;`” immediately after the “`begin pgm4_17;`” statement in the program. Recompile and run the program and ver-

---

1. Note that using the IN operator is much more efficient than calling the `chars.isLower` function. Don’t get the impression from this exercise that `chars.isLower` is the best way to check for a lower case character. The `chars.isLower` routine is appropriate in many cases, but this probably isn’t a good example of where you would want to use this function. The only reason this exercise uses this function is to introduce it to you.

2. Don’t forget, if you change the size of the character array in Program 13.1 then you will need to change the number of array elements in the initializer for that array as well.

ify that the BOUND instruction is no longer active by entering an index in the range 6..9. Describe the results in your laboratory report.

---

### 13.3.2 Using TEXT Constants in Your Programs

HLA's TEXT constants let you replace long repetitive sequences in your program with a single identifier, similar to the #define statement in C/C++<sup>3</sup>. This laboratory exercise demonstrates how you can use TEXT constants to save considerable typing in your programs.

Consider Program 13.2. This program uses TEXT constants to compress often-used text in three main areas: first, it reduces the strings "stdout.put" and "stdin.get" to the single identifiers *put* and *get* saving a bit of typing (since these calls occur frequently in HLA programs). Second, it replaces the string "(type uns32 i)" with the single identifier *ui*. Although this program only uses *ui* once, in a real program you might wind up using a single string like "(type uns32 i)" on several occasions. Finally, this program uses TEXT constants to combine several common exceptions into the *endOfTry* constant, saving considerable typing in each TRY..ENDTRY block.

---

```
// Demonstration of TEXT constants in a program.

program TextLab;
#include("stdlib.hhf");

const
 put: text := "stdout.put";
 get: text := "stdin.get";
 ui: text := "(type uns32 i)";

 VOR: string := "Value out of range";
 CE: string := "Conversion error";

 exRange: text :=
 "exception(ex.ValueOutOfRange); "
 "put(VOR, nl);";

 exConv: text :=
 "exception(ex.ConversionError); "
 "put(CE, nl);";

 endOfTry: text :=
 "exRange; exConv; endtry";

static

 i: int32;
 range: dword[2] := [1,10];

begin TextLab;

 try

 put("Enter an integer value: ");
```

---

3. HLA's TEXT constants don't support parameters making them weaker than C/C++'s #define macro capability. Fear not, however, HLA has its own macro facility that is much more powerful than C/C++'s. You will learn about HLA's macro facilities in the chapter on macros and the compile-time language.

```

 get(i);
 put("The value you entered was ", i, nl);

endOfTry;

try

 repeat

 put("Now enter a negative integer: ");
 get(i);

 until(i < 0);
 put("As an unsigned integer, 'i' is ", ui, nl);

endOfTry;

try

 repeat

 put("Now enter an integer between one and ten: ");
 get(i);
 mov(i, eax);
 bound(eax, range);

 until(i < 0);
 put("The value you entered was ", i, nl);

 exception(ex.BoundsInstr);

 put("The value was not in the range 1..10", nl);

endOfTry;

end TextLab;

```

---

---

### Program 13.2 TEXT Constant Laboratory Exercise Code

---

---

Exercise A: Compile and run this program. For each TRY..ENDTRY block, enter values that raise the conversion error exception and the value out of range exception<sup>4</sup>. For the last TRY..ENDTRY block, enter a value outside the range 1..10 to raise an *ex.BoundsInstr* exception. Describe what happens in your lab report.

Exercise B: Add a TEXT constant declaration for the *exBound* symbol. Set the value of the TEXT object equal to the string associated with the BOUND instruction exception (see the examples for *ex.ConversionError* and *ex.ValueOutOfRange* to figure out how to do this). Modify the last TRY..ENDTRY statement to use this TEXT constant in place of the associated exception handling section. Run the program to verify its operation. Include the modified program with your laboratory report.

Exercise C: Modify the first TRY..ENDTRY block above to read and display an unsigned integer value using the *ui* TEXT constant in place of the *i* variable. Verify, by running the program, that it will no longer let you enter negative values. Include the modified program with your lab report.

---

4. Entering a 12-digit integer value will raise the *ex.ValueOutOfRange* exception. Typing non-numeric characters will raise the *ex.ConversionError* exception.

Exercise D: In the *exRange* and *exConv* constants, the *put* statement uses the symbolic string constants *CE* and *VOR* to display the error message. Replace these symbolic identifiers with their corresponding literal string constants (Hint: you need to remember how to embed quotation marks inside a string). Run and test the program. Include the source code to this modification in your lab report and comment on the wisdom of using string constants rather than string literals in your programs.

### 13.3.3 Constant Expressions Lab Exercise

This laboratory exercise demonstrates the use of constant expressions in an HLA program. As you are reading through the following program, keep in mind that many of the constant expressions were added to this program simply to demonstrate various operators; you wouldn't normally use these operators in a trivial program such as this one. However, to write a complex program that fully uses constant expressions is beyond the scope of this laboratory exercise. Part of this laboratory exercise is to undo some of the excessive use of constant expressions in the program. So bear with this example.

---

```
// Demonstration of constant expressions in a program.

program ConstExprLab;
#include("stdlib.hhf");

const
 ElementsInArray := 10;

 sin: string := "stdin.";
 sout: string := "stdout.";

 put: text := sout + "put";
 get: text := sin + "get";
 flush: text := sin + "flushInput";

var
 input: uns32;
 GoodInput: boolean;
 InputValues: int32[ElementsInArray];

readonly

 IV_bounds: dword[2] := [0, ElementsInArray-1];

begin ConstExprLab;

 for(mov(0, ebx); ebx < ElementsInArray; inc(ebx)) do

 repeat

 mov(false, GoodInput);
 try

 put("Enter integer #", (type uns32 ebx), ": ");
 flush();
 get(input);

 bound(ebx, IV_bounds);
 mov(input, InputValues[ebx*4]);
 mov(true, GoodInput);

 end try

 until GoodInput;

 end for;

end ConstExprLab;
```

```

 exception(ex.ConversionError)

 put("Number contains illegal characters", nl);

 exception(ex.ValueOutOfRange)

 put("The number is way too large", nl);

 exception(ex.BoundsInstr)

 put("Array index is out of bounds", nl);

 endtry;

until(GoodInput);

endfor;

// Now print the values entered by the user in the reverse order
// they were entered. Note: this code doesn't use the scaled (*4)
// indexed addressing mode. So it initializes EBX with four times
// the index of the last element in the array.

mov((ElementsInArray - 1) * 4, ebx);
while((type int32 ebx) >= 0) do

 put
 (
 "Value at offset ",
 (type uns32 ebx):2,
 " was ",
 InputValues[ebx],
 nl
);

 // Since we're not using the scaled (*4) index addressing mode,
 // drop the count by four for each array element since it's an
 // array of dwords.

 sub(4, ebx);

endwhile;

end ConstExprLab;

```

---

### Program 13.3 Constant Expressions Laboratory Exercise

---

Exercise A: Compile this program and run it. Describe the operation of the program in your laboratory report.

Exercise B: One extreme use of constant expressions in this program appears in the following code:

```

sin: string := "stdin.";
sout: string := "stdout.";

put: text := sout + "put";
get: text := sin + "get";
flush: text := sin + "FlushInput";

```

Modify the program to eliminate the *sin* and *sout* constants from the code. The program should be easier to read once you have completed this task. Compile and run the program and verify that it produces the same results as before the change. Include the source code to the modified program with your lab report. Briefly explain why you think that the use of the string concatenation operator wasn't worth much in this code.

Exercise C: This program provides the *ElementsInArray* constant that lets you easily change the size of the array that this program works with. Change the value of this constant to five and recompile and run the program. Verify that it works correctly for five array elements (versus ten in the previous version). Identify all locations in the program that modifying the *ElementsInArray* constant affects (use a hi-liter or other such tool to make these points visible in the listing appearing in your lab report). Describe in the lab report write-up the effort that would be needed to change the size of the array had this program not used the *ElementsInArray* constant.

Exercise D: The *get* and *put* constants save considerable typing in this program. Can you think of a reason why it might not be such a good idea to use TEXT constants like these to save typing in your program? Justify your answer in your laboratory report.

### 13.3.4 Pointers and Pointer Constants Exercises

Pointers are especially important in assembly language programs. This laboratory exercise demonstrates that HLA programs often use pointers to access elements of an array. This program also demonstrates how to use the BOUND instruction to check to see if a pointer contains an address between two extremes.

Conceptually, this program is very simple. It asks the user for an integer and then prints that many characters out of an array (checking, of course, to verify that the program doesn't exceed array bounds). To print those characters, this program loads the base address of an array into a register and then increments that register to step through the array. Contrast this with examples appearing later in these lab exercises where the program leaves the register containing the base address unmodified and increments a separate index register.

```
// Demonstration of pointers and pointer constants in a program.

program PointerLab;
#include("stdlib.hhf");

const
 NumberOfChars := 8;

type
 CharPtr: pointer to char;

static

 CharArray: char[NumberOfChars] :=
 ['1', '2', '3', '4', '5', '6', '7', '8'];

 CA_bounds: CharPtr[2] := [&CharArray, &CharArray + (NumberOfChars-1)];

begin PointerLab;

 // Get the number of characters to print into EAX:

 stdout.put("How many characters would you like to print? ");
 stdin.getu32();

 // Get address of CharArray into EBX:
```

```

lea(ebx, CharArray);

// Print the specified number of characters:

while(eax > 0) do

 bound(ebx, CA_bounds);
 stdout.putc([ebx]);
 inc(ebx);
 dec(eax);

endwhile;
stdout.newln();

end PointerLab;

```

---

---

### Program 13.4 Pointers and Pointer Constants Laboratory Exercise Code

---

---

Exercise A: Compile and run this program. Describe its operation in your laboratory report.

Exercise B: This program contains a constant *NumberOfChars*. Change this constant from eight to ten and recompile the program. Explain why this one change is not sufficient to change the size of the array from eight to ten elements. Make an appropriate change to this program so that it will compile and run correctly. Compare the number of changes needed in the program to get it to compile and run with the number of changes that would be necessary had this program not used the *NumberOfChars* constant. Describe the benefits to this program of using the *NumberOfChars* constant.

Exercise C: This program does not contain a TRY..ENDTRY block to handle the BOUND instruction exception. Add such a statement to the program that will print a nice error message. If the exception occurs, the program should quit.

---

### 13.3.5 String Exercises

In this laboratory exercise you will work with statically and dynamically allocated strings. The first new feature found in this program is the *str.strvar* declaration. The *str.strvar* data type lets you statically allocate storage for a string variable in the STATIC section of your program<sup>5</sup>. This data type takes a single parameter that specifies the maximum number of legal characters in the string variable. This data type sets aside the appropriate amount of storage for the string, initializes the maximum length field to the value passed as a parameter, and then initializes the string variable (*s1* in the example below) with the address of this newly allocated string. The *str.strvar* data type is very useful for declaring small strings in your STATIC section because it provides both declaration and allocation in a single statement.

This program uses *str.strvar* to allocate storage for a ten character string. When the program starts running, it requests that the user enter a string longer than ten characters to demonstrate the *ex.StringOverflow* exception. Finally, this program concludes by demonstrating how to access the individual characters in a string.

---

---

```

// Demonstration of strings in a program.

program StringLab;
#include("stdlib.hhf");

```

---

5. Note that *str.strvar* is legal *only* in the STATIC section. You can not use it in any of the other HLA variable declaration sections.

```

static

 s1: str.strvar(10);
 s2: string;

begin StringLab;

 try

 stdout.put("Enter a string longer than 10 characters: ");
 stdin.gets(s1);
 str.length(s1);
 stdout.put
 (
 "The string you entered was only ",
 (type uns32 eax),
 " characters long, "
 nl
 "try a longer string next time"
 nl
);

 exception(ex.StringOverflow)

 stdout.put("stdin.gets raised the ex.StringOverflow exception" nl);

 endtry;

// Use stdin.a_gets to read a string and allocate storage for it.
// Print the characters in the string one at a time after reading
// the string.
//
//
// There is something wrong with this code, can you fix it?

stdout.put(nl "Enter a string of any length: ");
stdin.a_gets();
mov(eax, s2);
mov(eax, ebx);
str.length(eax);
stdout.put
(
 "The string length was ",
 (type uns32 eax),
 nl,
 "The string you entered was",
 nl
);

while(eax > 0) do

 stdout.put((type char [ebx]), nl);
 dec(eax);
 inc(ebx);

endwhile;
stdout.newln();

```

```
end StringLab;
```

---

### Program 13.5 String Exercises Code

---

---

Exercise A: Compile this program and run it. Be sure to follow all directions provided in the program. Describe what the program does in your lab report.

Exercise B: There is a defect in the way this program handles dynamically allocated strings. Locate the defect and correct it. Include a copy of the corrected program with your lab report. Note that this program runs correctly; you will have to analyze the source code to find the defect.

---

### 13.3.6 String and Character Set Exercises

In this laboratory exercise you'll be working with a program that disassembles an input string. The program begins by reading the user's full name (first and last name). It then extracts the first and last names into separate strings. Although this is a relatively simple program, it demonstrates a very important concept in string manipulation. Most complex programs that manipulate strings need to break those strings down into their constituent parts. The techniques this program uses are the basis for much larger and more complex programs.

This program also demonstrates the use of character sets and character set expressions. In particular, note the following constant declaration in the program:

```
NonAlphaChars: cset := -AlphabeticChars - {#0};
```

The “-” operator, prefacing a character set, takes the *complement* of that set. The complement of a set contains all the characters that are *not* in that set. So “-AlphabeticChars” returns the set of all characters that are not alphabetic. The “- {#0}” component of the expression above removes the NUL character from the set of nonalphabetic characters. (Note that in this case the “-” operator is a binary operator denoting set difference.) This operation removes the NUL character from the set, not because it's an alphabetic character, but because the program uses the *NonAlphaChars* set to skip over characters while looking for the last name. If a last name is not present, this code needs to stop scanning once it encounters the end of the string. The #0 character always marks the end of an HLA string. By removing #0 from the *NonAlphaChars* set, the code that skips non-alphabetic characters will automatically stop if it encounters the end of the string.

---

---

```
// Demonstration of strings and character sets in a program.
```

```
program strcsetLab;
#include("stdlib.hhf");

const
 AlphabeticChars: cset := {'a'..'z', 'A'..'Z' };
 NonAlphaChars: cset := -AlphabeticChars - {#0};

var
 StartOfFirstName: uns32;
 LengthOfFirstName: uns32;
 StartOfLastName: uns32;
 LengthOfLastName: uns32;

 FullName: string;
 FirstName: string;
 LastName: string;
```

```

begin strcsetLab;

 // Read the full name from the user:

 stralloc(256); // Allocate storage for the string.
 mov(eax, FullName);

 stdout.put("Enter your full name (first, then last): ");
 stdin.get(FullName);

 // Skip over any leading spaces in the name:

 mov(FullName, ebx);
 mov(0, esi);
 while((type char [ebx+esi]) = ' ') do

 inc(esi);

 endwhile;

 // Okay, presumably we're at the beginning of the first
 // name. Find the end of it here:

 mov(esi, StartOfFirstName);
 mov(esi, LengthOfFirstName);
 while(cs.member((type char [ebx+esi]), AlphabeticChars)) do

 inc(esi);

 endwhile;
 sub(esi, LengthOfFirstName);
 neg(LengthOfFirstName);

 // Skip over any non-alphabetic characters

 while(cs.member((type char [ebx+esi]), NonAlphaChars)) do

 inc(esi);

 endwhile;

 // Okay, find the end of the last name:

 mov(esi, StartOfLastName);
 while(cs.member((type char [ebx+esi]), AlphabeticChars)) do

 inc(esi);

 endwhile;
 sub(StartOfLastName, esi);
 mov(esi, LengthOfLastName);

 // Extract the first and last names from the string:

 str.a_substr(FullName, StartOfFirstName, LengthOfFirstName);
 mov(eax, FirstName);

 str.a_substr(FullName, StartOfLastName, LengthOfLastName);
 mov(eax, LastName);

```

```

// Display the results:

stdout.put("First: ", FirstName, nl);
stdout.put("Last: ", LastName, nl);

// Clean up the allocated storage:

strfree(FullName);
strfree(FirstName);
strfree(LastName);

end strcsetLab;

```

---

---

### Program 13.6 String and Character Set Exercises Code

---

---

Exercise A: Compile and run this program. Describe the operation of the program and its output in your laboratory report.

Exercise B: This program uses statements like “while( *cs.member*( (type char [ebx+esi]), *AlphabeticChars* )) do” to loop while the current character in the string is a member of some character set. Explain why you cannot use the “IN” operator described in this chapter in place of the *cs.member* function. (Hint: if the reason isn’t obvious, trying changing the program and compiling it.)

The following sample program also demonstrates the synergy between strings and character sets in a program. This program reads a string from the user and converts that string into a character set (effectively removing duplicate characters from the string). It then displays the character set, the vowels, the consonants, and non-alphabetic characters found in the string. This program demonstrates some run-time character set functions (like intersection) as well as compile-time constant expressions. This program also demonstrates the new form of the IN operator in boolean expressions that this chapter introduces.

---

---

```

// Demonstration of character sets and strings in a program.

program strcsetLab2;
#include("stdlib.hhf");

const

 AlphabeticChars: cset := { 'a'..'z', 'A'..'Z' };

 Vowels: cset := {
 'a', 'e', 'i', 'o', 'u', 'y', 'w',
 'A', 'E', 'I', 'O', 'U', 'Y', 'W'
 };

 Consonants: cset := AlphabeticChars - Vowels;

var

 InputLine: string;
 InputSet: cset;
 VowelSet: cset;
 ConsonantSet: cset;
 NonAlphaSet: cset;

begin strcsetLab2;

```

```

repeat

 stdout.put("Enter a line of text: ");
 stdin.flushInput();
 stdin.a_gets();
 mov(eax, InputLine);
 stdout.put(nl, "The input line: '", InputLine, "'" nl nl);

 cs.strToCset(InputLine, InputSet);
 stdout.put("Characters on this line: '", InputSet, "'" nl);

 cs.cpy(InputSet, VowelSet);
 cs.intersection(Vowels, VowelSet);
 stdout.put("Vowels on this line: '", VowelSet, "'" nl);

 cs.cpy(InputSet, ConsonantSet);
 cs.intersection(Consonants, ConsonantSet);
 stdout.put("Consonants on this line: '", ConsonantSet, "'" nl);

 cs.cpy(InputSet, NonAlphaSet);
 cs.intersection(-AlphabeticChars, NonAlphaSet);
 stdout.put
 (
 "Nonalphabetic characters on this line: '",
 NonAlphaSet,
 "'"
 nl
);
);

repeat

 stdout.put
 (
 "Would you like to try another line of text? (Y/N): "
);
 stdin.flushInput();
 stdin.getc();

 until(al in { 'Y', 'y', 'N', 'n' });

until(al in { 'n', 'N' });

end strcsetLab2;

```

### Program 13.7 Character Classification Program

---

---

Exercise A: Compile and run this program. Describe its output and operation in your laboratory report.

Exercise B: Modify this program to display any decimal digit characters appearing in the input string. Compile and run the program to test its operation. Include the program listing in your laboratory report.

### 13.3.7 Console Array Exercise

Perhaps the most commonly encountered two-dimensional object a programmer encounters is the video display. The Windows console window, for example, is typically an 80x25 array of characters<sup>6</sup>. The HLA Standard Library console module provides various routines that let you manipulate the matrix of characters on the screen. In the previous chapter, for example, you saw how to use the *console.fillRect* routine to fill a rectangular region of the screen with a given character and attribute. This laboratory exercise demonstrates how to extract a rectangular region from the screen and how to redraw that text taken from the screen. This sample program also demonstrates how to write an arbitrary matrix of text to the screen.

This program calls the HLA Standard Library *console.getRect* routine to read the data from a rectangular portion of the screen into a local array of characters. This program uses *console.getRect* to save the screen display upon entry into the program. In addition to *console.getRect*, this program uses *console.putRect* to rapidly write the contents of a two-dimensional array of characters to the console display. For example, this program calls *console.putRect* to restore the original screen display when this program quits.

Between saving and restoring the original screen contents, this program moves a sequence of asterisks around in a local 80x25 array of characters and (after each movement) copies the characters to the video display. This is an extremely slow way to redraw the screen; however, today's machines are so fast that this inefficiency works to this program's advantage - it's a built-in governor that slows down the program so you can see it work.

---

```
// Demonstration of arrays in a program.
//
// This code demonstrates how to access elements of
// a two-dimensional array. It also demonstrates how to
// use the console.getRect and console.putRect routines.

program consoleArrayLab;
#include("stdlib.hhf");

const
 NumCols := 80;
 NumRows := 25;

type
 screen: char[NumRows, NumCols];

var

 column: uns32;
 row: uns32;
 SnapShot: screen;

static

 playingField: screen := [NumRows dup [NumCols dup [' ']]];

begin consoleArrayLab;

 console.getRect(0, 0, NumRows-1, NumCols-1, (type char SnapShot));
 console.cls();

 // Fill an 80x24 region of the screen with a blue background.
```

---

6. Actually, under Windows the console window can be made various different sizes. 80x25, however, is the default size.

```

// Set the foreground attribute to yellow:

console.fillRect
(
 0,
 0,
 NumRows-1,
 NumCols-1,
 '\ ',
 win.bgnd_Blue | win.fgnd_Yellow
);

// Play the "game". Repeat the nested loops once for each
// row on the screen.

for(mov(0, row); row < NumRows; inc(row)) do

 // For each row, draw a row of asterisks across the screen
 // one character at a time by storing the asterisk into
 // the "playingField" array and then copying this array to
 // the screen.

 for(mov(0, column); column < NumCols; inc(column)) do

 intmul(NumCols, row, ebx);
 add(column, ebx);
 mov('*', playingField[ebx]);
 console.putRect
 (
 0,
 0,
 NumRows-1,
 NumCols-1,
 (type byte playingField)
);
 endfor;

 // Now erase the row of asterisks one character at a time
 // by overwriting the asterisks in "playingField" and drawing
 // the matrix to the screen after blotting out each character.

 for(mov(0, column); column < NumCols; inc(column)) do

 intmul(NumCols, row, ebx);
 add(column, ebx);
 mov('\ ', playingField[ebx]);
 console.putRect
 (
 0,
 0,
 NumRows-1,
 NumCols-1,
 (type byte playingField)
);
 endfor;

endfor;

stdout.put("Press Enter to continue: ");

```

```

stdin.readLine();
console.cls();
console.putRect
(
 0,
 0,
 NumRows-1,
 NumCols-1, (type byte SnapShot)
);
console.gotoxy(NumRows-1, 0);

end consoleArrayLab;

```

### Program 13.8 Console Matrix Program

---

Exercise A: Compile and run this program. Describe its operation and output in your laboratory report.

Exercise B: Change the NumCols and NumRows constants so that the program operates in a 40x20 window rather than an 80x25 window. Compile and rerun the program and verify that it still works properly. Include the source code for the modified program in your lab report.

Exercise C: Modify the program so that it draws the string of asterisks from top to bottom, then left to right rather than from left to right, then top to bottom. Include the source code to the modified program in your lab report.

---

### 13.3.8 Multidimensional Array Exercises

The program for this exercise demonstrates an *outer product* computation. An outer product is an operation that takes an N-element array and an M-element array and produces an NxM matrix with cell [i,j] containing the value specified by some function  $f(\text{Narray}[i], \text{Marray}[j])$  for all values  $0 \leq i < N$  and  $0 \leq j < M$ . The classic example of an outer product is the multiplication table you learned in elementary school (where the function is the multiplication operation). The program in this example computes an addition table by summing the elements of the two arrays together.

### Program 13.9 Addition Table Generator

---

Exercise A: Compile and run this program. Describe its output in your lab report.

Exercise B: Modify the NumRows and NumCols constants in this program to generate a 5x6 array rather than a 10x10 array. Recompile and run the program. Describe the output in your lab report.

Exercise C: (optional) Modify the program to use the line drawing graphic characters (see appendix B) rather than the ASCII dash, vertical bar, and hyphen characters.

### 13.3.9 Console Attributes Laboratory Exercise

The program in this laboratory exercise demonstrates the *console.info* call that returns various bits of interesting information about the Windows console device. This information comes in handy when writing console applications that work regardless of the size of the console window. For more information about the information that *console.info* returns, please see the definition of the windows console screen buffer info record in the "WIN32.HHF" header file.

Exercise A: Compile and run this program. Describe the console metrics for your particular system in your laboratory report.

Exercise B: Modify this program to save the screen text upon entry into the program and restore the screen when this program exits. Use the cursor position in the *csbi* record to restore the cursor to its original position upon program exit. Include the modified source code with your lab report.

### 13.3.10 Records, Arrays, and Pointers Laboratory Exercise

The following program demonstrates dynamic allocation of an array of records. It also demonstrates enumerated data types and record constants. This program asks the user to specify some number of students and then it inputs the data for the specified students and stores the data into the dynamic array it creates.

---

---

```

// Demonstration of a pointer to an array of records.
// This is a small student database program the lets the
// user input a bunch of student names and it prints a report
// after the data is entered.

### Program 13.11 Student Database Program

---

**Exercise A:** Compile and run this program. Describe its output in your lab report.

**Exercise B:** Modify this program to let the user specify that only those students in a single major be printed (by specifying a single letter to select the major- see the body of the code for details on this). Provide an "A)l" option that prints the full report as the program currently does.

---

### 13.3.11 Separate Compilation Exercises

In this laboratory exercise you will compile a multipart program and link it into a single executable file. You will also construct a makefile for the project and test the workings of the makefile by making minor modifications to the program. Finally, you will split the main program into two pieces and move one section into its own module.

The following listings provide the necessary source code for this program. Note that these modules can be found in the CH05 subdirectory of the accompanying CD. The main program is lab5\_1.hla; the header file is lab5\_1.hhf; the first unit can be found in lab5\_1db.hla; the second unit is in the file lab5\_1unita.hla.

### Program 13.15 The Second Unit Need by this Lab Exercise (DBunit.hla)

---

Exercise A: Compile this program with the following HLA command.

```
hla mainPgm lnitb DBunit
```

Run the program a few times and learn how to use it. This is a small (trivial) little database program that stores information about a private CD collection (for brevity, it only has 10 CDs in the database). When the user runs the program it will ask if they want to look up a CD by artist or by title. As you can see in the sample database, "Boston" is both a title and an artist. "Imaginos" is an example of a title. Run the program and

specify these values for artist and title to familiarize yourself with this code. If possible, include a printout of the program's operation with your lab report, otherwise describe the output in your lab report.

Exercise B: Determine the dependencies between these files. Write a makefile for this code. Include the makefile with your lab report. Verify that the makefile works properly by changing each of the files and then running the make program after each modification.

Exercise C: The *GetYorN* and *GetCinSet* procedures in the main program really belong in their own unit. Move these subroutines to the unit *InputUnit* in the file *inputunit.hla*. Create a header file named *InputUnit.hhf* to contain the external declarations. Modify your makefile to accommodate these changes. Recompile the system and verify that it still works. Include the modified source code and makefile in your lab report.

### 13.3.12 The HLA (Pseudo) Random Number Unit

In this laboratory exercise, you will test the quality of the two HLA random number generators. The following program code provides a simple test by plotting asterisks at random positions on the screen. This program works by choosing two random numbers, one between zero and 79, the other between zero and 23. Then the program uses the *console.puts* function to print a single asterisk at the (X,Y) coordinate on the screen specified by these two random numbers. After 10,000 iterations of this process the program stops and lets you observe the result. **Note:** since random number generators generate random numbers, you should not expect this program to fill the entire screen with asterisks in only 10,000 iterations.

```

program testRandom;
#include("stdlib.hhf");

begin testRandom;

 console.cls();
 mov(10_000, ecx);
 repeat

 // Generate a random X-coordinate
 // using rand.range.

 rand.range(0, 79);
 mov(eax, ebx); // Save the X-coordinate for now.

 // Generate a random Y-coordinate
 // using rand.urange.

 rand.urange(0, 23);

 // Print an asterisk at
 // the specified coordinate on the screen.

 console.puts(ax, bx, "*");

 // Repeat this 10,000 times to get
 // a good distribution of values.

 dec(ecx);

 until(@z);

 // Position the cursor at the bottom of the
 // screen so we can observe the results.

```

```

 console.gotoxy(24, 0);

end testRandom;

```

### Program 13.16 Screen Plot Test of the HLA Random Number Generators

Exercise A: Run this program and note how many “holes” are left unfilled on the screen. If possible, make a print-out of the screen to include with your lab manual. Compare the result of your output with another student’s output for this exercise. Did they get the same output as you? Explain why or why not in your lab report.

Exercise B: Add the statement “`rand.randomize()`” as the first statement in this program. Recompile and run the program. Compare this output to the output from Exercise A. Compare this output to that of another student in your class for this exercise. Did they get the same output as you? Explain why or why not in your lab report.

Exercise C: Remove the call to `rand.randomize` that you inserted in Exercise B. Bump up the number of iterations to 25,000. Does the program fill the screen with asterisks? Determine to the nearest 100, the minimum number of iterations it takes to completely fill the screen with asterisks.

### 13.3.13 File I/O in HLA

The HLA Standard Library provides a file input/output module that makes writing data to a file and reading data from a file almost as easy as working with the standard output and standard input devices. In this laboratory exercise you will discover how easy it is to read and write file data in HLA.

The following program code opens a new file, writes some data to it, closes that file, reopens it for reading, reads the data from the file, displays the data to the standard output, and finally closes the file.

```

program fileDemo;
#include("stdlib.hhf");

var
 fileHandle: dword;
 s: string;

begin fileDemo;

 // Note the use of instruction composition to
 // store the return value from stralloc (which
 // is in EAX) directly into s.

 mov(stralloc(256), s);

 // Open a brand new file and write some
 // data to it. Note that the filename "x.txt"
 // must not already exist or the fileio.OpenNew
 // call will raise an exception.

 mov(fileio.openNew("x.txt"), fileHandle);

 fileio.put
 (
 fileHandle,
 "Data Written to a text file" nl
)

```

```

 "-----" nl
 nl
);

for(mov(-5, ebx); (type int32 ebx) <= 5; inc(ebx)) do

 fileio.put(fileHandle, "ebx=", (type int32 ebx), nl);

endfor;

// Done writing the data to the file, close it.

fileio.close(fileHandle);

// Reopen the file, this time for reading:

mov(fileio.open("x.txt", win.GENERIC_READ), fileHandle);

// Read the data from the file and write it to the
// standard output device:

while(!fileio.eof(fileHandle)) do

 fileio.gets(fileHandle, s);
 stdout.put(s, nl);

endwhile;
fileio.close(fileHandle);
strfree(s);

end fileDemo;

```

---

---

### Program 13.17 HLA File I/O Demonstration

---

---

Exercise A: Compile and run this program. Note that this program creates a text file “x.txt” on your disk. Include a printout of this file with your laboratory report.

Exercise B: Modify this program so that it reads the filename from the user and opens the specified file. Compile and test the modified program. Include a printout of the program with your laboratory report. **Warning: when running this program, be careful not to specify the name of an existing file on your disk.** Remember, this program will delete any pre-existing data in the file you specify.

Exercise C: Split this program into two separate programs. The first program should write the data to the text file, the second program should read and display the data in the text file. Compile and run the programs to verify proper operation. Include the source listings of these two programs with your lab reports.

### Program 13.18 Instruction Timing Code (TimeArithmetic.hla)

---

Exercise A: Compile and run this program. Measure the times required by each instruction sequence in the program. Describe the differences in timing in your laboratory report.

Exercise B: Simply dividing the time measured for each section doesn't accurately compute the time for each instruction because you're also measuring the time required by the FOR loop as well as the MOV instruction and any other instructions appearing in the loop (that aren't the ADD, INTMUL, IMUL, IDIV, or SHL instructions). To get a better result, you should time an empty loop and subtract the time for a loop without the specified instruction (i.e., remove the ADD instruction from the first code section in Program 13.18 above and use the resulting code as your base code).

Exercise C: Modify the program so that it computes the time required by an empty loop. Run this program and report the results in your lab report. Subtract this time from your other results to get results that are closer to reality.

## 13.3.15 Using the RDTSC Instruction to Time a Code Sequence

One problem with timing statements as done in the previous section is that the time you obtain is extremely inaccurate. This is because Windows periodically interrupts the code, effectively freezing it in its tracks for a few moments, while other activities take place. Since your stopwatch is still running while the program is frozen, your timings will not accurately reflect the time it takes to execute these instructions.

On Pentium and later processors, Intel added the RDTSC (ReaD Time Stamp Counter) instruction to help software engineers better time certain instruction sequences. The Time Stamp Counter is a 64-bit internal register that the CPU increments by one on each clock cycle. Executing the RDTSC instruction copies this 64-bit value into the EDX:EAX register pair. By reading the value of the Time Stamp Counter before and after an instruction sequence, then computing the difference between these two values, you can effectively measure the time of some instructions in clock cycles.

There is one major problem with the RDTSC instruction: not all CPUs support this instruction. Intel CPUs earlier than the Pentium do not support this instruction. Furthermore, certain non-Intel CPUs do not support this instruction either. If you happen to have such a CPU, executing the RDTSC instruction will raise an "invalid instruction" exception. If this is the case for your machine, then simply skip this lab exercise.

There are two additional, but minor, problems with the RDTSC instruction. First, it produces a 64-bit result. Since we've only seen how to do 32-bit arithmetic on the 80x86, computing the difference of the two 64-bit values will prove to be difficult<sup>7</sup>. We can solve this problem by simply ignoring the H.O. DWORD of the 64-bit result that RDTSC returns. Once in a while we will get a nonsensical result (generally negative), but as long as we're willing to ignore such results and re-run the program to get correct results, we'll do fine. Note that the chapter on Advanced Arithmetic discusses extended precision arithmetic, for those who want to learn how to manipulate 64-bit (or larger) integer values.

The second problem with using RDTSC is that it is still possible for an interrupt to occur in the middle of the instruction sequence we're timing. This will produce inaccurate results. Fortunately, it is very rare for

---

7. Actually, we could use the FILD and FIST instructions on the FPU, but that won't prove to be necessary.

an interrupt to occur in the middle of a short instruction sequence, so it is unlikely that this will affect the results you get. To be sure this problem doesn't occur, all you've got to do is execute your program twice and verify that the results you obtain are similar; if one value is off by an order of magnitude, or more, then you should re-run the program a few more times.

### Program 13.19 Timing Code Using RDTSC

---

---

Exercise A: Compile and run this program. Compare the times produced by this program against the previous exercise (to compute time from clock cycles, multiply by one billion and divide by the clock frequency of your system). Describe the differences in timing in your laboratory report.

Exercise B: The RDTSC instruction is quite slow compared to many other instructions. Devise a short program to test the execution time of the RDTSC instruction. Report the result of this timing in your lab report.

---

### 13.3.16 Timing Floating Point Instructions

Floating point instructions tend to execute more slowly than their integer counterparts. In this laboratory exercise you will compute the running time of the FADD, FSUB, FMUL, and FDIV instructions. This code uses the RDTSC instruction. If your CPU does not support this instruction, modify the code to use the timing loops in the first lab exercise in this chapter and time your code that way.

### Program 13.20 Timing FADD, FSUB, FMUL, and FDIV

---

---

Exercise A: Compile and run this program. Compare the cycles counts (or times) produced by this program against the previous exercise. Describe the differences in timing in your laboratory report.

Exercise B: Floating point timings are very data dependent. Modify the program by changing the constants around. Retry the computations with constants that are close to one another and more widely separated.

rated than in this example. (Hint: create a CONST definition for the two constants this program uses in order to facilitate the changes; can you see the benefit of using CONST here?)

Exercise C: Modify the program so that the floating point control register specifies the 64-bit rounding mode (vs. 53 bits or 24 bits). Re-run the program and check the timings. Then set the round to 53 bits and 24 bits. Compare the results.

Exercise D: Modify the program to factor out the time required by the RDTSC instruction. Report your results in your lab report.

### 13.3.17 Table Lookup Exercise

The following laboratory exercise computes a sequence of sine values using table lookup and using the FPU FSIN instruction so you can see the difference in timing between the two techniques. Like the previous two exercises, this code uses the RDTSC instruction to time the sequences. If your CPU does not support the RDTSC instruction, rewrite the code to use surrounding loops as used in the first laboratory exercise of this chapter.

### Program 13.21 FSIN vs. Table Lookup

---

Exercise A: Compile and run this program. Compare the cycles counts between the two methods for computing SIN. Describe the differences in timing and comment on these differences in your laboratory report.

Exercise B: In one respect, this program cheats. The first loop in the program “touches” all the memory locations in the *sines* table so that they are all loaded into the cache before the code actually times the execution of the lookup table code. Remove this initial loop and rerun the program. Comment on the difference in timing. Comment on the effectiveness of the cache. Is it worthwhile to use a lookup table if you rarely access that table (and it’s data is not in cache)? Justify your answer.

## Volume Four: Intermediate Assembly Language

This volume completes the material traditionally taught in a 10 or 15 week course on assembly language programming (the difference between such courses is how many chapters they've skipped up to this point). This volume also completes this text's discussion of the essential material you need to know to start using assembly language effectively. Although there is still much for you to learn, after you complete this chapter any further study of assembly language tends to be more specialized. In any case, mastery of the material up to the end of this volume is an important milestone. Once you absorb and are able to apply this material, you can start calling yourself an "Assembly Language Programmer."

- Chapter One:    Advanced High Level Control Structures I
- This chapter completes the discussion of HLA's high level control structures. It completely discusses TRY..ENDTRY and introduces several new high level control structures.
- Chapter Two:    Low Level Control Structures
- This chapter discusses the "real" way to do control structures, using "pure" assembly language. This is a very important chapter; you cannot call yourself an assembly language programmer if you haven't mastered the low-level control structures.
- Chapter Three:  Intermediate Procedures
- This chapter extends the information on procedures found in the previous volume. This chapter discusses some of the low-level implementation details of procedures and describes how to call procedures and pass parameters using "pure" assembly language.
- Chapter Four:   Advanced Arithmetic
- This chapter discusses multiprecision and binary coded decimal arithmetic. It also describes how to input and output very large values (code included!).
- Chapter Five:   Bit Manipulation
- This chapter discusses bit operations in assembly language. You'll learn how to deal with packed data, insert and extract bit strings, count bits in an operand, and do all other sorts of bit-related stuff.
- Chapter Six:    The String Instructions
- This chapter discusses the 80x86 string instructions which are convenient for manipulating large blocks of memory.

**Volume Four:**

**Intermediate Assembly Language**

Chapter Seven: The HLA Compile-Time Language

This chapter begins the discussion of one of HLA's most powerful features - the HLA compile time language. In this chapter you'll learn about conditional compilation, compile-time loops, compile-time functions, generating tables, and lots of other features that make assembly language programming easier.

Chapter Eight: Macros

This chapter continues the discussion of the HLA compile-time language with a discussion of one of HLA's most powerful features - the HLA macro processor. In this chapter you'll learn how to extend the HLA language and do all those neat things that the HLA Standard Library provides.

Chapter Nine: Domain Specific Languages

This chapter describes how to design and implement your own programming language inside HLA.

Chapter Ten: Classes

This chapter describes classes and object-oriented programming in HLA.

Chapter Eleven: The MMX Instruction Set

This chapter describes the special MMX multimedia extensions on the Pentium and later chips.

Chapter Twelve Mixed Language Programming

This chapter describes how to call HLA procedures and access HLA data from other languages.

Chapter Thirteen: Questions, Projects, and Laboratory Exercises

Test your knowledge and see how well you've learned the material in this chapter!

# Advanced High Level Control Structures Chapter One

---

## 1.1 Chapter Overview

Volume One introduced some basic HLA control structures like the IF and WHILE statements (see “Some Basic HLA Control Structures” on page 21.). This section elaborates on some of those control structures (discussing features that were a little too advanced to present in Volume One) and it introduces the remaining high level language control structures that HLA provides.

This includes a full discussion of HLA’s boolean expressions, the TRY..ENDTRY statement, the RAISE statement, the BEGIN..END/EXIT/EXITIF statements, and the SWITCH/CASE/ENDSWITCH statement the HLA Standard Library provides.

---

## 1.2 Conjunction, Disjunction, and Negation in Boolean Expressions

One obvious omission in HLA’s high level control structures is the ability to use conjunction (logical AND), disjunction (logical OR), and negation (logical NOT) in run-time boolean expressions. This omission, however, has been in this text, not in the HLA language. HLA does provide these facilities, this section will describe their use.

HLA uses the “&&” operator to denote logical AND in a run-time boolean expression. This is a dyadic (two-operand) operator and the two operands must be legal run-time boolean expressions. This operator evaluates true if both operands evaluate to true. Example:

```
if(eax > 0 && ch = 'a') then

 mov(eax, ebx);
 mov(' ', ch);

endif;
```

The two MOV statements above execute only if EAX is greater than zero *and* CH is equal to the character ‘a’. If either of these conditions is false, then program execution skips over the two MOV instructions.

Note that the expressions on either side of the “&&” operator may be any expression that is legal in an IF statement, these expressions don’t have to be comparisons using one of the relational operators. For example, the following are all legal expressions:

```
@z && al in 5..10
al in { 'a'..'z' } && ebx
boolVar && !eax
!fileio.eof(fileHandle) && fileio.getc(fileHandle) <> ' '
```

HLA uses short circuit evaluation when compiling the “&&” operator. If the left-most operand evaluates false, then the code that HLA generates does not bother evaluating the second operand (since the whole expression must be false at that point). Therefore, in the last expression above, the code will not execute the call to *fileio.getc* if the file pointer is currently pointing at the end of the file.

Note that an expression like “*eax < 0 && ebx <> eax*” is itself a legal boolean expression and, therefore, may appear as the left or right operand of the “&&” operator. Therefore, expressions like the following are perfectly legal:

```
eax < 0 && ebx <> eax && !ecx
```

The “&&” operator is left associative, so the code that HLA generates evaluates the expression above in a left-to-right fashion. Note that if EAX is less than zero, the code will not test either of the remaining expres-

sions. Likewise, if EAX is not less than zero but EBX is equal to EAX, this code will not evaluate the third expression since the whole expression is false regardless of ECX's value.

HLA uses the “||” operator to denote disjunction (logical OR) in a run-time boolean expression. Like the “&&” operator, this operator expects two otherwise legal run-time boolean expressions as operands. This operator evaluates true if either (or both) operands evaluate true. Like the “&&” operator, the disjunction operator uses short-circuit evaluation. If the left operand evaluates true, then the code that HLA generates doesn't bother to test the value of the second operand. Instead, the code will transfer to the location that handles the situation when the boolean expression evaluates true. Examples of legal expressions using the “||” operator:

```
@z || al = 10
al in {'a'..'z'} || ebx
!boolVar || eax
```

As for the “&&” operator, the disjunction operator is left associative so multiple instances of the “||” operator may appear within the same expression. Should this be the case, the code that HLA generates will evaluate the expressions from left to right, e.g.,

```
eax < 0 || ebx <> eax || !ecx
```

The code above executes if either EAX is less than zero, EBX does not equal EAX, or ECX is zero. Note that if the first comparison is true, the code doesn't bother testing the other conditions. Likewise, if the first comparison is false and the second is true, the code doesn't bother checking to see if ECX is zero. The check for ECX equal to zero only occurs if the first two comparisons are false.

If both the conjunction and disjunction operators appear in the same expression then the “&&” operator takes precedence over the “||” operator. Consider the following expression:

```
eax < 0 || ebx <> eax && !ecx
```

The code HLA generates evaluates this as

```
eax < 0 || (ebx <> eax && !ecx)
```

If EAX is less than zero, then the code HLA generates does not bother to check the remainder of the expression, the entire expression evaluates true. However, if EAX is not less than zero, then both of the following conditions must evaluate true in order for the overall expression to evaluate true.

HLA allows you to use parentheses to surround subexpressions involving “&&” and “||” if you need to adjust the precedence of the operators. Consider the following expression:

```
(eax < 0 || ebx <> eax) && !ecx
```

For this expression to evaluate true, ECX must contain zero and either EAX must be less than zero or EBX must not equal EAX. Contrast this to the result obtained without the parentheses.

As you saw in Volume One (as well as in examples in this chapter), HLA uses the “!” operator to denote logical negation. However, the “!” operator may only prefix a register or boolean variable; you may not use it as part of a larger expression (e.g., “!eax < 0”). To achieve logical negative of an existing boolean expression you must surround that expression with parentheses and prefix the parentheses with the “!” operator, e.g.,

```
!(eax < 0)
```

This expression evaluates true if EAX is not less than zero.

The logical not operator is primarily useful for surrounding complex expressions involving the conjunction and disjunction operators. While it is occasionally useful for short expressions like the one above, it's usually easier (and more readable) to simply state the logic directly rather than convolute it with the logical not operator.

Note that HLA's “!” and “&” operators are distinct from “||” and “&&” and have completely different meanings. See the chapter on the HLA Run-Time Language in this volume for details.

### 1.3 TRY..ENDTRY

Volume One discusses the TRY..ENDTRY statement, but does not fully discuss all of the features available. This section will complete the discussion of TRY..ENDTRY and discuss some problems that could occur when you use this statement.

As you may recall, the TRY..ENDTRY statement surrounds a block of statements in order to capture any exceptions that occur during the execution of those statements. The system raises exceptions in one of three ways: through a hardware fault (such as a divide by zero error), through an operating system generated exception (e.g., the *ex.InvalidHandle* exception that Windows raises), or through the execution of the HLA RAISE statement. You can write an exception handler to intercept specific exceptions using the EXCEPTION clause. The following program provides a typical example of the use of this statement:

---

```

program testBadInput;
#include("stdlib.hhf");

static
 u: uns16;

begin testBadInput;

 try

 stdout.put("Enter an unsigned integer:");
 stdin.get(u);
 stdout.put("You entered: ", u, nl);

 exception(ex.ConversionError)

 stdout.put("Your input contained illegal characters" nl);

 exception(ex.ValueOutOfRange)

 stdout.put("The value was too large" nl);

 endtry;

end testBadInput;

```

---

#### Program 1.1 TRY..ENDTRY Example

---

HLA calls the statements between the TRY clause and the first EXCEPTION clause the *protected* statements. If an exception occurs within the protected statements, then the program will scan through each of the exceptions and compare the value of the current exception against the value in the parentheses after each of the EXCEPTION clauses<sup>1</sup>. This exception value is simply an *uns32* value. The value in the parentheses after each EXCEPTION clause, therefore, must be an unsigned 32-bit value. The HLA “excepts.hhf” header file predefines several exception constants; for example, *ex.ConversionError* is equal to five and *ex.ValueOutOfRange* is equal to three. Other than it would be an incredibly bad style violation, you could substitute “exception(5)” and “exception(3)” for the two EXCEPTION clauses above.

---

1. Note that HLA loads this value into the EAX register. So upon entry into an EXCEPTION clause, EAX contains the exception number.

---

### 1.3.1 Nesting TRY..ENDTRY Statements

If the program scans through all the exception clauses in a TRY..ENDTRY statement and does not match the current exception value, then the program searches through the EXCEPTION clauses of a *dynamically nested* TRY..ENDTRY block in an attempt to find an appropriate exception handler. For example, consider the following code:

---

```

program testBadInput2;
#include("stdlib.hhf");

static
 u: uns16;

begin testBadInput2;

 try

 try

 stdout.put("Enter an unsigned integer:");
 stdin.get(u);
 stdout.put("You entered: ", u, nl);

 exception(ex.ConversionError)

 stdout.put("Your input contained illegal characters" nl);

 endtry;

 stdout.put("Input did not fail due to a value out of range" nl);

 exception(ex.ValueOutOfRange)

 stdout.put("The value was too large" nl);

 endtry;

 end testBadInput2;

```

---

#### Program 1.2 Nested TRY..ENDTRY Statements

---

In this example one TRY statement is nested inside another. During the execution of the *stdin.get* statement, if the user enters a value greater than four billion and some change, then *stdin.get* will raise the *ex.ValueOutOfRange* exception. When the HLA run-time system receives this exception, it first searches through all the EXCEPTION clauses in the TRY..ENDTRY statement immediately surrounding the statement that raised the exception (this would be the nested TRY..ENDTRY in the example above). If the HLA run-time system fails to locate an exception handler for *ex.ValueOutOfRange* then it checks to see if the current TRY..ENDTRY is nested inside another TRY..ENDTRY (as is the case in Program 1.2). If so, the HLA run-time system searches for the appropriate EXCEPTION clause in that TRY..ENDTRY statement. Within this TRY..ENDTRY block the program finds an appropriate exception handler, so control transfers to the statements after the "exception( ex.ValueOutOfRange )" clause.

After leaving a TRY..ENDTRY block, the HLA run-time system no longer considers that block active and will not search through its list of exceptions when the program raises an exception<sup>2</sup>. This allows you to handle the same exception differently in different parts of the program.

If two nested TRY..ENDTRY statements handle the same exception, and the program raises an exception while executing in the nested TRY..ENDTRY sequence, then HLA transfers control directly to the exception handler provided by the innermost TRY..ENDTRY block. HLA does not automatically transfer control to the exception handler provided by the outer TRY..ENDTRY sequence.

If the program raises an exception for which there is no appropriate EXCEPTION clause active, control transfers to the HLA run-time system. It will stop the program and print an appropriate error message.

In the previous example (Program 1.2) the second TRY..ENDTRY statement was statically nested inside the enclosing TRY..ENDTRY statement<sup>3</sup>. As mentioned without comment earlier, if the most recently activated TRY..ENDTRY statement does not handle a specific exception, the program will search through the EXCEPTION clauses of any dynamically nesting TRY..ENDTRY blocks. Dynamic nesting does not require the nested TRY..ENDTRY block to physically appear within the enclosing TRY..ENDTRY statement. Instead, control could transfer from inside the enclosing TRY..ENDTRY protected block to some other point in the program. Execution of a TRY..ENDTRY statement at that other point dynamically nests the two TRY statements. Although you will see lots of ways to dynamically nest code a little later in this chapter, there is one method you are familiar with that will let you dynamically nest these statements: the procedure call. The following program provides yet another example of the sample programs in this section, this example demonstrates dynamic nesting via a procedure call:

---

```

program testBadInput3;
#include("stdlib.hhf");

 procedure getUns;
 static
 u: uns16;

 begin getUns;

 try

 stdout.put("Enter an unsigned integer:");
 stdin.get(u);
 stdout.put("You entered: ", u, nl);

 exception(ex.ConversionError)

 stdout.put("Your input contained illegal characters" nl);

 endtry;

 end getUns;

begin testBadInput3;

 try

 getUns();
 stdout.put("Input did not fail due to a value out of range" nl);

```

---

2. Unless, of course, the program re-enters the TRY..ENDTRY block via a loop or other control structure.

3. Statically nested means that one statement is physically nested within another in the source code. When we say one statement is nested within another, this typically means that the statement is statically nested within the other statement.

```

exception(ex.ValueOutOfRange)

 stdout.put("The value was too large" nl);

endtry;

end testBadInput3;

```

---

### Program 1.3 Dynamic Nesting of TRY..ENDTRY Statements

---

In Program 1.3 the main program executes the TRY statement that activates a value out of range exception handler, then it calls the *getUns* procedure. Inside the *getUns* procedure, the program executes a second TRY statement. This dynamically nests the TRY inside the TRY of the main program. Because the main program has not yet encountered its ENDTRY, the TRY..ENDTRY block in the main program is still active. However, upon execution of the TRY statement in *getUns*, the nested TRY..ENDTRY block takes precedence. If an exception occurs inside the *stdin.get* procedure, control transfers to the most recently activated TRY..ENDTRY block of statements and the program scans through the EXCEPTION clauses looking for a match to the current exception value. In the program above, if the exception is a conversion error exception, then the exception handler inside *getUns* will handle the error and print an appropriate message. After the execution of the exception handler, the program falls through to the bottom of *getUns* and it returns to the main program and prints the message "Input did not fail due to a value out of range". Note that if a nested exception handler processes an exception, the program does not automatically reraise this exception in other active TRY..ENDTRY blocks, even if they handle that same exception (*ex.ConversionError*, in this case).

Suppose, however, that *stdin.get* raises the *ex.ValueOutOfRange* exception rather than the *ex.ConversionError* exception. Since the TRY..ENDTRY statement inside *getUns* does not handle this exception, the program will search through the exception list of the enclosing TRY..ENDTRY statement. Since this statement is in the main program, the exception will cause the program to automatically return from the *getUns* procedure. Since the program will find the value out of range exception handler in the main program, it transfers control directly to the exception handler. Note that the program will not print the string "Input did not fail due to a value out of range" since control transfers directly from *stdin.get* to the exception handler.

---

## 1.3.2 The UNPROTECTED Clause in a TRY..ENDTRY Statement

Whenever a program executes the TRY clause, it preserves the current exception environment and sets up the system to transfer control to the EXCEPTION clauses within that TRY..ENDTRY statement should an exception occur. If the program successfully completes the execution of a TRY..ENDTRY protected block, the program restores the original exception environment and control transfers to the first statement beyond the ENDTRY clause. This last step, restoring the execution environment, is very important. If the program skips this step, any future exceptions will transfer control to this TRY..ENDTRY statement even though the program has already left the TRY..ENDTRY block. The following program demonstrates this problem:

---

```

program testBadInput4;
#include("stdlib.hhf");

static
 input: uns32;

begin testBadInput4;

 // This forever loop repeats until the user enters
 // a good integer and the BREAK statement below
 // exits the loop.

```

```

forever

 try

 stdout.put("Enter an integer value: ");
 stdin.get(input);
 stdout.put("The first input value was: ", input, nl);
 break;

 exception(ex.ValueOutOfRange)

 stdout.put("The value was too large, reenter." nl);

 exception(ex.ConversionError)

 stdout.put("The input contained illegal characters, reenter." nl);

 endtry;

endfor;

// Note that the following code is outside the loop and there
// is no TRY..ENDTRY statement protecting this code.

stdout.put("Enter another number: ");
stdin.get(input);
stdout.put("The new number is: ", input, nl);

end testBadInput4;

```

---

#### Program 1.4 Improperly Exiting a TRY..ENDTRY Statement

---

This example attempts to create a robust input system by putting a loop around the TRY..ENDTRY statement and forcing the user to reenter the data if the *stdin.get* routine raises an exception (because of bad input data). While this is a good idea, there is a big problem with this implementation: the BREAK statement immediately exits the FOREVER..ENDFOR loop without first restoring the exception environment. Therefore, when the program executes the second *stdin.get* statement, at the bottom of the program, the HLA exception handling code still thinks that it's inside the TRY..ENDTRY block. If an exception occurs, HLA transfers control back into the TRY..ENDTRY statement looking for an appropriate exception handler. Assuming the exception was *ex.ValueOutOfRange* or *ex.ConversionError*, Program 1.4 will print an appropriate error message *and then force the user to reenter the first value*. This isn't desirable.

Transferring control to the wrong TRY..ENDTRY exception handlers is only part of the problem. Another big problem with the code in Program 1.4 has to do with the way HLA preserves and restores the exception environment: specifically, HLA saves the old execution environment information on the stack. If you exit a TRY..ENDTRY without restoring the exception environment, this leaves garbage on the stack (the old execution environment information) and this extra data on the stack could cause your program to malfunction.

Although it is quite clear that a program should not exit from a TRY..ENDTRY statement in the manner that Program 1.4 uses, it would be nice if you could use a loop around a TRY..ENDTRY block to force the re-entry of bad data as this program attempts to do. To allow for this, HLA's TRY..ENDTRY provides an UNPROTECTED section. Consider the following program code:

---

```

program testBadInput5;
#include("stdlib.hhf");

```

```

static
 input: uns32;

begin testBadInput5;

 // This forever loop repeats until the user enters
 // a good integer and the BREAK statement below
 // exits the loop. Note that the BREAK statement
 // appears in an UNPROTECTED section of the TRY..ENDTRY
 // statement.

 forever

 try

 stdout.put("Enter an integer value: ");
 stdin.get(input);
 stdout.put("The first input value was: ", input, nl);

 unprotected

 break;

 exception(ex.ValueOutOfRange)

 stdout.put("The value was too large, reenter." nl);

 exception(ex.ConversionError)

 stdout.put("The input contained illegal characters, reenter." nl);

 endtry;

 endfor;

 // Note that the following code is outside the loop and there
 // is no TRY..ENDTRY statement protecting this code.

 stdout.put("Enter another number: ");
 stdin.get(input);
 stdout.put("The new number is: ", input, nl);

end testBadInput5;

```

---

---

### Program 1.5 The TRY..ENDTRY UNPROTECTED Section

---

---

Whenever the TRY..ENDTRY statement hits the UNPROTECTED clause, it immediately restores the exception environment from the stack. As the phrase suggests, the execution of statements in the UNPROTECTED section is no longer protected by the enclosing TRY..ENDTRY block (note, however, that any dynamically nesting TRY..ENDTRY statements will still be active, UNPROTECTED only turns off the exception handling of the TRY..ENDTRY statement that immediately contains the UNPROTECTED clause). Since the BREAK statement in Program 1.5 appears inside the UNPROTECTED section, it can safely transfer control out of the TRY..ENDTRY block without “executing” the ENDTRY since the program has already restored the former exception environment.

Note that the UNPROTECTED keyword must appear in the TRY..ENDTRY statement immediately after the protected block. I.e., it must precede all EXCEPTION keywords.

If an exception occurs during the execution of a TRY..ENDTRY sequence, HLA automatically restores the execution environment. Therefore, you may execute a BREAK statement (or any other instruction that transfers control out of the TRY..ENDTRY block) within an EXCEPTION clause without having to do anything special.

Since the program restores the exception environment upon encountering an UNPROTECTED block or an EXCEPTION block, an exception that occurs within one of these areas immediately transfers control to the previous (dynamically nesting) active TRY..ENDTRY sequence. If there is no nesting TRY..ENDTRY sequence, the program aborts with an appropriate error message.

### 1.3.3 The ANYEXCEPTION Clause in a TRY..ENDTRY Statement

In a typical situation, you will use a TRY..ENDTRY statement with a set of EXCEPTION clauses that will handle all possible exceptions that can occur in the protected section of the TRY..ENDTRY sequence. Often, it is important to ensure that a TRY..ENDTRY statement handles all possible exceptions to prevent the program from prematurely aborting due to an unhandled exception. If you have written all the code in the protected section, you will know the exceptions it can raise so you can handle all possible exceptions. However, if you are calling a library routine (especially a third-party library routine), making a Win32 API call, or otherwise executing code that you have no control over, it may not be possible for you to anticipate all possible exceptions this code could raise (especially when considering past, present, and future versions of this code). If that code raises an exception for which you do not have an EXCEPTION clause, this could cause your program to fail. Fortunately, HLA's TRY..ENDTRY statement provides the ANYEXCEPTION clause that will automatically trap any exception the existing EXCEPTION clauses do not handle.

The ANYEXCEPTION clause is similar to the EXCEPTION clause except it does not require an exception number parameter (since it handles any exception number). If the ANYEXCEPTION clause appears in a TRY..ENDTRY statement with other EXCEPTION sections, the ANYEXCEPTION section must be the last exception handler in the TRY..ENDTRY statement. An ANYEXCEPTION section may be the only exception handler in a TRY..ENDTRY statement.

If an otherwise unhandled exception transfers control to an ANYEXCEPTION section, the EAX register will contain the exception number. Your code in the ANYEXCEPTION block can test this value to determine the cause of the exception.

### 1.3.4 Raising User-Defined Exceptions

Although you typically use the TRY..ENDTRY statement to catch exceptions that Windows or the HLA Standard Library raises, it is also possible to create your own exceptions and process them via the TRY..ENDTRY statement. You accomplish this by assigning an unused exception number to your exception and raising this exception with the HLA RAISE statement.

The parameter you supply to the EXCEPTION statement is really nothing more than an unsigned integer constant. The HLA "excepts.hhf" header file provides definitions for the standard HLA Standard Library and Windows exception types. These names are nothing more than *dword* constants that have been given a descriptive name. HLA reserves the values zero through 1023 for HLA and HLA Standard Library exceptions; it also reserves all exception values greater than \$FFFF (65,535) for use by Windows. The values in the range 1024 through 65,535 are available for user-defined exceptions.

To create a user-defined exception, you would generally begin by defining a descriptive symbolic name for the exception<sup>4</sup>. Then within your code you can use the RAISE statement to raise that exception. The following program provides a short example of some code that uses a user-defined exception to trap empty strings:

4. Technically, you could use a literal numeric constant, e.g., EXCEPTION( 1024), but this is extremely poor programming style.

```

program userDefinedExceptions;
#include("stdlib.hhf");

 // Provide a descriptive name for the
 // user-defined exception.

const EmptyString:dword := 1024;

 // readAString-
 //
 // This procedure reads a string from the user
 // and returns a pointer to that string in the
 // EAX register. It raises the "EmptyString"
 // exception if the string is empty.

procedure readAString;
begin readAString;

 stdin.a_gets();
 if((type str.strRec [eax]).length == 0) then

 strfree(eax);
 raise(EmptyString);

 endif;

end readAString;

begin userDefinedExceptions;

 try

 stdout.put("Enter a non-empty string: ");
 readAString();
 stdout.put
 (
 "You entered the string '",
 (type string eax),
 "'\n"
);
 strfree(eax);

 exception(EmptyString)

 stdout.put("You entered an empty string", nl);

 endtry;

end userDefinedExceptions;

```

---

---

### Program 1.6 User-Defined Exceptions and the RAISE Statement

---

---

One important thing to notice in this example: the *readAString* procedure frees the string storage before raising the exception. It has to do this because the RAISE statement loads the EAX register with the exception number (1024 in this case), effectively obliterating the pointer to the string. Therefore, this code frees the storage before the exception and assumes that EAX does not contain a valid string pointer if an exception occurs.

In addition to raising exceptions you've defined, you can also use the RAISE statement to raise any exception. Therefore, if your code encounters an error converting some data, you could raise the *ex.ConversionError* exception to denote this condition. There is nothing sacred about the predefined exception values. Feel free to use their values as exceptions if they are descriptive of the error you need to handle.

---

### 1.3.5 Reraising Exceptions in a TRY..ENDTRY Statement

Once a program transfers control to an exception handling section, the exception is effectively dead. That is, after executing the associated EXCEPTION block, control transfers to the first statement after the ENDTRY and program execution continues as though an exception had not occurred. HLA assumes that the exception handler has taken care of the problem and it is okay to continue program execution after the ENDTRY statement. In some instances, this isn't an appropriate response.

Although falling through and executing the statements after the ENDTRY when an exception handler finishes is probably the most common response, another possibility is to reraise the exception at the end of the EXCEPTION sequence. This lets the current TRY..ENDTRY block accommodate the exception as best it can and then pass control to a dynamically nesting TRY..ENDTRY statement to complete the exception handling process. To reraise an exception all you need do is execute a RAISE statement at the end of the exception handler. Although you would typically reraise the same exception, there is nothing preventing you from raising a different exception at the end of your exception handler. For example, after handling a user-defined exception you've defined, you might want to raise a different exception (e.g., *ex.MemoryAllocationFailure*) and let an enclosing TRY..ENDTRY statement finish handling your exception.

---

### 1.3.6 A List of the Predefined HLA Exceptions

Appendix G in this text provides a listing of the HLA exceptions and the situations in which Windows or the HLA Standard Library raises these exceptions. The HLA Standard Library reference in Appendix F also lists the exceptions that each HLA Standard Library routine raises. You should skim over these appendices to familiarize yourself with the types of exceptions HLA raises and refer to these sections when calling Standard Library routines to ensure that you handle all the possible exceptions.

---

### 1.3.7 How to Handle Exceptions in Your Programs

When an exception occurs in a program there are four general ways to handle the exception: (1) correct the problem in the exception handler and restart the offending instruction (if this is possible), (2) report an error message and loop back to the offending code and re-execute the entire sequence, preferably with better input data that won't cause an exception, (3) report an error and reraise the exception (or raise a different exception) and leave it up to a dynamically nesting exception handler to deal with the problem, or (4) clean up the program's data as much as possible and abort program execution. The HLA run-time system only supports the last three options (i.e., it does not allow you to restart the offending instruction after some sort of correction), so we will ignore the first option in this text.

Reporting an error and looping back to repeat the offending code is an extremely common solution when then program raises an exception because of bad user input. The following program provides a typical example of this solution that forces a user to enter a valid unsigned integer value:

---

```

program repeatingBadCode;
#include("stdlib.hhf");

static
 u: uns16;

```

```

begin repeatingBadCode;

 forever

 try
 // Protected block. Read an unsigned integer
 // from the user and display that value if
 // there wasn't an error.

 stdout.put("Enter an unsigned integer:");
 stdin.get(u);

 // Clean up the exception and break out of
 // the forever loop if all went well.

 unprotected

 break;

 // If the user entered an illegal character,
 // print an appropriate error message.

 exception(ex.ConversionError)

 stdout.put("Your input contained illegal characters" nl);

 // If the user entered a value outside the range
 // 0..65535 then print an error message.

 exception(ex.ValueOutOfRange)

 stdout.put("The value was too large" nl);

 endtry;

 // If we get down here, it's because there was an exception.
 // Loop back and make the user reenter the value.

 endfor;

 // Only by executed the BREAK statement do we wind up down here.
 // That occurs if the user entered a value unsigned integer value.

 stdout.put("You entered: ", u, nl);

end repeatingBadCode;

```

---

### Program 1.7 Repeating Code via a Loop to Handle an Exception

---

Another way to handle an exception is to print an appropriate message (or take other corrective action) and then re-raise the exception or raise a different exception. This allows an enclosing exception handler to handle the exception. The big advantage to this scheme is that it minimizes the code you have to write to handle a given exception throughout your code (i.e., passing an exception on to a different handler that contains some complex code is much easier than replicating that complex code everywhere the exception can occur). However, this approach has its own problems. Primary among the problems is ensuring that there is some enclosing TRY..ENDTRY statement that will handle the exception for you. Of course, HLA automati-

cally encloses your entire program in one big TRY..ENDTRY statement, but the default handler simply prints a short message and then stops your program. This is unacceptable behavior in a robust program. At the very least, you should supply your own exception handler that surrounds the code in your main program that attempts to clean up the system before shutting it down if an otherwise unhandled exception comes along. Generally, however, you would like to handle the exception without shutting down the program. Ensuring that this always occurs if you re-raise an exception can be difficult.

The last alternative, and certainly the least desirable of the four, is to clean up the system as much as possible and terminate program execution. Cleaning up the system includes writing transient data in memory to files, closing the files, releasing system resources (i.e., peripheral devices and memory), and, in general, preserving as much of the user's work as possible before quitting the program. Although you would like to continue program execution whenever an exception occurs, sometimes it is impossible to recover from an invalid operation (either on the part of the user or because of an error in your program) and continue execution. In such a situation you want to shut the program down as gracefully as possible so the user can restart the program and continue where they left off.

Of course, the absolute worst thing you can do is allow the program to terminate without attempting to save user data or release system resources. The user of your application will not have kind things to say about your program if they use it for three or four hours and the program aborts and loses all the data they've entered (requiring them to spend another three or four hours entering that data). Telling the user to "save your data often" is not a good substitute for automatically saving their data when an exception occurs.

The easiest way to handle an arbitrary (and unexpected) exception is to place a TRY..ANYEXCEPTION..ENDTRY statement around your main program. If the program raises an exception, you should save the value in EAX upon entry into the ANYEXCEPTION section (this contains the exception number) and then save any important data and release any resources your program is using. After this, you can re-raise the exception and let the default handler print the error message and terminate your program.

### 1.3.8 Registers and the TRY..ENDTRY Statement

The TRY..ENDTRY statement preserves about 16 bytes of data on the stack whenever you enter a TRY..ENDTRY statement. Upon leaving the TRY..ENDTRY block (or hitting the UNPROTECTED clause), the program restores the exception environment by popping this data off the stack. As long as no exception occurs, the TRY..ENDTRY statement does not affect the values of any registers upon entry to or upon exit from the TRY..ENDTRY statement. However, this claim is not true if an exception occurs during the execution of the protected statements.

Upon entry into an EXCEPTION clause the EAX register contains the exception number and the state of all other general purpose registers is undefined. Since Windows may have raised the exception in response to a hardware error (and, therefore, has played around with the registers), you can't even assume that the general purpose registers contain whatever values they happened to contain at the point of the exception. Since the underlying code that HLA generates for exceptions is subject to change in different versions of the compiler, it is never a good idea to experimentally determine what values registers contain in an exception handler and depend upon those values in your code.

Since entry into an exception handler can scramble all the register values, you must ensure that you reload important registers if the code following your ENDTRY clause assumes that the registers contain valid values (i.e., set in the protected section or set prior to executing the TRY..ENDTRY statement). Failure to do so will introduce some nasty defects into your program (and these defects may be very intermittent and difficult to detect since exceptions rarely occur and may not always destroy the value in a particular register). The following code fragment provides a typical example of this problem and its solution:

```
static
 array: uns32 [8];
 .
 .
 .
 for(mov(0, ebx); ebx < 8; inc(ebx)) do

 push(ebx); // Must preserve EBX in case there is an exception.
```

```

 forever
 try

 stdin.geti32();
 unprotected break;

 exception(ex.ConversionError)

 stdout.put("Illegal input, please reenter value: ");

 endtry;
endfor;
pop(ebx); // Restore EBX's value.
mov(eax, array[ebx*4]);

endifor;

```

Because the HLA exception handling mechanism messes with the registers, and because exception handling is a relatively inefficient process, you should never use the TRY..ENDTRY statement as a generic control structure (e.g., using it to simulate a SWITCH/CASE statement by raising an integer selector and using the EXCEPTION clauses as the cases to process). Doing so will have a very negative impact on the performance of your program and may introduce subtle defects because exceptions scramble the registers.

For proper operation, the TRY..ENDTRY statement assumes that you only use the EBP register to point at *activation records* (the chapter on intermediate procedures discusses activation records). By default, HLA programs automatically use EBP for this purpose; as long as you do not modify the value in EBP, your programs will automatically use EBP to maintain a pointer to the current activation record. If you attempt to use the EBP register as a general purpose register to hold values and compute arithmetic results, HLA's exception handling capabilities will no longer function properly (not to mention you will lose access to procedure parameters and variables in the VAR section). Therefore, you should never use the EBP register as a general purpose register. Of course, this same discussion applies to the ESP register.

---

## 1.4 BEGIN..EXIT..EXITIF..END

HLA provides a structured GOTO via the EXIT and EXITIF statements. The EXIT and EXITIF statements let you exit a block of statements surrounded by a BEGIN..END pair. These statements behave much like the BREAK and BREAKIF statements (that let you exit from an enclosing loop) except, of course, they jump out of a BEGIN..END block rather than a loop. The EXIT and EXITIF statements are *structured gotos* because they do not let you jump to an arbitrary point in the code, they only let you exit from a block delimited by the BEGIN..END pair.

The EXIT and EXITIF statements take the following forms:

```

exit identifier;
exitif(boolean_expression) identifier;

```

The *identifier* component at the end of these two statements must match the identifier following the BEGIN and END keywords (e.g., a procedure or program name). The EXIT statement immediately transfers control to the “end identifier;” clause. The EXITIF statement evaluates the boolean expression immediately following the EXITIF reserved word and transfer control to the specified END clause only if the expression evaluates true. If the boolean expression evaluates false, the control transfers to the first statement following the EXITIF statement.

If you specify the name of a procedure as the identifier for an EXIT statement, the program will return from the procedure upon encountering the EXIT statement<sup>5</sup>. *Note that the EXIT statement does not auto-*

---

5. This is true for the EXITIF statement as well, though, of course, the program will only exit the procedure if the boolean expression in the EXITIF statement evaluates true.

*matically restore any registers you pushed on the stack upon entry into the procedure.* If you need to pop data off the stack, you must do this before executing the EXIT statement.

If you specify the name of your main program as the identifier following the EXIT (or EXITIF) statement, your program will terminate upon encountering the EXIT statement. With EXITIF, your program will only terminate if the boolean expression evaluates true. Note that your program will still terminate even if you execute the “exit MainPgmName;” statement within a procedure nested inside your main program. You do not have to execute the EXIT statement in the main program to terminate the main program.

HLA lets you place arbitrary BEGIN..END blocks within your program, they are not limited to surrounding your procedures or main program. The syntax for an arbitrary BEGIN..END block is

```
begin identifier;

 <statements>

end identifier;
```

The identifier following the END clause must match the identifier following the corresponding BEGIN statement. Naturally, you can nest BEGIN..END blocks, but the identifier following an END clause must match the identifier following the previous unmatched (by an END) BEGIN clause.

One interesting use of the BEGIN..END block is that it lets you easily escape a deeply nested control structure without having to completely restructure the program. Typically, you would use this technique to exit a block of code on some special condition and the TRY..ENDTRY statement would be inappropriate (e.g., you might need to pass values in registers to the outside code, an EXCEPTION clause can't guarantee register status). The following program demonstrates the use of the BEGIN..EXIT..END sequence to bail out of some deeply nested code.

```
program beginEndDemo;
#include("stdlib.hhf");

### Program 1.8 Demonstration of BEGIN..EXIT..END Sequence

---

---

In this program, the “begin goodDate;” statement surrounds a section of code that checks to see if the date entered by a user is a valid date in the 100 years from 2000..2099. If the user enters an invalid date, it prints an appropriate error message, otherwise the program quits without further user interaction. While you could restructure this code to avoid the use of the EXITIF statement, the resulting code would probably be more difficult to understand. The nice thing about the design of the code is that it uses refinement to test for a legal date. That is, it tests to see if one component is legal, then tests to see if the next component of the date is legal, and works downward in this fashion. In the middle of the tests, this code determines that the date is legal. To restructure this code to work without the EXITIF (or other GOTO type instruction) would require using negative logic at each step (asking is this component *not* a legal date). That logic would be quite a bit more complex and much more difficult to read, understand, and verify. Hence, this example is preferable even if it contains a structured form of the GOTO statement.

Because the BEGIN..END statement uses a label, that the EXIT and EXITIF statements specify, you can nest BEGIN..END blocks and break out of several nested blocks with a single EXIT/EXITIF statement. Figure 1.1 provides a schematic of this capability.

**Figure 1.1** Nesting BEGIN..END Blocks

This ability to break out of nested BEGIN..END blocks is very powerful. Contrast this with the BREAK and BREAKIF statements that only let you exit the loop that immediately contains the BREAK or BREAKIF. Of course, if you need to exit out of multiple nested loops you won't be able to use the BREAK/BREAKIF statement to achieve this, but you can surround your loops with a BEGIN..END sequence and use the EXIT/EXITIF statement to leave those loops. The following program demonstrates how this could work, using the EXITIF statement to break out of two nested loops.

```

program brkNestedLoops;
#include("stdlib.hhf")

static
 i:int32;

begin brkNestedLoops;

```

```

// DL contains the last value to print on each line.
for(mov(0, dl); dl <= 7; inc(dl)) do
 begin middleLoop;
 // DH ranges over the values to print.
 for(mov(0, dh); dh <= 7; inc(dh)) do
 // "i" specifies the field width
 // when printing DH, it also specifies
 // the maximum number of times to print DH.
 for(mov(2, i); i <= 4; inc(i)) do
 // Break out of both inner loops
 // when DH becomes equal to DL.
 exitif(dh >= dl) middleLoop;
 // The following statement prints
 // a triangular shaped object composed
 // of the values that DH goes through.
 stdout.puti8Size(dh, i, '.');
 endfor;
 endfor;
endfor;
end middleLoop;
stdout.newln();
endfor;
end brkNestedLoops;

```

### Program 1.9 Breaking Out of Nested Loops Using EXIT/EXITIF

---

---

## 1.5 CONTINUE..CONTINUEIF

The CONTINUE and CONTINUEIF statements are very similar to the BREAK and BREAKIF statements insofar as they affect control flow within a loop. The CONTINUE statement immediately transfers control to the point in the loop where the current iteration completes and the next iteration begins. The CONTINUEIF statement first checks a boolean expression and transfers control if the expression evaluates false.

The phrase “where the current iteration completes and the next iteration begins” has a different meaning for nearly every loop in HLA. For the WHILE..ENDWHILE loop, control transfers to the top of the loop at the start of the test for loop termination. For the FOREVER..ENDFOR loop, control transfers to the top of the loop (no test for loop termination). For the FOR..ENDFOR loop, control transfers to the bottom of the loop where the increment operation occurs (i.e., to execute the third component of the FOR loop). For the REPEAT..UNTIL loop, control transfers to the bottom of the loop, just before the test for loop termination. The following diagrams show how the CONTINUE statement behaves.

**Figure 1.2** Behavior of CONTINUE in a WHILE Loop

---

**Figure 1.3** Behavior of CONTINUE in a FOREVER Loop

---

**Figure 1.4** Behavior of CONTINUE in a FOR Loop

---

**Figure 1.5 Behavior of CONTINUE in a REPEAT..UNTIL Loop**

It turns out that CONTINUE is rarely needed in common programs. Most of the time an IF..ENDIF statement provides the same functionality as CONTINUE (or CONTINUEIF) while being much more readable. Nevertheless, there are a few instances you will encounter where the CONTINUE or CONTINUEIF statements provide exactly what you need. However, if you find yourself using the CONTINUE or CONTINUEIF statements on a frequent basis, you should probably reconsider the logic in your programs.

## 1.6 SWITCH..CASE..DEFAULT..ENDSWITCH

The HLA language does not provide a selection statement similar to SWITCH in C/C++ or CASE in Pascal/Delphi. This omission was intentional; by leaving the SWITCH statement out of the language it is possible to demonstrate how to extend the HLA language by adding new control structures. In the chapters on Macros and the HLA Compile-time Language, this text will demonstrate how you can add your own statements, like SWITCH, to the HLA language. In the meantime, although HLA does not provide a SWITCH statement, the HLA Standard Library provides a macro that provides this capability for you. If you include the “hll.hhf” header file (which “stdlib.hhf” automatically includes for you), then you can use the SWITCH statement exactly as though it were a part of the HLA language.

The HLA Standard Library SWITCH statement has the following syntax:

**Figure 1.6 Syntax for the SWITCH..CASE..DEFAULT..ENDSWITCH Statement**

Like most HLA high level language statements, there are several restrictions on the SWITCH statement. First of all, the SWITCH clause does not allow a general expression as the selection value. The SWITCH clause will only allow a value in a 32-bit general purpose register. In general you should only use EAX, EBX, ECX, EDX, ESI, and EDI since EBP and ESP are reserved for special purposes.

The second restriction is that the HLA SWITCH statement supports a maximum of 256 different case values. Few SWITCH statements use anywhere near this number, so this shouldn't prove to be a problem. Note that each CASE in Figure 1.6 allows a constant list. This could be a single unsigned integer value or a comma separated list of values, e.g.,

```

 case(10)
-or-
 case(5, 6, 8)

```

Each value in the list of constants counts as one case constant towards the maximum of 256 possible constants. So the second CASE clause above contributes three constants towards the total maximum of 256 constants.

Another restriction on the HLA SWITCH statement is that the difference between the largest and smallest values in the case list must be 1,024. Therefore, you cannot have CASEs (in the same SWITCH statement) with values like 1, 10, 100, 1,000, and 10,000 since the difference between the smallest and largest values, 9999, exceeds 1,024.

The DEFAULT section, if it appears in a SWITCH statement, must be the last section in the SWITCH statement. If no DEFAULT section is present and the value in the 32-bit register does not match one of the CASE constants, then control transfers to the first statement following the ENDSWITCH clause.

Here is a typical example of a SWITCH..ENDSWITCH statement:

```

switch(eax)

 case(1)

 stdout.put("Selection #1:" nl);
 << Code for case #1 >>

```

```

case(2, 3)

 stdout.put("Selections (2) and (3):" nl);
 << code for cases 2 & 3 >>

case(5,6,7,8,9)

 stdout.put("Selections (5)..(9)" nl);
 << code for cases 5..9 >

default

 stdout.put("Selection outside range 1..9" nl);
 << default case code >>

endswitch;

```

The SWITCH statement in a program lets your code choose one of several different code paths depending upon the value of the case selection variable. Among other things, the SWITCH statement is ideal for processing user input that selects a menu item and executes different code depending on the user's selection.

Later in this volume you will see how to implement a SWITCH statement using low-level machine instructions. Once you see the implementation you will understand the reasons behind these limitations in the SWITCH statement. You will also see why the CASE constants must be constants and not variables or registers.

## 1.7 Putting It All Together

This chapter completes the discussion of the high level control structures built into the HLA language or provided by the HLA Standard Library (i.e., SWITCH). First, this chapter gave a complete discussion of the TRY..ENDTRY and RAISE statements. Although Volume One provided a brief discussion of exception handling and the TRY..ENDTRY statement, this particular statement is too complex to fully describe earlier in this text. This chapter completes the discussions of this important statement and suggests ways to use it in your programs that will help make them more robust.

After discussing TRY..ENDTRY and RAISE, this chapter discusses the EXIT and EXITIF statements and describes how to use them to prematurely exit a procedure or the program. This chapter also discusses the BEGIN..END block and describes how to use the EXIT and EXITIF statements to exit such a block. These statements provide a structured GOTO (JMP) in the HLA language.

Although you will not use them as frequently as the BREAK and BREAKIF statements, the CONTINUE and CONTINUEIF statements are helpful once in a while for jumping over the remainder of a loop body and starting the next loop iteration. This chapter discusses the syntax of these statements and warns against overusing them.

This chapter concludes with a discussion of the SWITCH/CASE/DEFAULT/ENDCASE statement. This statement isn't actually a part of the HLA language - instead it is provided by the HLA Standard Library as an example of how you can extend the language. If you would like details on extending the HLA language yourself, see the chapter on "Domain Specific Languages."

# Low-Level Control Structures

# Chapter Two

---

## 2.1 Chapter Overview

This chapter discusses “pure” assembly language control statements. The last section of this chapter discusses *hybrid* control structures that combine the features of HLA’s high level control statements with the 80x86 control instructions.

---

## 2.2 Low Level Control Structures

Until now, most of the control structures you’ve seen and have used in your programs have been very similar to the control structures found in high level languages like Pascal, C++, and Ada. While these control structures make learning assembly language easy they are not true assembly language statements. Instead, the HLA compiler translates these control structures into a sequence of “pure” machine instructions that achieve the same result as the high level control structures. This text uses the high level control structures to avoid your having to learn too much all at once. Now, however, it’s time to put aside these high level language control structures and learn how to write your programs in *real* assembly language, using low-level control structures.

---

## 2.3 Statement Labels

HLA low level control structures make extensive use of *labels* within your code. A low level control structure usually transfers control from one point in your program to another point in your program. You typically specify the destination of such a transfer using a statement label. A statement label consists of a valid (unique) HLA identifier and a colon, e.g.,

```
label:
```

Of course, like procedure, variable, and constant identifiers, you should attempt to choose descriptive and meaningful names for your labels. The identifier “label” is hardly descriptive or meaningful.

Statement labels have one important attribute that differentiates them from most other identifiers in HLA: you don’t have to declare a label before you use it. This is important, because low-level control structures must often transfer control to a label at some point later in the code, therefore the label may not be defined at the point you reference it.

You can do two things with labels: transfer control to a label via a jump (*goto*) instruction and you can take the address of a label. There is very little else you can directly do with a label (of course, there is very little else you would want to do with a label, so this is hardly a restriction). The following program demonstrates two ways to take the address of a label in your program and print out the address (using the LEA instruction and using the “&” address-of operator):

---

```
program labelDemo;
#include("stdlib.hhf");

begin labelDemo;

 lbl1:

 lea(ebx, lbl1);
 lea(eax, lbl2);
 stdout.put("&lbl1=$", ebx, " &lbl2=", eax, nl);
```

```

 lbl2:

end labelDemo;

```

---

---

### Program 2.1 Displaying the Address of Statement Labels in a Program

---

---

HLA also allows you to initialize *dword* variables with the addresses of statement labels. However, there are some restrictions on labels that appear in the initialization portions of variable declarations. The most important restriction is that you must define the statement label at the same lex level as the variable declaration. That is, if you reference a statement label in the initialization section of a variable declaration appearing in the main program, the statement label must also be in the main program. Conversely, if you take the address of a statement label in a local variable declaration, that symbol must appear in the same procedure as the local variable. The following program demonstrates the use of statement labels in variable initialization:

---

---

```

program labelArrays;
#include("stdlib.hhf");

static
 labels:dword[2] := [&lbl1, &lbl2];

 procedure hasLabels;
 static
 stmtLbls: dword[2] := [&label1, &label2];

 begin hasLabels;

 label1:

 stdout.put
 (
 "stmtLbls[0]= $", stmtLbls[0], nl,
 "stmtLbls[1]= $", stmtLbls[4], nl
);

 label2:

 end hasLabels;

begin labelArrays;

 hasLabels();
 lbl1:

 stdout.put("labels[0]= $", labels[0], " labels[1]=", labels[4], nl);

 lbl2:

end labelArrays;

```

---

---

### Program 2.2 Initializing DWORD Variables with the Address of Statement Labels

---

---

## 2.4 Unconditional Transfer of Control (JMP)

The JMP (jump) instruction unconditionally transfers control to another point in the program. There are three forms of this instruction: a direct jump, and two indirect jumps. These instructions take one of the following three forms:

```

jmp label;
jmp(reg32);
jmp(mem32);

```

For the first (direct) jump above, you normally specify the target address using a statement label (see the previous section for a discussion of statement labels). The statement label is usually on the same line as an executable machine instruction or appears by itself on a line preceding an executable machine instruction. The direct jump instruction is the most commonly used of these three forms. It is completely equivalent to a GOTO statement in a high level language<sup>1</sup>. Example:

```

<< statements >>
 jmp laterInPgm;
 .
 .
 .
laterInPgm:
 << statements >>

```

The second form of the JMP instruction above, “jmp( reg<sub>32</sub> );”, is a *register indirect* jump instruction. This instruction transfers control to the instruction whose address appears in the specified 32-bit general purpose register. To use this form of the JMP instruction you must load the specified register with the address of some machine instruction prior to the execution of the JMP. You could use this instruction to implement a state machine (see “State Machines and Indirect Jumps” on page 761) by loading a register with the address of some label at various points throughout your program; then, arriving along different paths, a point in the program can determine what path it arrived upon by executing the indirect jump. The following short sample program demonstrates how you could use the JMP in this manner:

---

```

program regIndJmp;
#include("stdlib.hhf");

static
 i:int32;

begin regIndJmp;

 // Read an integer from the user and set EBX to
 // denote the success or failure of the input.

 try

 stdout.put("Enter an integer value between 1 and 10: ");
 stdin.get(i);
 mov(i, ebx);
 if(ebx in 1..10) then

 mov(&GoodInput, ebx);

 else

```

---

1. Unlike high level languages, where your instructors usually forbid you to use GOTO statements, you will find that the use of the JMP instruction in assembly language is absolutely essential.

```

 mov(&valRange, ebx);

 endif;

 exception(ex.ConversionError)

 mov(&convError, ebx);

 exception(ex.ValueOutOfRange)

 mov(&valRange, ebx);

endtry;

// Okay, transfer control to the appropriate
// section of the program that deals with
// the input.

jmp(ebx);

valRange:
 stdout.put("You entered a value outside the range 1..10" nl);
 jmp Done;

convError:
 stdout.put("Your input contained illegal characters" nl);
 jmp Done;

GoodInput:
 stdout.put("You entered the value ", i, nl);

Done:

end regIndJmp;

```

---

### Program 2.3 Using Register Indirect JMP Instructions

---

The third form of the JMP instruction is a memory indirect JMP. This form of the JMP instruction fetches a *dword* value from the specified memory location and transfers control to the instruction at the address specified by the contents of the memory location. This is similar to the register indirect JMP except the address appears in a memory location rather than in a register. The following program demonstrates a rather trivial use of this form of the JMP instruction:

---

```

program memIndJmp;
#include("stdlib.hhf");

static
 LabelPtr:dword := &stmtLabel;

begin memIndJmp;

 stdout.put("Before the JMP instruction" nl);
 jmp(LabelPtr);

 stdout.put("This should not execute" nl);

```

```

stmtLabel:

 stdout.put("After the LabelPtr label in the program" nl);

end memIndJump;

```

---

## Program 2.4 Using Memory Indirect JMP Instructions

---

**Warning:** unlike the HLA high level control structures, the low-level JMP instructions can get you into a lot of trouble. In particular, if you do not initialize a register with the address of a valid instruction and you jump indirect through that register, the results are undefined (though this will usually cause a Windows general protection fault). Similarly, if you do not initialize a *dword* variable with the address of a legal instruction, jumping indirect through that memory location will probably crash your program.

---

## 2.5 The Conditional Jump Instructions

Although the JMP instruction provides transfer of control, it does not allow you to make any serious decisions. The 80x86's conditional jump instructions handle this task. The conditional jump instructions are the basic tool for creating loops and other conditionally executable statements like the IF..ENDIF statement.

The conditional jumps test one or more flags in the flags register to see if they match some particular pattern (just like the SET $cc$  instructions). If the flag settings match a particular pattern control transfers to the target location. If the match fails, the CPU ignores the conditional jump and execution continues with the next instruction. Some conditional jump instructions simply test the setting of the sign, carry, overflow, and zero flags. For example, after the execution of a SHL instruction, you could test the carry flag to determine if the SHL shifted a one out of the H.O. bit of its operand. Likewise, you could test the zero flag after a TEST instruction to see if any specified bits were one. Most of the time, however, you will probably execute a conditional jump after a CMP instruction. The CMP instruction sets the flags so that you can test for less than, greater than, equality, etc.

The conditional JMP instructions take the following form:

```
Jcc label;
```

The “cc” in *Jcc* indicates that you must substitute some character sequence that specifies the type of condition to test. These are the same characters the SET $cc$  instruction uses. For example, “JS” stands for jump if the sign flag is set.” A typical JS instruction looks like this

```
js ValueIsNegative;
```

In this example, the JS instruction transfers control to the *ValueIsNegative* statement label if the sign flag is currently set; control falls through to the next instruction following the JS instruction if the sign flag is clear.

Unlike the unconditional JMP instruction, the conditional jump instructions do not provide an indirect form. The only form they allow is a branch to a statement label in your program. Conditional jump instructions have a restriction that the target label must be within 32,768 bytes of the jump instruction. However, since this generally corresponds to somewhere between 8,000 and 32,000 machine instructions, it is unlikely you will ever encounter this restriction.

Note: Intel's documentation defines various synonyms or instruction aliases for many conditional jump instructions. The following tables list all the aliases for a particular instruction. These tables also list out the opposite branches. You'll soon see the purpose of the opposite branches.

| JNG         | Jump if not greater than (not >)        | Sign ≠ Ovrflw or Zero = 1 | JLE     | JG       |
| JE          | Jump if equal (=)                       | Zero = 1                  | JZ      | JNE      |
| JNE         | Jump if not equal (≠)                   | Zero = 0                  | JNZ     | JE       |

One brief comment about the “opposites” column is in order. In many instances you will need to be able to generate the opposite of a specific branch instructions (lots of examples of this appear throughout the remainder of this chapter). With only two exceptions, a very simple rule completely describes how to generate an opposite branch:

- If the second letter of the *Jcc* instruction is *not* an “n”, insert an “n” after the “j”. E.g., JE becomes JNE and JL becomes JNL.
- If the second letter of the *Jcc* instruction *is* an “n”, then remove that “n” from the instruction. E.g., JNG becomes JG and JNE becomes JE.

The two exceptions to this rule are JPE (jump if parity is even) and JPO (jump if parity is odd). These exceptions cause few problems because (a) you’ll hardly ever need to test the parity flag, and (b) you can use the aliases JP and JNP synonyms for JPE and JPO. The “N/No N” rule applies to JP and JNP.

Though you *know* that JGE is the opposite of JL, get in the habit of using JNL rather than JGE as the opposite jump instruction for JL. It’s too easy in an important situation to start thinking “greater is the opposite of less” and substitute JG instead. You can avoid this confusion by always using the “N/No N” rule.

The 80x86 conditional jump instruction give you the ability to split program flow into one of two paths depending upon some logical condition. Suppose you want to increment the AX register if BX is equal to CX. You can accomplish this with the following code:

```

 cmp(bx, cx);
 jne SkipStmts;
 inc(ax);
SkipStmts:

```

The trick is to use the *opposite* branch to skip over the instructions you want to execute if the condition is true. Always use the “opposite branch (N/no N)” rule given earlier to select the opposite branch.

You can also use the conditional jump instructions to synthesize loops. For example, the following code sequence reads a sequence of characters from the user and stores each character in successive elements of an array until the user presses the Enter key (carriage return):

```

 mov(0, edi);
RdLnLoop:
 stdin.getc(); // Read a character into the AL register.
 mov(al, Input[edi]); // Store away the character
 inc(edi); // Move on to the next character
 cmp(al, stdin.cr); // See if the user pressed Enter
 jne RdLnLoop;

```

For more information concerning the use of the conditional jumps to synthesize IF statements, loops, and other control structures, see “Implementing Common Control Structures in Assembly Language” on page 736.

Like the SET $cc$  instructions, the conditional jump instructions come in two basic categories – those that test specific processor flags (e.g., JZ, JC, JNO) and those that test some condition (less than, greater than, etc.). When testing a condition, the conditional jump instructions almost always follow a CMP instruction. The CMP instruction sets the flags so you can use a JA, JAE, JB, JBE, JE, or JNE instruction to test for unsigned less than, less than or equal, equality, inequality, greater than, or greater than or equal. Simultaneously, the CMP instruction sets the flags so you can also do a signed comparison using the JL, JLE, JE, JNE, JG, and JGE instructions.

The conditional jump instructions only test flags, they do not affect any of the 80x86 flags.

## 2.6 “Medium-Level” Control Structures: JT and JF

HLA provides two special conditional jump instructions: JT (jump if true) and JF (jump if false). These instructions take the following syntax:

```

 jt(boolean_expression) target_label;
 jf(boolean_expression) target_label;

```

The *boolean\_expression* is the standard HLA boolean expression allowed by IF..ENDIF and other HLA high level language statements. These instructions evaluate the boolean expression and jump to the specified label if the expression evaluates true (JT) or false (JF).

These are not real 80x86 instructions. HLA compiles them into a sequence of one or more 80x86 machine instructions that achieve the same result. In general, you should not use these two instructions in your main code; they offer few benefits over using an IF..ENDIF statement and they are no more readable than the pure assembly language sequences they compile into. HLA provides these “medium-level” instructions so that you may create your own high level control structures using macros (see the chapters on Macros, the HLA Run-Time Language, and Domain Specific Languages for more details).

## 2.7 Implementing Common Control Structures in Assembly Language

Since a primary goal of this chapter is to teach you how to use the low-level machine instructions to implement decisions, loops, and other control constructs, it would be wise to show you how to simulate these high level statements using “pure” assembly language. The following sections provide this information.

## 2.8 Introduction to Decisions

In its most basic form, a decision is some sort of branch within the code that switches between two possible execution paths based on some condition. Normally (though not always), conditional instruction sequences are implemented with the conditional jump instructions. Conditional instructions correspond to the IF..THEN..ENDIF statement in HLA:

```

 if(expression) then
 << statements >>
 endif

```

```
endif;
```

Assembly language, as usual, offers much more flexibility when dealing with conditional statements. Consider the following C/C++ statement:

```
if(((x < y) && (z > t)) || (a != b))
 stmt1;
```

A “brute force” approach to converting this statement into assembly language might produce:

```
mov(x, eax);
cmp(eax, y);
setl(bl); // Store X<Y in bl.
mov(z, eax);
cmp(eax, t);
setg(bh); // Store Z > T in bh.
and(bh, bl); // Put (X<Y) && (Z>T) into bl.
mov(a, eax);
cmp(eax, b);
setne(bh); // Store A != B into bh.
or(bh, bl); // Put (X<Y) && (Z>T) || (A!=B) into bl
je SkipStmt1; // Branch if result is false (OR sets Z-Flag if false).

<Code for stmt1 goes here>
```

```
SkipStmt1:
```

As you can see, it takes a considerable number of conditional statements just to process the expression in the example above. This roughly corresponds to the (equivalent) C/C++ statements:

```
bl = x < y;
bh = z > t;
bl = bl && bh;
bh = a != b;
bl = bl || bh;
if(bl)
 stmt1;
```

Now compare this with the following “improved” code:

```
mov(a, eax);
cmp(eax, b);
jne DoStmt;
mov(x, eax);
cmp(eax, y);
jnl SkipStmt;
mov(z, eax);
cmp(eax, t);
jng SkipStmt;
DoStmt:
 << Place code for Stmt1 here >>
SkipStmt:
```

Two things should be apparent from the code sequences above: first, a single conditional statement in C/C++ (or some other HLL) may require several conditional jumps in assembly language; second, organization of complex expressions in a conditional sequence can affect the efficiency of the code. Therefore, care should be exercised when dealing with conditional sequences in assembly language.

Conditional statements may be broken down into three basic categories: IF statements, SWITCH/CASE statements, and indirect jumps. The following sections will describe these program structures, how to use them, and how to write them in assembly language.

## 2.8.1 IF..THEN..ELSE Sequences

The most commonly used conditional statement is the IF..THEN or IF..THEN..ELSE statement. These two statements take the form shown in Figure 2.1:

**Figure 2.1 IF..THEN..ELSE..ENDIF and IF..ENDIF Statement Flow**

The IF..ENDIF statement is just a special case of the IF..ELSE..ENDIF statement (with an empty ELSE block). Therefore, we'll only consider the more general IF..ELSE..ENDIF form. The basic implementation of an IF..THEN..ELSE statement in 80x86 assembly language looks something like this:

```
{Sequence of statements to test some condition}
 Jcc ElseCode
{Sequence of statements corresponding to the THEN block}

 jmp EndOfIF
```

```
ElseCode:
 {Sequence of statements corresponding to the ELSE block}
```

```
EndOfIF:
```

Note: *Jcc* represents some conditional jump instruction.

For example, to convert the C/C++ statement:

```
if(a == b)
 c = d;
else
 b = b + 1;
```

to assembly language, you could use the following 80x86 code:

```

 mov(a, eax);
 cmp(eax, b);
 jne ElsePart;
 mov(d, c);
 jmp EndOfIf;

ElseBlk:
 inc(b);

EndOfIf:

```

For simple expressions like “( a == b )” generating the proper code for an IF.ELSE..ENDIF statement is almost trivial. Should the expression become more complex, the associated assembly language code complexity increases as well. Consider the following C/C++ IF statement presented earlier:

```

if(((x > y) && (z < t)) || (a != b))
 c = d;

```

When processing complex IF statements such as this one, you’ll find the conversion task easier if you break this IF statement into a sequence of three different IF statements as follows:

```

if(a != b) C = D;
else if(x > y)
 if(z < t)
 C = D;

```

This conversion comes from the following C/C++ equivalences:

```

if(expr1 && expr2) stmt;

```

is equivalent to

```

if(expr1) if(expr2) stmt;

```

and

```

if(expr1 || expr2) stmt;

```

is equivalent to

```

if(expr1) stmt;
else if(expr2) stmt;

```

In assembly language, the former IF statement becomes:

```

// if(((x > y) && (z < t)) || (a != b))
// c = d;

 mov(a, eax);
 cmp(eax, b);
 jne DoIF;
 mov(x, eax);
 cmp(eax, y);
 jng EndOfIF;
 mov(z, eax);
 cmp(eax, t);
 jnl EndOfIF;

DoIf:
 mov(d, c);

EndOfIF:

```

As you can probably tell, the code necessary to test a condition can easily become more complex than the statements appearing in the ELSE and THEN blocks. Although it seems somewhat paradoxical that it may take more effort to test a condition than to act upon the results of that condition, it happens all the time. Therefore, you should be prepared for this situation.

Probably the biggest problem with the implementation of complex conditional statements in assembly language is trying to figure out what you've done after you've written the code. Probably the biggest advantage high level languages offer over assembly language is that expressions are much easier to read and comprehend in a high level language. This is one of the primary reasons HLA supports high level language control structures. The high level language version is self-documenting whereas assembly language tends to hide the true nature of the code. Therefore, well-written comments are an essential ingredient to assembly language implementations of `if.then..else` statements. An elegant implementation of the example above is:

```
// IF ((X > Y) && (Z < T)) OR (A != B) C = D;
// Implemented as:
// IF (A != B) THEN GOTO DoIF;

 mov(a, eax);
 cmp(eax, b);
 jne DoIF;

// if NOT (X > Y) THEN GOTO EndOfIF;

 mov(x, eax);
 cmp(eax, y);
 jng EndOfIF;

// IF NOT (Z < T) THEN GOTO EndOfIF ;

 mov(z, eax);
 cmp(eax, t);
 jnl EndOfIf;

// THEN Block:

DoIf:
 mov(d, c);

// End of IF statement

EndOfIF:
```

Admittedly, this appears to be going overboard for such a simple example. The following would probably suffice:

```
// if(((x > y) && (z < t)) || (a != b)) c = d;
// Test the boolean expression:

 mov(a, eax);
 cmp(eax, b);
 jne DoIF;
 mov(x, eax);
 cmp(eax, y);
 jng EndOfIF;
 mov(z, eax);
 cmp(eax, t);
 jnl EndOfIf;

; THEN Block:

DoIf:
 mov(d, c);

; End of IF statement

EndOfIF:
```

However, as your IF statements become complex, the density (and quality) of your comments become more and more important.

## 2.8.2 Translating HLA IF Statements into Pure Assembly Language

Translating HLA IF statements into pure assembly language is very easy. The boolean expressions that the HLA IF supports were specifically chosen to expand into a few simple machine instructions. The following paragraphs discuss the conversion of each supported boolean expression into pure machine code.

### **if( *flag\_specification* ) then <<stmts>> endif;**

This form is, perhaps, the easiest HLA IF statement to convert. To execute the code immediately following the THEN keyword if a particular flag is set (or clear), all you need do is skip over the code if the flag is clear (set). This requires only a single conditional jump instruction for implementation as the following examples demonstrate:

```
// if(@c) then inc(eax); endif;

 jnc SkipTheInc;

 inc(eax);

SkipTheInc:

// if(@ns) then neg(eax); endif;

 js SkipTheNeg;

 neg(eax);

SkipTheNeg:
```

### **if( *register* ) then <<stmts>> endif;**

This form of the IF statement uses the TEST instruction to check the specified register for zero. If the register contains zero (false), then the program jumps around the statements after the THEN clause with a JZ instruction. Converting this statement to assembly language requires a TEST instruction and a JZ instruction as the following examples demonstrate:

```
// if(eax) then mov(false, eax); endif;

 test(eax, eax);
 jz DontSetFalse;

 mov(false, eax);

DontSetFalse:

// if(al) then mov(bl, cl); endif;

 test(al, al);
 jz noMove;

 mov(bl, cl);

noMove:
```

### **if( *!register* ) then <<stmts>> endif;**

This form of the IF statement uses the TEST instruction to check the specified register to see if it is zero. If the register is not zero (true), then the program jumps around the statements after the THEN clause with a

JNZ instruction. Converting this statement to assembly language requires a TEST instruction and a JNZ instruction in a manner identical to the previous examples.

**if( *boolean\_variable* ) then <<stmts>> endif;**

This form of the IF statement compares the boolean variable against zero (false) and branches around the statements if the variable does contain false. HLA implements this statement by using the CMP instruction to compare the boolean variable to zero and then it uses a JZ (JE) instruction to jump around the statements if the variable is false. The following example demonstrates the conversion:

```
// if(bool) then mov(0, al); endif;
```

```
 cmp(bool, false);
 je SkipZeroAL;

 mov(0, al);

SkipZeroAL:
```

**if( !*boolean\_variable* ) then <<stmts>> endif;**

This form of the IF statement compares the boolean variable against zero (false) and branches around the statements if the variable contains true (i.e., the opposite condition of the previous example). HLA implements this statement by using the CMP instruction to compare the boolean variable to zero and then it uses a JNZ (JNE) instruction to jump around the statements if the variable contains true. The following example demonstrates the conversion:

```
// if(!bool) then mov(0, al); endif;
```

```
 cmp(bool, false);
 jne SkipZeroAL;

 mov(0, al);

SkipZeroAL:
```

**if( *mem\_reg relop mem\_reg\_const* ) then <<stmts>> endif;**

HLA translates this form of the IF statement into a CMP instruction and a conditional jump that skips over the statements on the opposite condition specified by the *relop* operator. The following table lists the correspondence between operators and condition jump instructions:

**Table 4: IF Statement Conditional Jump Instructions**

| Relop    | Conditional jump instruction if both operands are unsigned | Conditional jump instruction if either operand is signed |
|----------|------------------------------------------------------------|----------------------------------------------------------|
| = or ==  | JNE                                                        | JNE                                                      |
| <> or != | JE                                                         | JE                                                       |
| <        | JNB                                                        | JNL                                                      |
| <=       | JNBE                                                       | JNLE                                                     |
| >        | JNA                                                        | JNG                                                      |
| >=       | JNAE                                                       | JNGE                                                     |

Here are a few examples of IF statements translated into pure assembly language that use expressions involving relational operators:

```
// if(al == ch) then inc(cl); endif;

 cmp(al, ch);
 jne SkipIncCL;

 inc(cl);

SkipIncCL:

// if(ch >= 'a') then and($5f, ch); endif;

 cmp(ch, 'a');
 jnae NotLowerCase

 and($5f, ch);

NotLowerCase:

// if((type int32 eax) < -5) then mov(-5, eax); endif;

 cmp(eax, -5);
 jnl DontClipEAX;

 mov(-5, eax);

DontClipEAX:

// if(si <> di) then inc(si); endif;

 cmp(si, di);
 je DontIncSI;

 inc(si);

DontIncSI:
```

**if( *reg/mem* in *LowConst..HiConst* ) then <<stmts>> endif;**

HLA translates this IF statement into a pair of CMP instructions and a pair of conditional jump instructions. It compares the register or memory location against the lower valued constant and jumps if less than (below) past the statements after the THEN clause. If the register or memory location's value is greater than or equal to *LowConst*, the code falls through to the second CMP/conditional jump pair that compares the register or memory location against the higher constant. If the value is greater than (above) this constant, a conditional jump instruction skips the statements in the THEN clause. Example:

```
// if(eax in 1000..125_000) then sub(1000, eax); endif;

 cmp(eax, 1000);
 jb DontSub1000;
 cmp(eax, 125_000);
 ja DontSub1000;

 sub(1000, eax);

DontSub1000:

// if(i32 in -5..5) then add(5, i32); endif;
```

```

cmp(i32, -5);
jl NoAdd5;
cmp(i32, 5);
jg NoAdd5;

 add(5, i32);

NoAdd5:

```

**if( *reg/mem* not in *LowConst..HiConst* ) then <<stmts>> endif;**

This form of the HLA IF statement tests a register or memory location to see if its value is outside a specified range. The implementation is very similar to the code above except you branch to the THEN clause if the value is less than the *LowConst* value or greater than the *HiConst* value and you branch over the code in the THEN clause if the value is within the range specified by the two constants. The following examples demonstrate how to do this conversion:

```

// if(eax not in 1000..125_000) then add(1000, eax); endif;

 cmp(eax, 1000);
 jb Add1000;
 cmp(eax, 125_000);
 jbe SkipAdd1000;

 Add1000:
 add(1000, eax);

 SkipAdd1000:

// if(i32 not in -5..5) then mov(0, i32); endif;

 cmp(i32, -5);
 jl Zeroi32;
 cmp(i32, 5);
 jle SkipZero;

 Zeroi32:
 mov(0, i32);

 SkipZero:

```

**if( *reg<sub>8</sub>* in *CSetVar/CSetConst* ) then <<stmts>> endif;**

This statement checks to see if the character in the specified eight-bit register is a member of the specified character set. HLA emits code that is similar to the following for instructions of this form:

```

movzx(reg8, eax);
bt(eax, CsetVar/CsetConst);
jnc SkipPastStmts;

 << stmts >>

 SkipPastStmts:

```

This example modifies the EAX register (the code HLA generates does not, because it pushes and pops the register it uses). You can easily swap another register for EAX if you've got a value in EAX you need to preserve. In the worst case, if no registers are available, you can push EAX, execute the MOVZX and BT instructions, and then pop EAX's value from the stack. The following are some actual examples:

```

// if(al in { 'a'..'z' }) then or($20, al); endif;

movzx(al, eax);
bt(eax, { 'a'..'z' }); // See if we've got a lower case char.
jnc DontConvertCase;

 or($20, al); // Convert to uppercase.

DontConvertCase:

// if(ch in { '0'..'9' }) then and($f, ch); endif;

push(eax);
movzx(ch, eax);
bt(eax, { 'a'..'z' }); // See if we've got a lower case char.
pop(eax);
jnc DontConvertNum;

 and($f, ch); // Convert to binary form.

DontConvertNum:

```

### 2.8.3 Implementing Complex IF Statements Using Complete Boolean Evaluation

The previous section did not discuss how to translate boolean expressions involving conjunction (AND) or disjunction (OR) into assembly language. This section will begin that discussion. There are two different ways to convert complex boolean expressions involving conjunction and disjunction into assembly language: using complete boolean evaluation or short circuit evaluation. This section discusses complete boolean evaluation. The next section discusses short circuit boolean evaluation, which is the scheme that HLA uses when converting complex boolean expressions to assembly language.

Using complete boolean evaluation to evaluate a boolean expression for an IF statement is almost identical to converting arithmetic expressions into assembly language. Indeed, the previous volume covers this conversion process (see “Logical (Boolean) Expressions” on page 584). About the only thing worth noting about that process is that you do not need to store the ultimate boolean result in some variable; once the evaluation of the expression is complete you check to see if you have a false (zero) or true (one, or non-zero) result to determine whether to branch around the THEN portion of the IF statement. As you can see in the examples in the preceding sections, you can often use the fact that the last boolean instruction (AND/OR) sets the zero flag if the result is false and clears the zero flag if the result is true. This lets you avoid explicitly testing the result. Consider the following IF statement and its conversion to assembly language using complete boolean evaluation:

```

if(((x < y) && (z > t)) || (a != b))
 Stmt1;

mov(x, eax);
cmp(eax, y);
setl(bl); // Store x<y in bl.
mov(z, eax);
cmp(eax, t);
setg(bh); // Store z > t in bh.
and(bh, bl); // Put (x<y) && (z>t) into bl.
mov(a, eax);
cmp(eax, b);
setne(bh); // Store a != b into bh.
or(bh, bl); // Put (x<y) && (z>t) || (a != b) into bl
je SkipStmt1; // Branch if result is false (OR sets Z-Flag if false).

```

```
<< Code for Stmt1 goes here >>
```

```
SkipStmt1:
```

This code computes a boolean value in the BL register and then, at the end of the computation, tests this resulting value to see if it contains true or false. If the result is false, this sequence skips over the code associated with *Stmt1*. The important thing to note in this example is that the program will execute each and every instruction that computes this boolean result (up to the JE instruction).

For more details on complete boolean evaluation, see “Logical (Boolean) Expressions” on page 584.

## 2.8.4 Short Circuit Boolean Evaluation

If you are willing to spend a little more effort studying a complex boolean expression, you can usually convert it to a much shorter and faster sequence of assembly language instructions using *short-circuit boolean evaluation*. Short-circuit boolean evaluation attempts to determine whether an expression is true or false by executing only a portion of the instructions that compute the complete expression. By executing only a portion of the instructions, the evaluation is often much faster. For this reason, plus the fact that short circuit boolean evaluation generally doesn’t require the use of any temporary registers, HLA uses short circuit evaluation when translating complex boolean expressions into assembly language.

To understand how short-circuit boolean evaluation works, consider the expression “A && B”. Once we determine that A is false, there is no need to evaluate B since there is no way the expression can be true. If A and B represent sub-expressions rather than simple variables, you can begin to see the savings that are possible with short-circuit boolean evaluation. As a concrete example, consider the sub-expression “((x<y) && (z>t))” from the previous section. Once you determine that x is not less than y, there is no need to check to see if z is greater than t since the expression will be false regardless of z and t’s values. The following code fragment shows how you can implement short-circuit boolean evaluation for this expression:

```
// if((x<y) && (z>t)) then ...

 mov(x, eax);
 cmp(eax, y);
 jnl TestFails;
 mov(z, eax);
 cmp(eax, t);
 jng TestFails;

 << Code for THEN clause of IF statement >>

TestFails:
```

Notice how the code skips any further testing once it determines that x is not less than y. Of course, if x is less than y, then the program has to test z to see if it is greater than t; if not, the program skips over the THEN clause. Only if the program satisfies both conditions does the code fall through to the THEN clause.

For the logical OR operation the technique is similar. If the first sub-expression evaluates to true, then there is no need to test the second operand. Whatever the second operand’s value is at that point, the full expression still evaluates to true. The following example demonstrates the use of short-circuit evaluation with disjunction (OR):

```
// if(ch < 'A' || ch > 'Z') then stdout.put("Not an upper case char"); endif;

 cmp(ch, 'A');
 jb ItsNotUC
 cmp(ch, 'Z');
 jna ItWasUC;

 ItsNotUC:
 stdout.put("Not an upper case char");
```

```
ItWasUC:
```

Since the conjunction and disjunction operators are commutative, you can evaluate the left or right operand first if it is more convenient to do so. As one last example in this section, consider the full boolean expression from the previous section:

```
// if(((x < y) && (z > t)) || (a != b)) Stmt1;

mov(a, eax);
cmp(eax, b);
jne DoStmt1;
mov(x, eax);
cmp(eax, y);
jnl SkipStmt1;
mov(z, eax);
cmp(eax, t);
jng SkipStmt1;

DoStmt1:
<< Code for Stmt1 goes here >>

SkipStmt1:
```

Notice how the code in this example chose to evaluate “a != b” first and the remaining sub-expression last. This is a common technique assembly language programmers use to write better code.

---

## 2.8.5 Short Circuit vs. Complete Boolean Evaluation

One fact about complete boolean evaluation is that every statement in the sequence will execute when evaluating the expression. Short-circuit boolean evaluation may not require the execution of every statement associated with the boolean expression. As you’ve seen in the previous two sections above, code based on short-circuit evaluation is probably faster<sup>2</sup>. So it would seem that short-circuit evaluation is the technique of choice when converting complex boolean expressions to assembly language.

Sometimes, unfortunately, short-circuit boolean evaluation may not produce the correct result. In the presence of *side-effects* in an expression, short-circuit boolean evaluation will produce a different result than complete boolean evaluation. Consider the following C/C++ example:

```
if((x == y) && (++z != 0)) stmt;
```

Using complete boolean evaluation, you might generate the following code:

```
mov(x, eax); // See if x == y
cmp(eax, y);
sete(bl);
inc(z); // ++z
cmp(z, 0); // See if incremented z is zero.
setne(bh);
and(bh, bl); // Test x == y && ++z != 0
jz SkipStmnt;

<< code for stmt goes here >>

SkipStmnt:
```

Using short-circuit boolean evaluation, you might generate the following code:

---

2. Note that this does not always mean that the program will run faster. Jumps (conditional or otherwise) are often very slow executing instructions. Sometimes it’s faster to execute several instructions in a row rather than execute a few instructions that include a conditional jump.

```

mov(x, eax); // See if x == y
cmp(eax, y);
jne SkipStmt;
inc(z); // ++z
cmp(z, 0); // See if incremented z is zero.
je SkipStmt;

<< code for stmt goes here >>

```

SkipStmt:

Notice a very subtle, but important difference between these two conversions: if it turns out that  $x$  is equal to  $y$ , then the first version above *still increments*  $z$  and compares it to zero before it executes the code associated with *stmt*; the short-circuit version, on the other hand skips over the code that increments  $z$  if it turns out that  $x$  is equal to  $y$ . Therefore, the behavior of these two code fragments is different with respect to what happens to  $z$  if  $x$  is equal to  $y$ . Neither implementation is particularly wrong, depending on the circumstances you may or may not want the code to increment  $z$  if  $x$  is equal to  $y$ . However, it is important that you realize that these two conversion methods produce different results so you can choose an appropriate implementation if the effect of this code on  $z$  matters to your program.

Many programs take advantage of short-circuit boolean evaluation and rely upon the fact that the program may not evaluate certain components of the expression. The following C/C++ code fragment demonstrates what is probably the most common example that requires short-circuit boolean evaluation:

```
if(Ptr != NULL && *Ptr == 'a') stmt;
```

If it turns out that  $Ptr$  is NULL in this IF statement, then the expression is false and there is no need to evaluate the remainder of the expression (and, therefore, code that uses short-circuit boolean evaluation will not evaluate the remainder of this expression). This statement relies upon the semantics of short-circuit boolean evaluation for correct operation. Were C/C++ to use complete boolean evaluation, and the variable  $Ptr$  contained NULL, then the second half of the expression would attempt to dereference a NULL pointer (which tends to crash most programs). Consider the translation of this statement using complete and short-circuit boolean evaluation:

// Complete boolean evaluation:

```

mov(Ptr, eax);
test(eax, eax); // Check to see if EAX is zero (NULL is zero).
setne(bl);
mov([eax], al); // Get *Ptr into AL.
cmp(al, 'a');
sete(bh);
and(bh, bl);
jz SkipStmt;

<< code for stmt goes here >>

```

SkipStmt:

Notice in this example that if  $Ptr$  contains NULL (zero), then this program will attempt to access the data at location zero in memory via the “mov( [eax], al );” instruction. Under Win32 this will cause a memory access fault (general protection fault). Now consider the short-circuit boolean conversion:

// Short-circuit boolean evaluation

```

mov(Ptr, eax); // See if Ptr contains NULL (zero) and
test(eax, eax); // immediately skip past Stmt if this
jz SkipStmt; // is the case

mov([eax], al); // If we get to this point, Ptr contains
cmp(al, 'a'); // a non-NULL value, so see if it points
jne SkipStmt; // at the character 'a'.

```

```
<< code for stmt goes here >>
```

```
SkipStmt:
```

As you can see in this example, the problem with dereferencing the NULL pointer doesn't exist. If *Ptr* contains NULL, this code skips over the statements that attempt to access the memory address *Ptr* contains.

## 2.8.6 Efficient Implementation of IF Statements in Assembly Language

Encoding IF statements efficiently in assembly language takes a bit more thought than simply choosing short-circuit evaluation over complete boolean evaluation. To write code that executes as quickly as possible in assembly language you must carefully analyze the situation and generate the code appropriately. The following paragraphs provide some suggestions you can apply to your programs to improve their performance.

### Know your data!

A mistake programmers often make is the assumption that data is random. In reality, data is rarely random and if you know the types of values that your program commonly uses, you can use this knowledge to write better code. To see how, consider the following C/C++ statement:

```
if((a == b) && (c < d)) ++i;
```

Since C/C++ uses short-circuit evaluation, this code will test to see if *a* is equal to *b*. If so, then it will test to see if *c* is less than *d*. If you expect *a* to be equal to *b* most of the time but don't expect *c* to be less than *d* most of the time, this statement will execute slower than it should. Consider the following HLA implementation of this code:

```
mov(a, eax);
cmp(eax, b);
jne DontIncI;

mov(c, eax);
cmp(eax, d);
jnl DontIncI;

inc(i);

DontIncI:
```

As you can see in this code, if *a* is equal to *b* most of the time and *c* is not less than *d* most of the time, you will have to execute the first three instructions nearly every time in order to determine that the expression is false. Now consider the following implementation of the above C/C++ statement that takes advantage of this knowledge and the fact that the “&&” operator is commutative:

```
mov(c, eax);
cmp(eax, d);
jnl DontIncI;

mov(a, eax);
cmp(eax, b);
jne DontIncI;

inc(i);

DontIncI:
```

In this example the code first checks to see if *c* is less than *d*. If most of the time *c* is less than *d*, then this code determines that it has to skip to the label *DontIncI* after executing only three instructions in the typical case (compared with six instructions in the previous example). This fact is much more obvious in

assembly language than in a high level language; this is one of the main reasons that assembly programs are often faster than their high level language counterparts: optimizations are more obvious in assembly language than in a high level language. Of course, the key here is to understand the behavior of your data so you can make intelligent decisions such as the one above.

### Rearranging Expressions

Even if your data is random (or you can't determine how the input values will affect your decisions), there may still be some benefit to rearranging the terms in your expressions. Some calculations take far longer to compute than others. For example, the DIV instruction is much slower than a simple CMP instruction. Therefore, if you have a statement like the following you may want to rearrange the expression so that the CMP comes first:

```
if((x % 10 = 0) && (x != y)) ++x;
```

Converted to assembly code, this IF statement becomes:

```
mov(x, eax); // Compute X % 10
cdq(); // Must sign extend EAX -> EDX:EAX
imod(10, edx:eax); // Remember, remainder goes into EDX
test(edx, edx); // See if EDX is zero.
jnz SkipIF

mov(x, eax);
cmp(eax, y);
je SkipIF

inc(x);

SkipIF:
```

The IMOD instruction is very expensive (often 50-100 times slower than most of the other instructions in this example). Unless it is 50-100 times more likely than the remainder is zero rather than x is equal to y, it would be better to do the comparison first and the remainder calculation afterwards:

```
mov(x, eax);
cmp(eax, y);
je SkipIF

mov(x, eax); // Compute X % 10
cdq(); // Must sign extend EAX -> EDX:EAX
imod(10, edx:eax); // Remember, remainder goes into EDX
test(edx, edx); // See if EDX is zero.
jnz SkipIF

inc(x);

SkipIF:
```

Of course, in order to rearrange the expression in this manner, the code must not assume the use of short-circuit evaluation semantics (since the && and || operators are not commutative if the code must compute one subexpression before another).

### Destructuring Your Code

Although there is a lot of good things to be said about structured programming techniques, there are some drawbacks to writing structured code. Specifically, structured code is sometimes less efficient than unstructured code. Most of the time this is tolerable because unstructured code is difficult to read and maintain; it is often acceptable to sacrifice some performance in exchange for maintainable code. In certain

instances, however, you may need all the performance you can get. In those rare instances you might choose to compromise the readability of your code in order to gain some additional performance.

One classic way to do this is to use code movement to move code your program rarely uses out of the way of code that executes most of the time. For example, consider the following pseudo C/C++ statement:

```
if(See_If_an_Error_Has_Ocurred)
{
 << Statements to execute if no error >>
}
else
{
 << Error handling statements >>
}
```

In normal code, one does not expect errors to be frequent. Therefore, you would normally expect the THEN section of the above IF to execute far more often than the ELSE clause. The code above could translate into the following assembly code:

```
cmp(See_If_an_Error_Has_Ocurred, true);
je HandleTheError

 << Statements to execute if no error >>
 jmp EndOfIF;

HandleTheError:
 << Error handling statements >>

EndOfIf:
```

Notice that if the expression is false this code falls through to the normal statements and then jumps over the error handling statements. Instructions that transfer control from one point in your program to another (e.g., JMP instructions) tend to be slow. It is much faster to execute a sequential set of instructions rather than jump all over the place in your program. Unfortunately, the code above doesn't allow this. One way to rectify this problem is to move the ELSE clause of the code somewhere else in your program. That is, you could rewrite the code as follows:

```
cmp(See_If_an_Error_Has_Ocurred, true);
je HandleTheError

 << Statements to execute if no error >>

EndOfIf:
```

At some other point in your program (typically after a JMP instruction) you would insert the following code:

```
HandleTheError:
 << Error handling statements >>
 jmp EndOfIf;
```

Note that the program isn't any shorter. The JMP you removed from the original sequence winds up at the end of the ELSE clause. However, since the ELSE clause rarely executes, moving the JMP instruction from the THEN clause (which executes frequently) to the ELSE clause is a big performance win because the THEN clause executes using only straight-line code. This technique is surprisingly effective in many time-critical code segments.

There is a difference between writing *destructured* code and writing *unstructured* code. Unstructured code is written in an unstructured way to begin with. It is generally hard to read, difficult to maintain, and it often contains defects. Destructured code, on the other hand, starts out as structured code and you make a conscious decision to eliminate the structure in order to gain a small performance boost. Generally, you've already tested the code in its structured form before destructuring it. Therefore, destructured code is often easier to work with than unstructured code.

### Calculation Rather than Branching

On many processors in the 80x86 family, branches are very expensive compared to many other instructions (perhaps not as bad as IMOD or IDIV, but typically an order of magnitude worse than instructions like ADD and SUB). For this reason it is sometimes better to execute more instructions in a sequence rather than fewer instructions that involve branching. For example, consider the simple assignment “EAX = abs(EAX);” Unfortunately, there is no 80x86 instruction that computes the absolute value of an integer value. The obvious way to handle this is with an instruction sequence like the following:

```
test(eax, eax);
jns ItsPositive;

neg(eax);

ItsPositive:
```

However, as you can plainly see in this example, it uses a conditional jump to skip over the NEG instruction (that creates a positive value in EAX if EAX was negative). Now consider the following sequence that will also do the job:

```
// Set EDX to $FFFF_FFFF if EAX is negative, $0000_0000 if EAX is
// zero or positive:

cdq();

// If EAX was negative, the following code inverts all the bits in EAX,
// otherwise it has no effect on EAX.

xor(edx, edx);

// If EAX was negative, the following code adds one to EAX, otherwise
// it doesn't modify EAX's value.

and(1, edx); // EDX = 0 or 1 (1 if EAX was negative).
add(edx, eax);
```

This code will invert all the bits in EAX and then add one to EAX if EAX was negative prior to the sequence (i.e., it takes the two's complement [negates] the value in EAX). If EAX was zero or positive, then this code does not change the value in EAX.

Note that this sequence takes four instructions rather than the three the previous example requires. However, since there are no transfer of control instructions in this sequence, it may execute faster on many CPUs in the 80x86 family.

## 2.8.7 SWITCH/CASE Statements

The HLA SWITCH statement takes the following form :

```

switch(reg32)
 case(const1)
 <<stmts1>>

 case(const2)
 <<stmts2>>
 .
 .
 .
 case(constn)
 <<stmtsn >>

 default // Note that the default section is optional
 <<stmtsdefault >>

endswitch;

```

When this statement executes, it checks the value of register against the constants  $\text{const}_1 \dots \text{const}_n$ . If a match is found then the corresponding statements execute. HLA places a few restrictions on the SWITCH statement. First, the HLA SWITCH statement only allows a 32-bit register as the SWITCH expression. Second, all the constants appearing as CASE clauses must be unique. The reason for these restrictions will become clear in a moment.

Most introductory programming texts introduce the SWITCH/CASE statement by explaining it as a sequence of IF..THEN..ELSEIF statements. They might claim that the following two pieces of HLA code are equivalent:

```

switch(eax)
 case(0) stdout.put("I=0");
 case(1) stdout.put("I=1");
 case(2) stdout.put("I=2");
endswitch;

if(eax = 0) then stdout.put("I=0")
elseif(eax = 1) then stdout.put("I=1")
elseif(eax = 2) then stdout.put("I=2");

```

While semantically these two code segments may be the same, their implementation is usually different. Whereas the IF..THEN..ELSEIF chain does a comparison for each conditional statement in the sequence, the SWITCH statement normally uses an indirect jump to transfer control to any one of several statements with a single computation. Consider the two examples presented above, they could be written in assembly language with the following code:

```

// IF..THEN..ELSE form:

mov(i, eax);
test(eax, eax); // Check for zero.
jnz Not0;
 stdout.put("I=0");
 jmp EndCase;

Not0:
 cmp(eax, 1);
 jne Not1;
 stdou.put("I=1");
 jmp EndCase;

Not1:
 cmp(eax, 2);
 jne EndCase;
 stdout.put("I=2");
EndCase:

```

```
// Indirect Jump Version

readonly
 JmpTbl:dword[3] := [&Stmt0, &Stmt1, &Stmt2];
 .
 .
 .
 mov(i, eax);
 jmp(JmpTbl[eax*4]);

 Stmt0:
 stdout.put("I=0");
 jmp EndCase;

 Stmt1:
 stdout.put("I=1");
 jmp EndCase;

 Stmt2:
 stdout.put("I=2");

 EndCase:
```

The implementation of the IF.THEN..ELSEIF version is fairly obvious and doesn't need much in the way of explanation. The indirect jump version, however, is probably quite mysterious to you; so let's consider how this particular implementation of the SWITCH statement works.

Remember that there are three common forms of the JMP instruction (see “Unconditional Transfer of Control (JMP)” on page 731). The standard unconditional JMP instruction, like the “jmp EndCase;” instructions in the previous examples, transfer control directly to the statement label specified as the JMP operand. The second form of the JMP instruction (i.e., “jmp Reg<sub>32</sub>;”) transfers control to the memory location specified by the address found in a 32-bit register. The third form of the JMP instruction, the one the example above uses, transfers control to the instruction specified by the contents of *dword* memory location. As this example clearly illustrates, that memory location can use any addressing mode. You are not limited to the displacement-only addressing mode. Now let's consider exactly how this second implementation of the SWITCH statement works.

To begin with, a SWITCH statement requires that you create an array of pointers with each element containing the address of a statement label in your code (those labels must be attached to the sequence of instructions to execute for each case in the SWITCH statement). In the example above, the *JmpTbl* array serves this purpose. Note that this code initializes *JmpTbl* with the address of the statement labels *Stmt0*, *Stmt1*, and *Stmt2*. The program places this array in the READONLY section because the program should never change these values during execution.

**Warning: whenever you initialize an array with a set of address of statement labels as in this example, the declaration section in which you declare the array (e.g., READONLY in this case) must be in the same procedure that contains the statement labels<sup>3</sup>.**

During the execution of this code sequence, the program loads the EAX register with *I*'s value. Then the program uses this value as an index into the *JmpTbl* array and transfers control to the four-byte address found at the specified location. For example, if EAX contains zero, the “jmp( JmpTbl[*eax*\*4]);” instruction will fetch the *dword* at address *JmpTbl*+0 (*eax*\*4=0). Since the first double word in the table contains the address of *Stmt0*, the JMP instruction will transfer control to the first instruction following the *Stmt0* label. Likewise, if *I* (and therefore, EAX) contains one, then the indirect JMP instruction fetches the double word at offset four from the table and transfers control to the first instruction following the *Stmt1* label (since the address of *Stmt1* appears at offset four in the table). Finally, if *I*/EAX contains two, then this code fragment

---

3. If the SWITCH statement appears in your main program, you must declare the array in the declaration section of your main program.

transfers control to the statements following the *Stmt2* label since it appears at offset eight in the *JmpTbl* table.

Two things should become readily apparent: the more (consecutive) cases you have, the more efficient the jump table implementation becomes (both in terms of space and speed) over the IF/ELSEIF form. Except for trivial cases, the SWITCH statement is almost always faster and usually by a large margin. As long as the CASE values are consecutive, the SWITCH statement version is usually smaller as well.

What happens if you need to include non-consecutive CASE labels or you cannot be sure that the SWITCH value doesn't go out of range? In HLA, such an occurrence will transfer control to the first statement after the ENDSWITCH clause. However, this doesn't happen in the example above. If variable *I* does not contain zero, one, or two, the result of executing the code above is undefined. For example, if *I* contains five when you execute the code in the previous example, the indirect JMP instruction will fetch the *dword* at offset 20 (5\*4) in *JmpTbl* and transfer control to that address. Unfortunately, *JmpTbl* doesn't have six entries; so the program will wind up fetching the value of the third double word following *JmpTbl* and using that as the target address. This will often crash your program or transfer control to an unexpected location. Clearly this code does not behave like the HLA SWITCH statement, nor does it have desirable behavior.

The solution is to place a few instructions before the indirect JMP to verify that the SWITCH selection value is within some reasonable range. In the previous example, we'd probably want to verify that *I*'s value is in the range 0..2 before executing the JMP instruction. If *I*'s value is outside this range, the program should simply jump to the *EndCase* label (this corresponds to dropping down to the first statement after the ENDSWITCH clause). The following code provides this modification to the previous example:

```
readonly
 JmpTbl:dword[3] := [&Stmt0, &Stmt1, &Stmt2];
 .
 .
 .
 mov(i, eax);
 cmp(eax, 2); // Verify that I is in the range
 ja EndCase; // 0..2 before the indirect JMP.
 jmp(JmpTbl[eax*4]);

 Stmt0:
 stdout.put("I=0");
 jmp EndCase;

 Stmt1:
 stdout.put("I=1");
 jmp EndCase;

 Stmt2:
 stdout.put("I=2");

 EndCase:
```

Although the example above handles the problem of selection values being outside the range zero through two, it still suffers from a couple of severe restrictions:

- The cases must start with the value zero. That is, the minimum CASE constant has to be zero in this example.
- The case values must be contiguous; there cannot be any gaps between any two case values.

Solving the first problem is easy and you deal with it in two steps. First, you must compare the case selection value against a lower and upper bounds before determining if the case value is legal, e.g.,

```
// SWITCH statement specifying cases 5, 6, and 7:
// WARNING: this code does *NOT* work. Keep reading to find out why.

 mov(i, eax);
 cmp(eax, 5);
```

```

jb EndCase
cmp(eax, 7); // Verify that I is in the range
ja EndCase; // 5..7 before the indirect JMP.
jmp(JumpTbl[eax*4]);

```

```

Stmt5:
 stdout.put("I=5");
 jmp EndCase;

```

```

Stmt6:
 stdout.put("I=6");
 jmp EndCase;

```

```

Stmt7:
 stdout.put("I=7");

```

```

EndCase:

```

As you can see, this code adds a pair of extra instructions, `CMP` and `JB`, to test the selection value to ensure it is in the range five through seven. If not, control drops down to the `EndCase` label, otherwise control transfers via the indirect `JMP` instruction. Unfortunately, as the comments point out, this code is broken. Consider what happens if variable `i` contains the value five: The code will verify that five is in the range five through seven and then it will fetch the dword at offset 20 ( $5 * \text{size}(\text{dword})$ ) and jump to that address. As before, however, this loads four bytes outside the bounds of the table and does not transfer control to a defined location. One solution is to subtract the smallest case selection value from `EAX` before executing the `JMP` instruction. E.g.,

```

// SWITCH statement specifying cases 5, 6, and 7:
// WARNING: there is a better way to do this. Keep reading.

```

```

readonly
 JumpTbl:dword[3] := [&Stmt5, &Stmt6, &Stmt7];
 .
 .
 .
 mov(i, eax);
 cmp(eax, 5);
 jb EndCase
 cmp(eax, 7); // Verify that I is in the range
 ja EndCase; // 5..7 before the indirect JMP.
 sub(5, eax); // 5->0, 6->1, 7->2.
 jmp(JumpTbl[eax*4]);

```

```

Stmt5:
 stdout.put("I=5");
 jmp EndCase;

```

```

Stmt6:
 stdout.put("I=6");
 jmp EndCase;

```

```

Stmt7:
 stdout.put("I=7");

```

```

EndCase:

```

By subtracting five from the value in `EAX` this code forces `EAX` to take on the values zero, one, or two prior to the `JMP` instruction. Therefore, case selection value five jumps to `Stmt5`, case selection value six transfers control to `Stmt6`, and case selection value seven jumps to `Stmt7`.

There is a sneaky way to slightly improve the code above. You can eliminate the SUB instruction by merging this subtraction into the JMP instruction's address expression. Consider the following code that does this:

```
// SWITCH statement specifying cases 5, 6, and 7:

readonly
 JmpTbl:dword[3] := [&Stmt5, &Stmt6, &Stmt7];
 .
 .
 .
 mov(i, eax);
 cmp(eax, 5);
 jb EndCase
 cmp(eax, 7); // Verify that I is in the range
 ja EndCase; // 5..7 before the indirect JMP.
 jmp(JmpTbl[eax*4 - 5*@size(dword)]);

 Stmt5:
 stdout.put("I=5");
 jmp EndCase;

 Stmt6:
 stdout.put("I=6");
 jmp EndCase;

 Stmt7:
 stdout.put("I=7");

 EndCase:
```

The HLA SWITCH statement provides a DEFAULT clause that executes if the case selection value doesn't match any of the case values. E.g.,

```
switch(ebx)

 case(5) stdout.put("ebx=5");
 case(6) stdout.put("ebx=6");
 case(7) stdout.put("ebx=7");
 default
 stdout.put("ebx does not equal 5, 6, or 7");

endswitch;
```

Implementing the equivalent of the DEFAULT clause in pure assembly language is very easy. Just use a different target label in the JB and JA instructions at the beginning of the code. The following example implements an HLA SWITCH statement similar to the one immediately above:

```
// SWITCH statement specifying cases 5, 6, and 7 with a DEFAULT clause:

readonly
 JmpTbl:dword[3] := [&Stmt5, &Stmt6, &Stmt7];
 .
 .
 .
 mov(i, eax);
 cmp(eax, 5);
 jb DefaultCase;
 cmp(eax, 7); // Verify that I is in the range
 ja DefaultCase; // 5..7 before the indirect JMP.
 jmp(JmpTbl[eax*4 - 5*@size(dword)]);
```

```

Stmt5:
 stdout.put("I=5");
 jmp EndCase;

Stmt6:
 stdout.put("I=6");
 jmp EndCase;

Stmt7:
 stdout.put("I=7");
 jmp EndCase;

DefaultCase:
 stdout.put("I does not equal 5, 6, or 7");
EndCase:

```

The second restriction noted earlier, that the case values need to be contiguous, is easy to handle by inserting extra entries into the jump table. Consider the following HLA SWITCH statement:

```

switch(ebx)

 case(1) stdout.put("ebx = 1");
 case(2) stdout.put("ebx = 2");
 case(4) stdout.put("ebx = 4");
 case(8) stdout.put("ebx = 8");
 default
 stdout.put("ebx is not 1, 2, 4, or 8");

endswitch;

```

The minimum switch value is one and the maximum value is eight. Therefore, the code before the indirect JMP instruction needs to compare the value in EBX against one and eight. If the value is between one and eight, it's still possible that EBX might not contain a legal case selection value. However, since the JMP instruction indexes into a table of dwords using the case selection table, the table must have eight dword entries. To handle the values between one and eight that are not case selection values, simply put the statement label of the default clause (or the label specifying the first instruction after the ENDSWITCH if there is no DEFAULT clause) in each of the jump table entries that don't have a corresponding CASE clause. The following code demonstrates this technique for the above HLA SWITCH statement:

```

readonly
 JumpTbl2: dword :=
 [
 &Case1, &Case2, &dfltCase, &Case4,
 &dfltCase, &dfltCase, &dfltCase, &Case8
];
 .
 .
 .
 cmp(ebx, 1);
 jb dfltCase;
 cmp(ebx, 8);
 ja dfltCase;
 jmp(JumpTbl2[ebx*4 - 1*@size(dword)]);

 Case1:
 stdout.put("ebx = 1");
 jmp EndOfSwitch;

 Case2:

```

```

 stdout.put("ebx = 2");
 jmp EndOfSwitch;

Case4:
 stdout.put("ebx = 4");
 jmp EndOfSwitch;

Case8:
 stdout.put("ebx = 8");
 jmp EndOfSwitch;

dfltCase:
 stdout.put("ebx is not 1, 2, 4, or 8");

EndOfSwitch:

```

There is a problem with this implementation of the SWITCH statement. If the CASE values contain non-consecutive entries that are widely spaced the jump table could become exceedingly large. The following SWITCH statement would generate an extremely large code file:

```

switch(ebx)

 case(1) stmt1;
 case(100) stmt2;
 case(1_000) stmt3;
 case(10_000) stmt4;
 default stmt5;

endswitch;

```

In this situation, your program will be much smaller if you implement the SWITCH statement with a sequence of IF statements rather than using an indirect jump statement. However, keep one thing in mind—the size of the jump table does not normally affect the execution speed of the program. If the jump table contains two entries or two thousand, the SWITCH statement will execute the multi-way branch in a constant amount of time. The IF statement implementation requires a linearly increasing amount of time for each case label appearing in the case statement.

Probably the biggest advantage to using assembly language over a HLL like Pascal or C/C++ is that you get to choose the actual implementation. In some instances you can implement a SWITCH statement as a sequence of IF..THEN..ELSEIF statements, or you can implement it as a jump table, or you can use a hybrid of the two:

```

switch(eax)

 case(0) stmt0;
 case(1) stmt1;
 case(2) stmt2;
 case(100) stmt3;
 default stmt4;

endswitch;

```

could become:

```

cmp(eax, 100);
je DoStmt3;
cmp(eax, 2);
ja TheDefaultCase;
jmp(JumpTbl[eax*4]);
etc.

```

Of course, you could do this in HLA using the following code high-level control structures:

```

if(ebx = 100) then stmt3
else
 switch(eax)
 case(0) stmt0;
 case(1) stmt1;
 case(2) stmt2;
 Otherwise stmt4
 endswitch;
endif;

```

But this tends to destroy the readability of the program. On the other hand, the extra code to test for 100 in the assembly language code doesn't adversely affect the readability of the program (perhaps because it's so hard to read already). Therefore, most people will add the extra code to make their program more efficient.

The C/C++ SWITCH statement is very similar to the HLA SWITCH statement. There is only one major semantic difference: the programmer must explicitly place a BREAK statement in each CASE clause to transfer control to the first statement beyond the SWITCH. This BREAK corresponds to the JMP instruction at the end of each CASE sequence in the assembly code above. If the corresponding BREAK is not present, C/C++ transfers control into the code of the following CASE. This is equivalent to leaving off the JMP at the end of the CASE'S sequence:

```

switch (i)
{
 case 0: stmt1;
 case 1: stmt2;
 case 2: stmt3;
 break;
 case 3: stmt4;
 break;
 default: stmt5;
}

```

This translates into the following 80x86 code:

```

readonly
 JumpTbl: dword[4] := [&case0, &case1, &case2, &case3];
 .
 .
 .
 mov(i, ebx);
 cmp(ebx, 3);
 ja DefaultCase;
 jmp(JumpTbl[ebx*4]);

 case0:
 stmt1;

 case1:
 stmt2;

 case2:
 stmt3;
 jmp EndCase; // Emitted for the break stmt.

 case3:
 stmt4;
 jmp EndCase; // Emitted for the break stmt.

 DefaultCase:
 stmt5;

 EndCase:

```

## 2.9 State Machines and Indirect Jumps

Another control structure commonly found in assembly language programs is the *state machine*. A state machine uses a *state variable* to control program flow. The FORTRAN programming language provides this capability with the assigned GOTO statement. Certain variants of C (e.g., GNU's GCC from the Free Software Foundation) provide similar features. In assembly language, the indirect jump provides a mechanism to easily implement state machines.

So what is a state machine? In very basic terms, it is a piece of code<sup>4</sup> which keeps track of its execution history by entering and leaving certain "states". For the purposes of this chapter, we'll not use a very formal definition of a state machine. We'll just assume that a state machine is a piece of code which (somehow) remembers the history of its execution (its *state*) and executes sections of code based upon that history.

In a very real sense, all programs are state machines. The CPU registers and values in memory constitute the "state" of that machine. However, we'll use a much more constrained view. Indeed, for most purposes only a single variable (or the value in the EIP register) will denote the current state.

Now let's consider a concrete example. Suppose you have a procedure which you want to perform one operation the first time you call it, a different operation the second time you call it, yet something else the third time you call it, and then something new again on the fourth call. After the fourth call it repeats these four different operations in order. For example, suppose you want the procedure to ADD EAX and EBX the first time, subtract them on the second call, multiply them on the third, and divide them on the fourth. You could implement this procedure as follows:

```

procedure StateMachine;
static
 State:byte := 0;
begin StateMachine;

 cmp(State, 0);
 jne TryState1;

 // State 0: Add EBX to EAX and switch to state 1:

 add(ebx, eax);
 inc(State);
 exit StateMachine;

TryState1:
 cmp(State, 1);
 jne TryState2;

 // State 1: subtract ebx from EAX and switch to state 2:

 sub(ebx, eax);
 inc(State); // State 1 becomes State 2.
 exit StateMachine;

TryState2:
 cmp(State, 2);
 jne MustBeState3;

 // If this is state 2, multiply EAX by EAX and switch to state 3:

 intmul(ebx, eax);
 inc(State); // State 2 becomes State 3.
 exit StateMachine;

 // If it isn't one of the above states, we must be in state 3

```

---

4. Note that state machines need not be software based. Many state machines' implementation are hardware based.

```

// So divide eax by ebx and switch back to state zero.

MustBeState3:
push(edx); // Preserve this 'cause it gets whacked by DIV.
xor(edx, edx); // Zero extend EAX into EDX.
div(ebx, edx:eax);
pop(edx); // Restore EDX's value preserved above.
mov(0, State); // Reset the state back to zero.

end StateMachine;

```

Technically, this procedure is not the state machine. Instead, it is the variable *State* and the *CMP/JNE* instructions which constitute the state machine.

There is nothing particularly special about this code. It's little more than a *SWITCH* statement implemented via the *IF.THEN..ELSEIF* construct. The only thing special about this procedure is that it remembers how many times it has been called<sup>5</sup> and behaves differently depending upon the number of calls. While this is a *correct* implementation of the desired state machine, it is not particularly efficient. The astute reader, of course, would recognize that this code could be made a little faster using an actual *SWITCH* statement rather than the *IF.THEN..ELSEIF* implementation. However, there is a better way...

The more common implementation of a state machine in assembly language is to use an *indirect jump*. Rather than having a state variable which contains a value like zero, one, two, or three, we could load the state variable with the *address* of the code to execute upon entry into the procedure. By simply jumping to that address, the state machine could save the tests above needed to execute the proper code fragment. Consider the following implementation using the indirect jump:

```

procedure StateMachine;
static
 State:dword := &State0;
begin StateMachine;

 jmp(State);

 // State 0: Add EBX to EAX and switch to state 1:

State0:
 add(ebx, eax);
 mov(&State1, State);
 exit StateMachine;

State1:

 // State 1: subtract ebx from EAX and switch to state 2:

 sub(ebx, eax);
 mov(&State2, State); // State 1 becomes State 2.
 exit StateMachine;

State2:
